The variables that describe the hazard H, and which are outputs of the fire occurrence and behavior models, are *Burnt area detailed*, *Fire type and FWI*. *Fire type* can be a surface fire with flame length <3.5m, surface fire with flame length >3.5m and crown fire. Burnt area is here expressing wildfire severity.

Vulnerability is expressed by the suppression effectiveness and the damage on houses and vegetated areas (nodes *House damage*, *Area damage* and *Construction type*). The node *Fire Containment in 24 hrs* and its parents represent the probability of a fire being contained by the firefighting crews within 24 hrs. *Fire containment in 24 hrs* is influenced by *FWI*, *Time for ground attack, Air suppression* and *Vegetation type*. The nodes influencing the vulnerability variable *Fire containment in 24 hrs* are based on (Plucinski *et al*. 2012, Plucinski 2012), where fire containment is the dependent variable and the parameters are defined as a result of logistic regression analysis (Table 1). The probability P of fire containment in 24hrs is defined as,

$$\ln\left(\frac{P}{1-P}\right) = b_0 + b_1 FFDI + b_2 groundtime + b_3 airtime \quad (9)$$

wherein *FFDI* is the McArthur Forest Fire Danger Index, $groundtime$ is the time needed for ground suppression crews to reach a fire spot and $airtime$ is the corresponding time for air suppression crews.

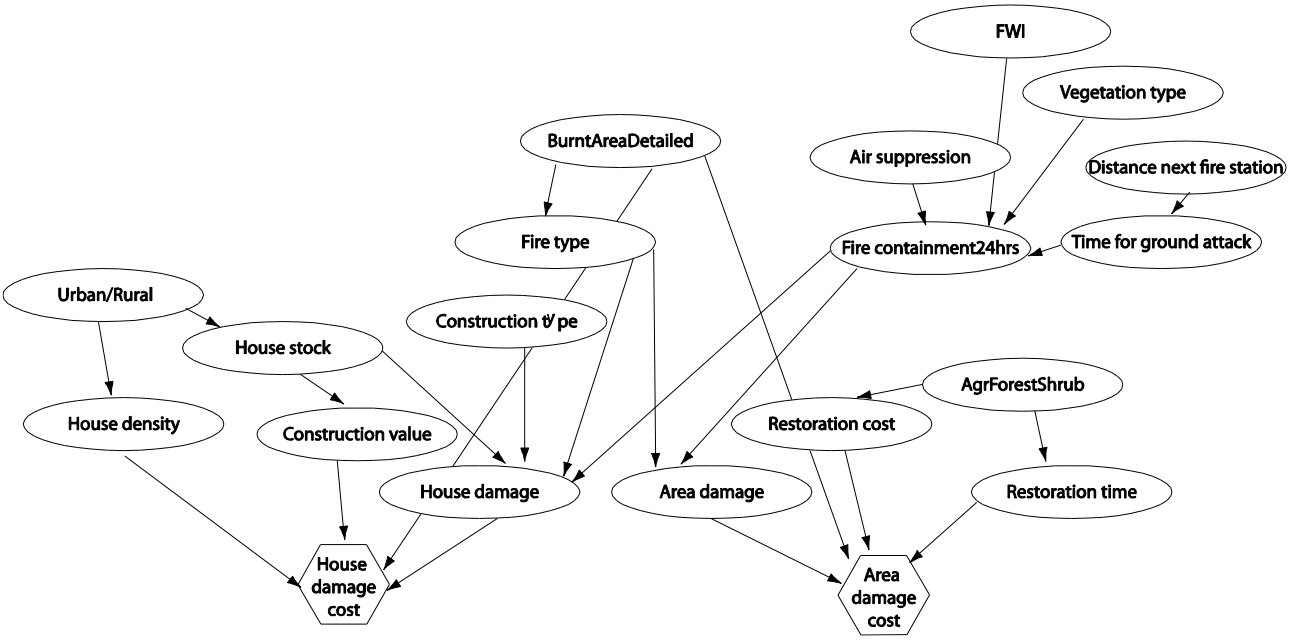

Figure 3. Bayesian network for fire consequences

The vulnerability node *House damage* represents the degree of damage, i.e. the susceptibility of the house portfolio in the cell. The vulnerability is influenced by *Fire type*, *Fire containment in 24 hrs*, *Construction type* and *House stock*. It is expressed as percentage of houses totally damaged in 1 km².

The node *Area damage* is the corresponding vulnerability node for the vegetated area damage. It represents the degree of damage in 1 km². It is expressed as a percentage of the total area (1km²).
Urban/Rural, *House Stock*, *Construction Value*, *House Density*, *Land Cover types*, *AgricultureForestShrub*, *Restoration cost*, *Restoration time* are considered as exposure indicators. *Urban/Rural* discriminates urban from rural areas, which influences the house density [house/km²] and the house stock. *House stock* accounts for the house type portfolio in the mesoscale. It describes the combination of house types in 1km², which include single houses, semi-detached/row houses, and apartments. The node House damage cost is calculated as

$$\begin{aligned} &House\ damage\ cost \\ &= Burnt\ area \cdot House\ damage \cdot Construction\ value \cdot House\ density \end{aligned} \tag{10}$$

The node *Land Cover types*, represents the land cover types as classified in the nomenclature of the Corine Land cover types. The node *AgricultureForestShrub* classifies the land cover types based on the vegetation type. *Restoration cost* [€] is the cost for restoring previous land cover based on premiums paid country wise by the EU Rural Development Programs. *Restoration time* [yrs] is the time needed for restoring previous land cover type (Oehler *et al*. 2012). The node *Area damage cost* is calculated based on results in (Oehler, Oliveira *et al*. 2012) as

$$\begin{aligned} &Area\ damage\ cost = \\ &Burnt\ Area \cdot Area\ damaged \cdot Restoration\ cost \cdot (1+r)^{Restoration\ time} \end{aligned} \tag{11}$$

where $r = 3\%$ is the discount rate.

Table 1. Fire Containment in 24hrs: regression parameters (Eq.9) (Plucinski et al. 2012), (Plucinski 2012)

Vegetation Type	Suppression	b_0 intercept	b_1 F/G FDI	b_2 ground time	b_3 air time

forest	ground&air	3.83561	−0.05031	−0.29845	−0.34783
shrub	ground&air	3.75257	−0.03704	−0.3184	−0.08101

2.5. Fire risk model

The Fire risk model of Figure 4 is obtained as the combination of the fire occurrence model, the fire behavior model and the fire consequences model. This model predicts the risk to Houses and vegetated areas.

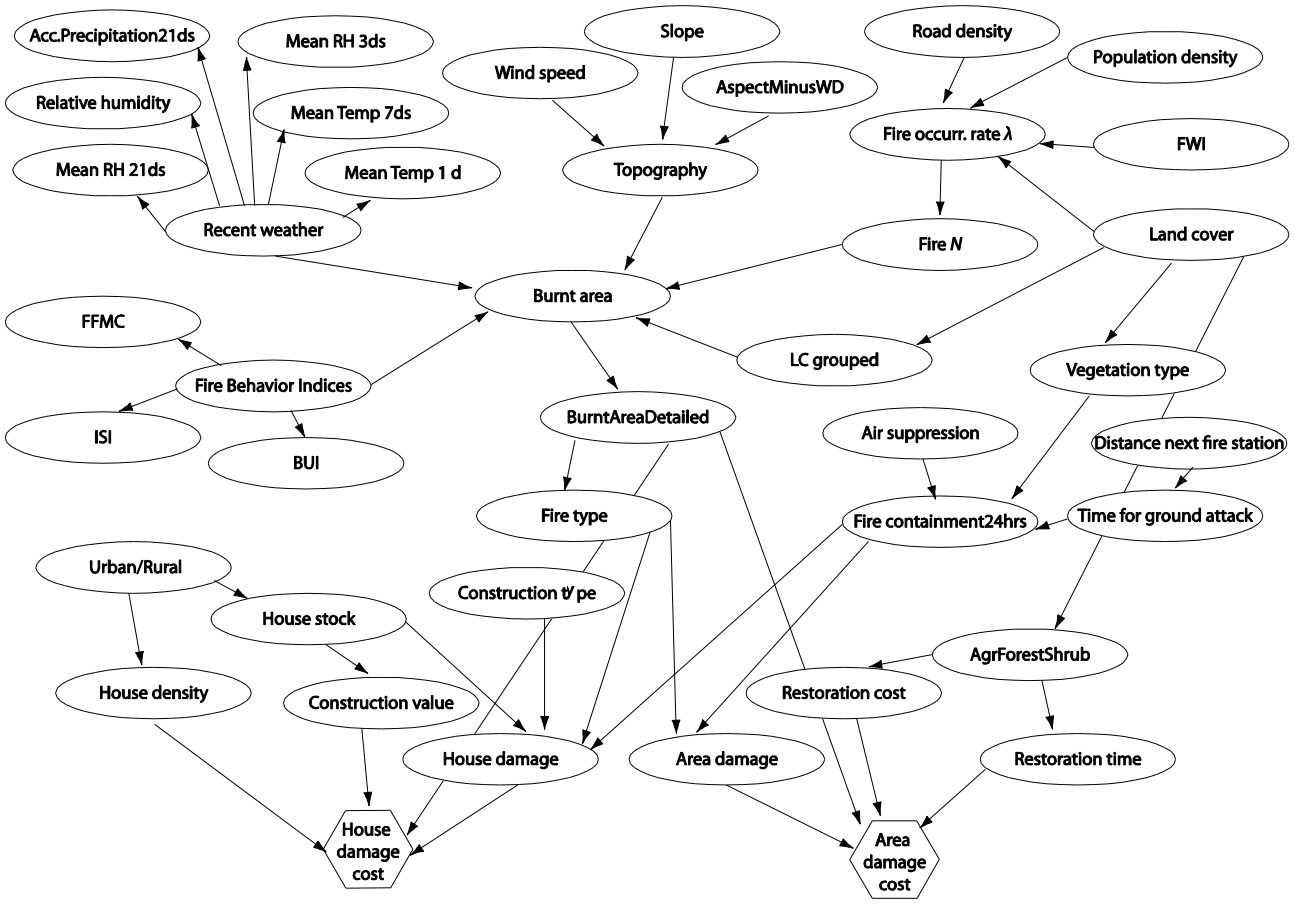

Figure 4. Combined Bayesian network for fire risk.

The BN is coupled with a GIS. Spatial feature groups, such as points, lines and polygons, are processed, stored and managed in a GIS database. Georeferenced spatial features are projected onto a grid with 1 km² cell size, which serves as the spatial resolution of the model. The geospatial features are associated with variables in the BN. In each cell, an instance of the BN models the wildfire risk. With the specific geospatial features associated with a cell, the wildfire risk associated to that cell can be calculated from the BN model. Spatial dependence is represented through the dependence of the observed indicator variables, but not through the BN itself. ArcGIS 10.1 is used for geospatial analysis and mapping (ESRI 2012).
The parameters of the exposure indicators are learned with the attribute data of the geospatial features. Evidence (information on the observed variables) is given on the hazard characteristics and exposure indicators and is propagated in the network and the posterior marginal distributions for each variable are estimated.

Testbed implementation

The BN model is established for Cyprus. The conditional probability distributions of the BN variables are populated with data from the time period 2006-2009, regression model results and expert knowledge. Data from 2010 for Cyprus are used as verification dataset. The results are shown in daily maps with 1 km² spatial resolution.
Figure 5 and Figure 6 exemplarily show the estimated expected damage cost (risk) for the two days of 2010 that had the maximum number of registered fires. The figures differentiate between house risk,

vegetated area risk and the accumulated risk. The calculated FWI with 1km² spatial resolution for each day is displayed as well. The risk in each spatial-temporal unit is low due to the low probability of fire occurrence (in the order of 10^{-5}). In both examples, the highest values of risk occur in wildland-urban interface areas.
The effect of different influencing variables on the probability of fire occurrence is shown inTable 2. For fire behaviour, Table 3 summarizes the effect of the direct influencing variables on the probability of a burnt area > 0.1 km².

Table2. Effect of influencing variables on fire occurrence probability

Variable	States	Pr(Fire) Prior: 9.45e-5	Change in Probability [%]

Concluding remarks

While the understanding and prediction of wildfire occurrence has made significant progress in recent years, research on wildfire risk estimation based on exposure and vulnerability quantification is still evolving (Tutsch *et al*. 2010). Wildfire risk estimation may be facilitated by Bayesian Networks, which, as demonstrated in this paper, can be employed to model the wildfire risk in the mesoscale. The mesoscale requires that the indicators included in the model are representative for a 1 km² spatial

unit. This has strong implications on the modelling; as an example, it is necessary to identify representative building stocks and construction types not of individual buildings, but of portfolios of buildings. A main advantage of the BN is that different models from different sources can easily be combined. Of the BN for wildfire risk proposed in this paper, some parts are learned from data, some parts are derived from models published in the literature and other parts are based on expert knowledge. The graphical nature of the BN facilitates to consistently combine these model parts probabilistically and, not least, also facilitates the communication of the final model.

Abstract
We explore the forecasting capability of two spatially-explicit fire spread models, HFire and FARSITE, and the potential of combining fire spread models and satellite data. A well-documented wildfire that occurred in southern Portugal in July 2012 (approx. 24800ha) is investigated. Accuracy of the fire spread models is evaluated by comparing simulated fire spread perimeters with the reported spatio-temporal distribution of the wildfire event, at three different time steps. Results show good agreement between the simulated and observed burned area perimeters (Sørensen metric). Some differences are found in specific fire propagation time intervals. When simulations are initialized using the reported ignition point, FARSITE progressively shows an underestimation of the fire's time of arrival, whereas HFire shows an overestimation for some time steps. Initializing fire-spread simulations with active-fires ignition points improves time of arrival predictions for some time steps. FARSITE is able to predict abrupt changes in rate of spread and fire line intensity, consistent with the reported information for the wildfire event. Both models show good capability to forecast fire spread. The use of fire spread models with satellite data has great potential since the combination of both improves fire growth and behavior predictions, providing valuable supplementary information to fire management and decision support during large wildfire events.

Keywords*: HFire, FARSITE, fire spread modelling, satellite active-fires, fire suppression, MODIS, fire behaviour*

Introduction

Portugal has one of the highest fire incidences in southern Europe with extreme landscape susceptibility to fire, aggravated during the last four decades due to rural abandonment (Pereira *et al*. 2005). In recent years, catastrophic fires that occurred under extreme weather conditions have challenged the country's fire suppression capabilities.
In Portugal, burnt area extent is mainly controlled by two factors: long dry periods without precipitation in late spring and early summer (climate anomaly), and the occurrence of very intense hot and dry spells in days of extreme synoptic conditions (weather anomaly) and in fact, 80% of the burnt area is due to fire events occurring in 10% of summer days (Pereira *et al*. 2005). During the 2003 fire season, extremely anomalous weather conditions were observed, with a devastating sequence of large wildfires resulting in a total of 450.000ha of burned area, approximately twice the previous highest record (220.000ha in 1998) and four times the 1980-2004 average (Trigo *et al*. 2006). Future climatic scenarios show an increase in fire risk in the Mediterranean basin (Mouillot *et al*. 2002; Moriondo *et al*. 2006; Flannigan *et al*. 2009). In particular, Portugal is expected to experience a temperature increase in spring and summer and an increase in the frequency of heat waves (Ramos *et al*., 2011), likely leading to longer and more severe fire seasons with greater incidence of large uncontrolled wildfires.
Predicting fire spread and behaviour during large wildfire events can greatly improve the efficiency of fire suppression, providing valuable information during firefighting activities enabling more efficient resource allocation and implementation of control lines. One of the most effective tools to study how

the main drivers of wildfire spread and behaviour interact - meteorological conditions, topography and vegetation - is fire spread modelling (Keane *et al*. 2004).
Recently, some authors have also explored the potential of satellite data to monitor large wildfire events (Smith *et al*. 2005; Loboda *et al*. 2007). For example, the MODerate Resolution Imaging Spectroradiometer sensor (MODIS) has been integrated in operational systems to assist fire managers detecting active-fires that are burning at the time of overpass (Lee *et al*., 2002), providing inter- and intra-daily spatio-temporal distributions of individual wildfire events propagation, which is usually done by post-fire collection of field data and interviews. Coen & Schroeder (2013) have used spatially remote sensing data to initialize and evaluate coupled weather-wildfire growth model simulations, with improved results from this approach arising from initialization with more current weather analyses and updated maps of fire location.
In this paper, we explore the capability of two spatially-explicit landscape fire spread models - HFire (Petersen *et al*. 2009) and FARSITE (Finney 1998) - to forecast fire spread and behavior during a large fire event, and the advantage of combining fire-spread modelling with satellite data. Inaccuracies in input data (e.g. maps of surface fuels developed without field validation; inaccurate estimates of canopy cover and crown characteristics) produce errors that propagate during simulations. Combining simulations with satellite-derived active-fires from consecutive MODIS passages can help overcome some of these errors, since simulations are updated in space and time at each passage. The feasibility of these approaches is examined based on the analysis of a well-documented wildfire that occurred in Tavira, southern Portugal in July 2012 (Tavira wildfire hereafter). The performance of both fire spread models is evaluated by comparing the observed fire perimeter with the simulated fire perimeters and the temporal distribution of the Tavira wildfire, derived from the information reported for the event. A performance assessment from the combined use of both tools is also performed.

Methods

Fire spread models

HFire (Highly Optimized Tolerance Fire Spread Model) (Morais 2001) is a computationally efficient raster-based fire growth model capable of simulating surface fire spread (Rothermel 1972) through shrubland fuels. HFire uses an adaptive time step allowing for the fire to spread into a cell from all neighbouring cells over multiple time steps (contact-based approach). It has been developed to support simulations of single fire events and long-term fire regimes (Petersen at al. 2009; Petersen *et al*. 2011).
FARSITE (Fire Area Simulator) is a two-dimensional deterministic fire growth and behaviour model, developed by the USDA Forest Service, and widely used to simulate wildfire spread (e.g. Keane *et al*. 2001; Stratton 2004; Loureiro *et al*. 2006; Arca *et al*. 2007). FARSITE incorporates a surface fire spread model (Rothermel 1972), and additional crown fire spread, spotting, post-frontal combustion and fire acceleration models. The spatial growth of fire perimeters is based on Huygens' Principle of wave propagation (Finney 1998).

Model inputs and parameters

The variables required for modelling an individual fire event are similar in both fire spread models (Table 1).

Table 1. List of input variables and outputs for FARSITE and HFire landscape fire spread models.

Inputs types	HFire	FARSITE	
Landscape (GIS layers)	Elevation (m) Slope (º) Aspect (º) Fuel (categories)	Latitude (º) Elevation (m) Slope (º) Aspect (º) Fuel (categories)	Canopy cover (%) Canopy height (m) Canopy base height (m) Canopy bulk density (kg m^{-3})
Fuel	Fuel model Fuel moisture (10-hr, live herbaceous, live woody) (%)	Fuel model, Fuel rate of spread adjustment Fuel moisture (1-hr, 10-hr, 100-hr, live herbaceous, live woody) (%)	
Weather		Precipitation (mm) Relative humidity (%) Temperature (ºC) Cloud cover (%)	
Winds	Wind speed (km h^{-1}) Wind direction (º)	Wind speed (km h^{-1}) Wind direction (º)	
Ignition	Ignition point	Ignition point	
Outputs	Burned area Time of arrival (hours)	Fire perimeters Fire behavior parameters: Time of arrival (hr); Fire line intensity (kW m^{-1}); Flame length (m); Rate of spread (m min^{-1}); Heat per unit area (kJ m^{-2}); Reaction intensity (kW m^{-2}) Crown-noCrown (cat.); Spread direction (cat.)	

Aspect, elevation and slope maps were derived from the Digital Elevation Model provided by the Shuttle Radar Topography Mission (90m resolution). Canopy cover was derived from the MODIS tree cover dataset (250m resolution) (DiMiceli *et al*. 2011).
Fuel maps consisting of the 13 fire behavior fuel models (Anderson 1982) were produced by the Tavira and São Brás de Alportel municipalities, for the Municipal Forest Defense Plan Against Fires.
In order to have the most representative wind data at the time of the fire, wind speed and direction were obtained from the ENEOP2-MJ250 (Exploração de Parques Eólicos SA) station (Viegas *et al*. 2012). WindNinja (Forthofer *et al*. 2009) was used to model the prevailing hourly wind inputs, simulating the spatially varying wind fields given the effect of topography. The meteorological data used in this study was collected from the Faz Fato weather station (http://www.wunderground.com/). Temperature, relative humidity and precipitation were summarized on a daily basis, using the time of maximum and minimum temperature. Cloud cover was assumed to be zero for the entire simulation period.
Reference values for live fuel moisture in the dry season for chaparral fuels (Morais 2001) were used for live herbaceous and woody fuels, 50% and 70 % respectively, in both models. The 10-hr dead fuel moisture, required by HFire in an hourly basis, was estimated using an algorithm based on Nelson's dead fuel moisture model (Nelson, 2000), which determines moisture content of dead and down woody fuels. For FARSITE, initial fuel moistures were set at 5, 8 and 10% for 1-hr, 10-hr and 100-hr dead fuels respectively. These values were empirically derived from the previous estimates for HFire.

2.3. Case Study – background and description

All the descriptive information referred in this section, related with the case study, was obtained from three reports (ANPC 2012; ICNF 2012; Viegas *et al*. 2012). These reports thoroughly describe the development and behavior of the Tavira wildfire event, providing the qualitative and quantitative information necessary to assess the performance of the fire spread models.

The Tavira wildfire occurred between the 18th and 21st of July 2012, in the Tavira and São Brás de Alportel municipalities (Figure 1). It burned approximately 24.800ha, mainly through shrubland (61% of the affected area), and was one of the largest fires recorded in the last years.

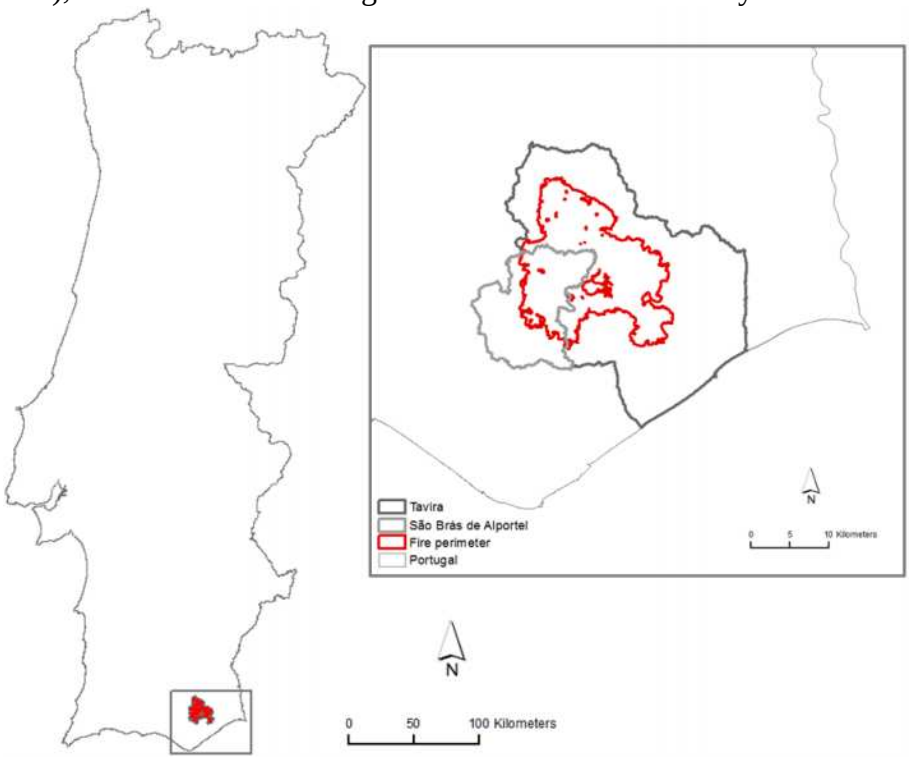

Figure 1. Location of the Tavira Wildfire occurred in July 2012 (Portugal)

The area affected by the fire is orographically heterogeneous, with steep slopes (>20%) covering most of the area and higher elevation in the north part of the Tavira municipality. Less steep terrain (between 0 and 20%) and lower elevation are found at the southeast area of Tavira and southwest area of the São Brás de Alportel municipality, reaching zero meters at several locations (Figure 2). Maximum temperature presents annual mean values between 10°C and 22°C, ranging from 25°C to more than 30°C in August, with maximum absolute temperatures around 39°C. In the summer, relative humidity registers mean values below 65%.

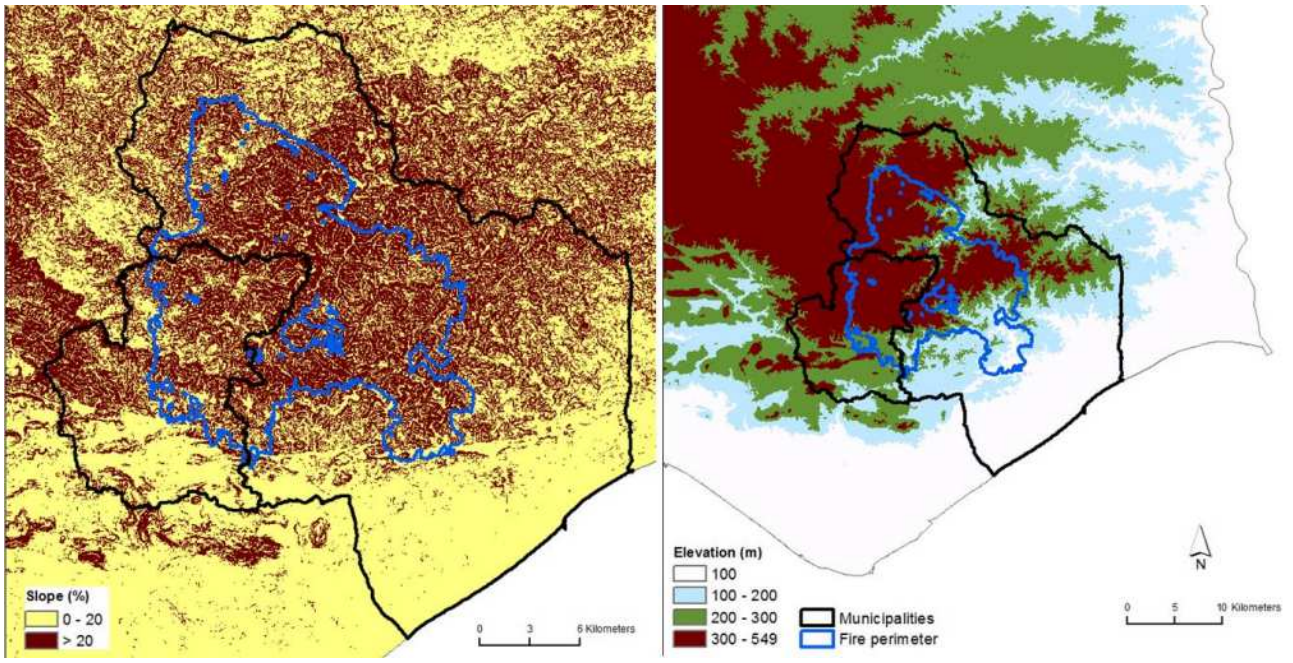

Figure 2. Slope and elevation maps of the study area

In 2012, the precipitation was 45% below the normal record and all the study area was in extreme drought condition, with a soil water content value below 10% at the time of the fire. The vegetation moisture content was estimated to be less than 80% for woody fuels, from 5 to 7% for fine fuels, and no higher than 7% for herbaceous fuels. In addition, the years of 2010 and 2011 experienced above average precipitation favoring vegetation growth and fuel build up. Fire danger as per the Canadian Fire Weather Index (FWI) System was *Extreme* with FWI=56.7 as the average for the most active period of the fire.

The Tavira wildfire was first reported at 14h10 July 18th, contained at 17h46 on July 21st and considered completely extinguished on July 27th. Two important stages for our analysis are identified and will be briefly described.

First stage – Initial development, from 14h10 July 18th to 18h00 July 19th (approx. 28 hours)

The fire burned approximately 5000ha (approx. 20% of total burned area) under favorable conditions for fire spread: fuel moisture was very low, allowing for embers (projected up to hundreds of meters) to ignite and result in multiple spot fires; weak wind but highly variable in direction, causing the fire to spread in every direction and making the initial attack difficult. Fire suppression was hampered by the unfavorable steep, rugged terrain. The unfavorable steep, rugged terrain hampered fire suppression. The fire started spreading through steep slopes along the Ribeira de Odeleite basin (Figura 3).

Second stage – conflagration with very fast spread towards south, from 18h00 July 19th to 1h00 July 20 (approx.7 hours)

The fire reached the Ribeira de Odeleite basin and turned into a major conflagration, turning fire suppression extremely difficult. Several factors led to this loss of control. Reaching Ribeira de Odeleite, the fire increased its intensity by aligning with canyons and steep slopes, spreading alongside the basin. An increase in wind speed led to fast and intense fire growth towards south with a 10km fire front with two advanced fronts heading west and east to the São Brás de Alportel and the Tavira municipalities respectively. Spotting occurred up to two kilometers from the fire front. Fire spread between this stage and the final southern limit in approximately 7 hours.

2.4. Simulation framework

The spatial resolution of the gridded data was set to 100 meters and the temporal resolution was set to 1 hour time step for both models. Fire suppression activities were not simulated in either model. In

FARSITE, fire acceleration and No-Wind No-Slope rate of spread for the spread rate of backing fires, were enabled during simulations. Rate of spread adjustment was set to 1.0 (no adjustment). Three different time steps (Table 2), i.e. burning periods are simulated, based on the documented Tavira wildfire development and behavior (Figure 3).

Table 2. Time steps used to evaluate FARSITE and HFire performances.

Time step	Time of arrival	Milestones
1	2012-7-19 18h00	The fire reached Ribeira de Odeleite
2	2012-7-19 21h00	Blow-up fire behavior, until the fire front reached the area burned in 2009
3	2012-7-20 1h00	The fire reached its south limit

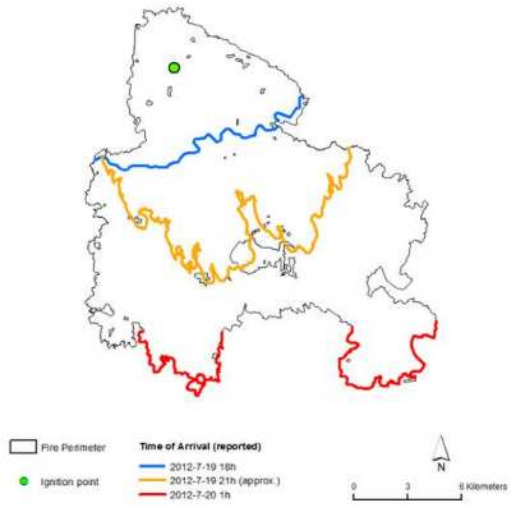

Figure 3. Spatial representation of the fire's time of arrival, for the three defined time steps (Time step 1 corresponds to Ribeira de Odeleite)

Three simulations were performed for both fire-spread models: simulation 1 - initialized at the reported ignition point (start: 2012-7-18 14h); simulation 2 and 3 – initialized with satellite-derived active-fires ignition points from MODIS passages (start: 2012-7-18 22h and 2012-7-19 14h, respectively).

2.5. Simulations performance assessment

The performance of the fire simulations was assessed both spatially and temporally, using the observed burned scar fire perimeter (ICNF 2012) as reference. We used the Sørensen coefficient (Legendre and Legendre, 1998) which indicates the exclusive association between the simulated and the reference burned areas (Eq. 1):

$$SC = \frac{2a}{(2a + b + c)} \quad \text{(Eq. 1)}$$

where *a* is the intersection of the burned area in the two models, *b* is the area burned exclusively by the model, and *c* the area exclusively burned in the actual event. A value of 1.0 indicates perfect agreement.

Other descriptors used to evaluate fire spread simulations performances were the time of arrival (TOA), rate of spread (ROS) and fire line intensity (FLI). FLI is commonly used as a measure of fire suppression capacity (Andrews and Rothermel 1982).

Results and discussion

The Tavira wildfire spread mainly towards southeast, with winds from northeast, which is clearly observed in the simulations performed with FARSITE (Figure 4) and HFire (Figure 5). However, both models underestimated the burned area in the west part. The wind forecast predicted winds from east, which was not reflected in the wind data used to simulate the event and can explain the lack of burn in the west flank of the fire.

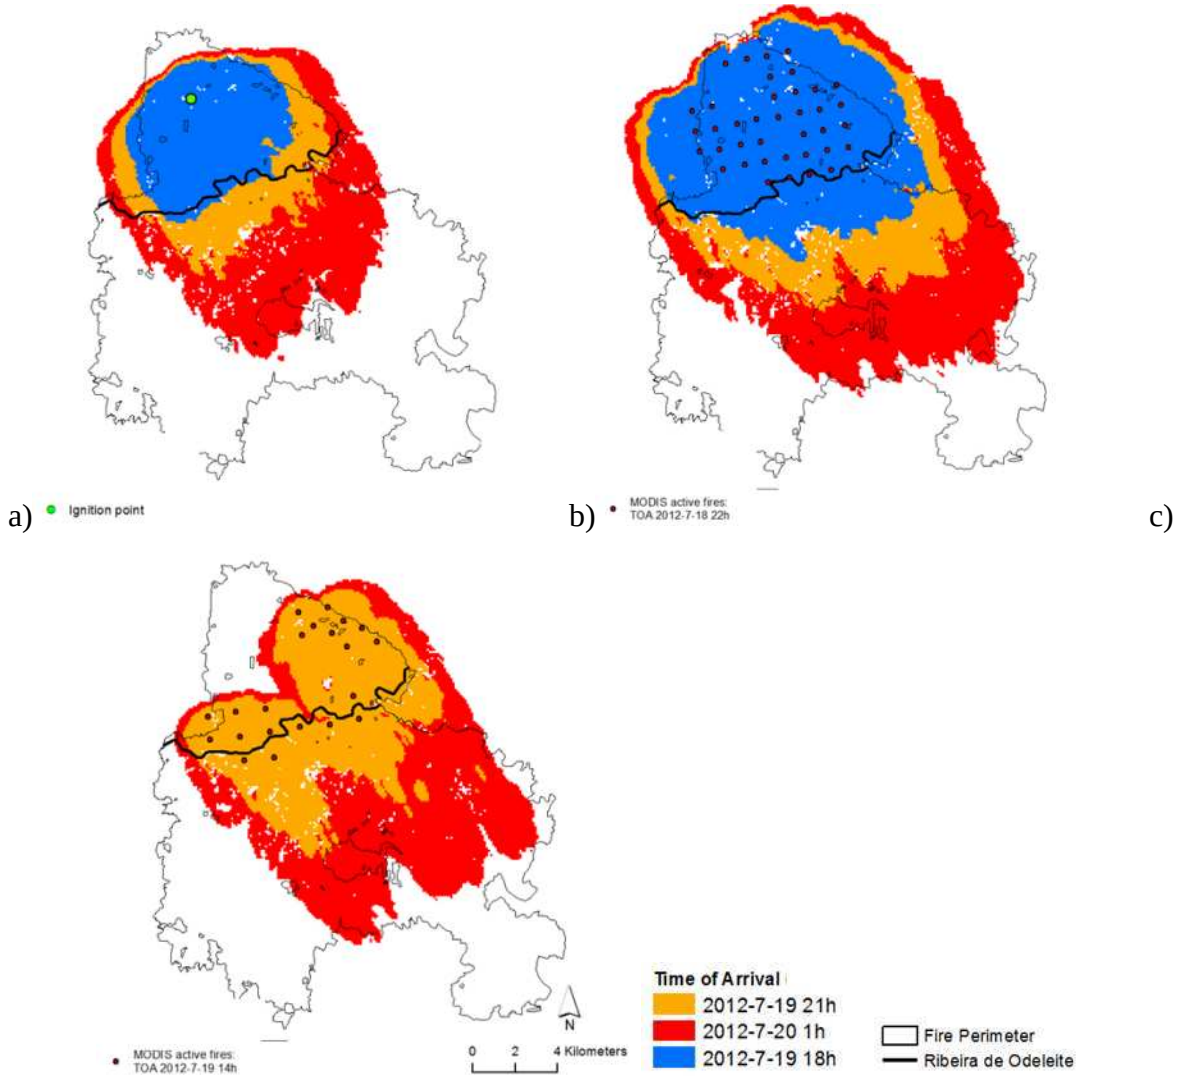

Figure 4. Spatial representation of the simulated time of arrival at the different time steps, using FARSITE. a) Simulation 1 - initialized at the reported ignition point (start: 2012-7-18 14h); b) Simulation 2 - initialized with satellite-derived active-fires ignition points (start: 2012-7-18 22h); c) Simulation 3 - initialized with satellite-derived active-fires ignition points (start: 2012-7-19 14h).

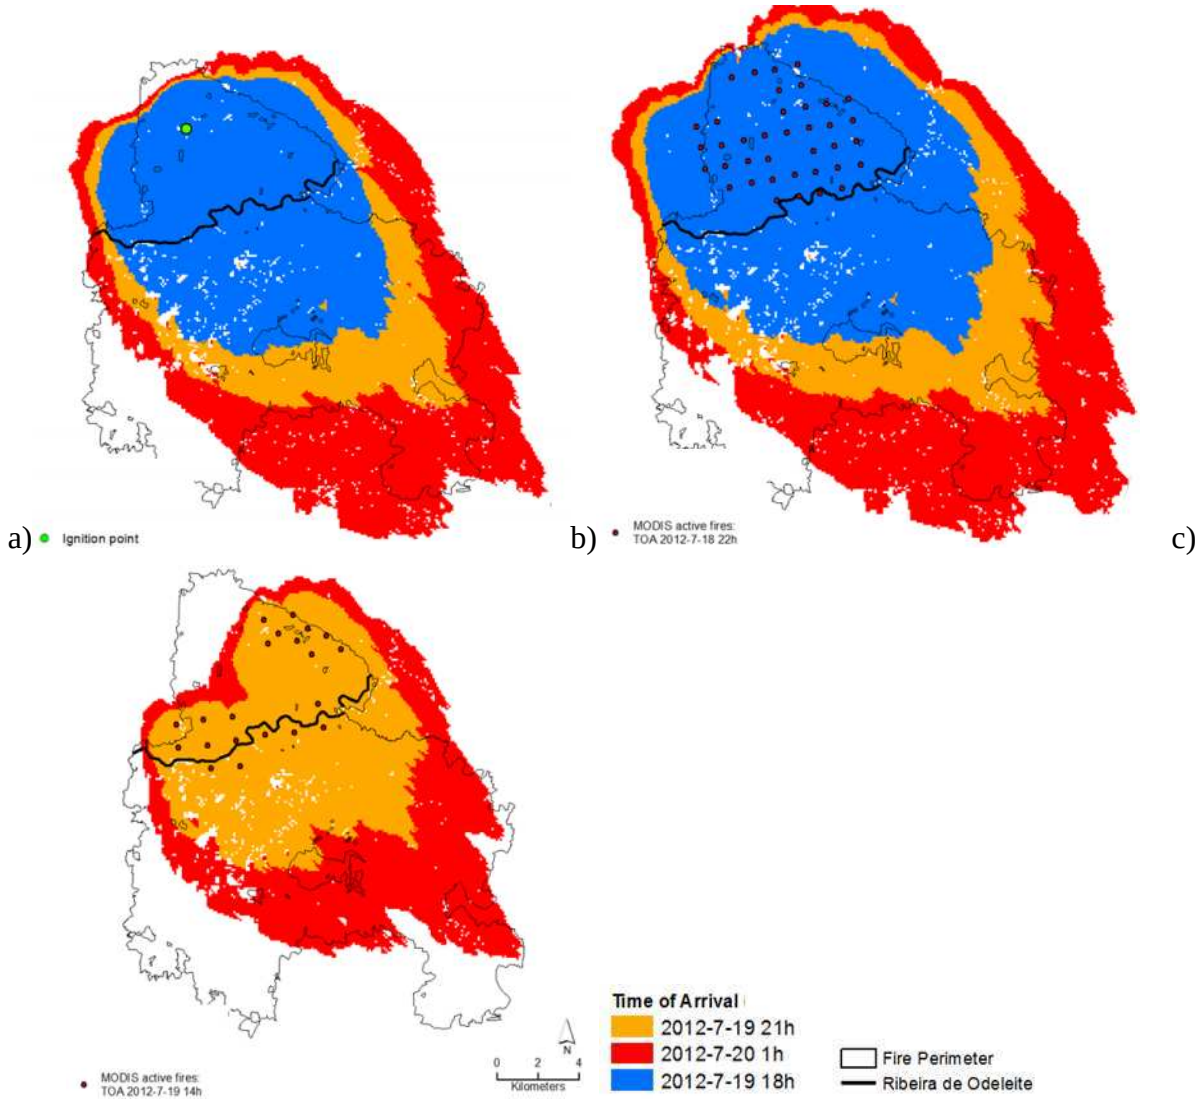

Figure 5. Spatial representation of the simulated time of arrival at the different time steps, using HFire. a) Simulation 1 - initialized at the reported ignition point (start: 2012-7-18 14h); b) Simulation 2 - initialized with satellite-derived active-fires ignition points (start: 2012-7-18 22h); c) Simulation 3 - initialized with satellite-derived active-fires ignition points (start: 2012-7-19 14h).

To evaluate FARSITE and HFire performances, the spatial and temporal agreement between the three time steps of the Tavira wildfire (Table 2, Figure 3) are compared with the three time steps obtained for each simulation with both models.

FARSITE's simulations of burned area and TOA are shown in Figure 4. FARSITE's simulation 1 shows good agreement between the simulated and observed TOA for time step 1, but both estimated TOA for time steps 2 and 3 were underestimated. As expected, starting simulation 2 with active-fires ignition points from the MODIS passage at 22h00 July 18th, improved the estimated TOA of time step 2, now equivalent to the observed TOA for the Tavira wildfire, but continued to underestimate time step 3. Starting simulation 3 with active-fires ignition points from the MODIS passage at 14h00 July19th, underestimated both the estimated TOA for time steps 2 and 3. These differences are probably due to different fuel models available at the start of each simulation, given that in simulation 2 the fire started spreading mainly through grass (fuel models 1 and 2), and in simulation 3 it began to spread mainly through shrub (fuel model 6). Duguy (2007) and Arca (2005) refer the need to increase the ROS adjustment factor for fuel model 6, in order to tune fire spread growth during simulations. Since

this fuel model covers approximately 46% of the area affected by the fire, it can be one of the reasons why all simulations underestimated time step 3, and simulation 3 in particular underestimated time steps 2 and 3.

TOA of time steps 1 and 2 were overestimated for HFire's simulations 1 and 2 (Figure 4). Starting simulation 2 with active fires ignition points from the MODIS passage at 22h00 July 18th, did not change the fire´s time of arrival. Setting the ignition points with active fires from the MODIS passage, at 14h00 July 19th, improved the estimated TOA of time step 2, now equivalent to the observed TOA for the Tavira wildfire, but underestimated time step 3. Again, this underestimation may be related to the fuel type at the ignition location.

The SC values were calculated for each FARSITE and HFire simulations, at the defined times steps (Table 3). Results show good agreement between observed and modeled perimeters for time step 3, for both fire spread models.

Table 3. Values of the Sørensen coefficient for time steps 1, 2 and 3, for the 3 simulations performed with FARSITE and HFire.

		Simulation 1	**Simulation 2**	**Simulation 3**
FARSITE	Time step 1	0.29	0.43	-
	Time step 2	0.41	0.55	0.40
	Time step 3	0.60	0.71	0.68
HFire	Time step 1	0.60	0.61	-
	Time step 2	0.72	0.72	0.53
	Time step 3	0.73	0.68	0.74

Overall results show the best TOA estimates for FARSITE and better SC values for HFire, which was also able to burn into areas that did not burn in FARSITE. When Petersen (2009) compared both models performances, concluded that HFire was better at using narrow corridors to reach additional areas of fuel. While vector-based fire growth models (like FARSITE) produce more realistic fire shapes, raster-based models like HFire can cope better with heterogeneity in fuels and weather (French *et al*. 1990).

For the period between time step 2 and 3, the reported ROS ranged from 20m/min to 25m/min. Figure 6 shows the spatio-temporal variation of the ROS simulated by FARSITE. The simulations predict lower spread rates in the same period. The mean values of ROS for the referred time step, for simulations 1, 2 and 3, were 9 ± 6 m/min, 12 ± 10 m/min, 10 ± 8 m/min respectively. These values are an underestimation of the observed ROS. Nevertheless, simulation 2 presented higher ROS values when compared to simulation 1 and 3. Arca (2005) developed a custom fuel model for shrubland vegetation (maquis) that provided more realistic values of ROS when compared to the values obtained using the standard fuel models. Custom fuel models have also been developed for Portugal (Fernandes *et al*. 2009), and will be considered in future work to produce more realistic ROS estimates.

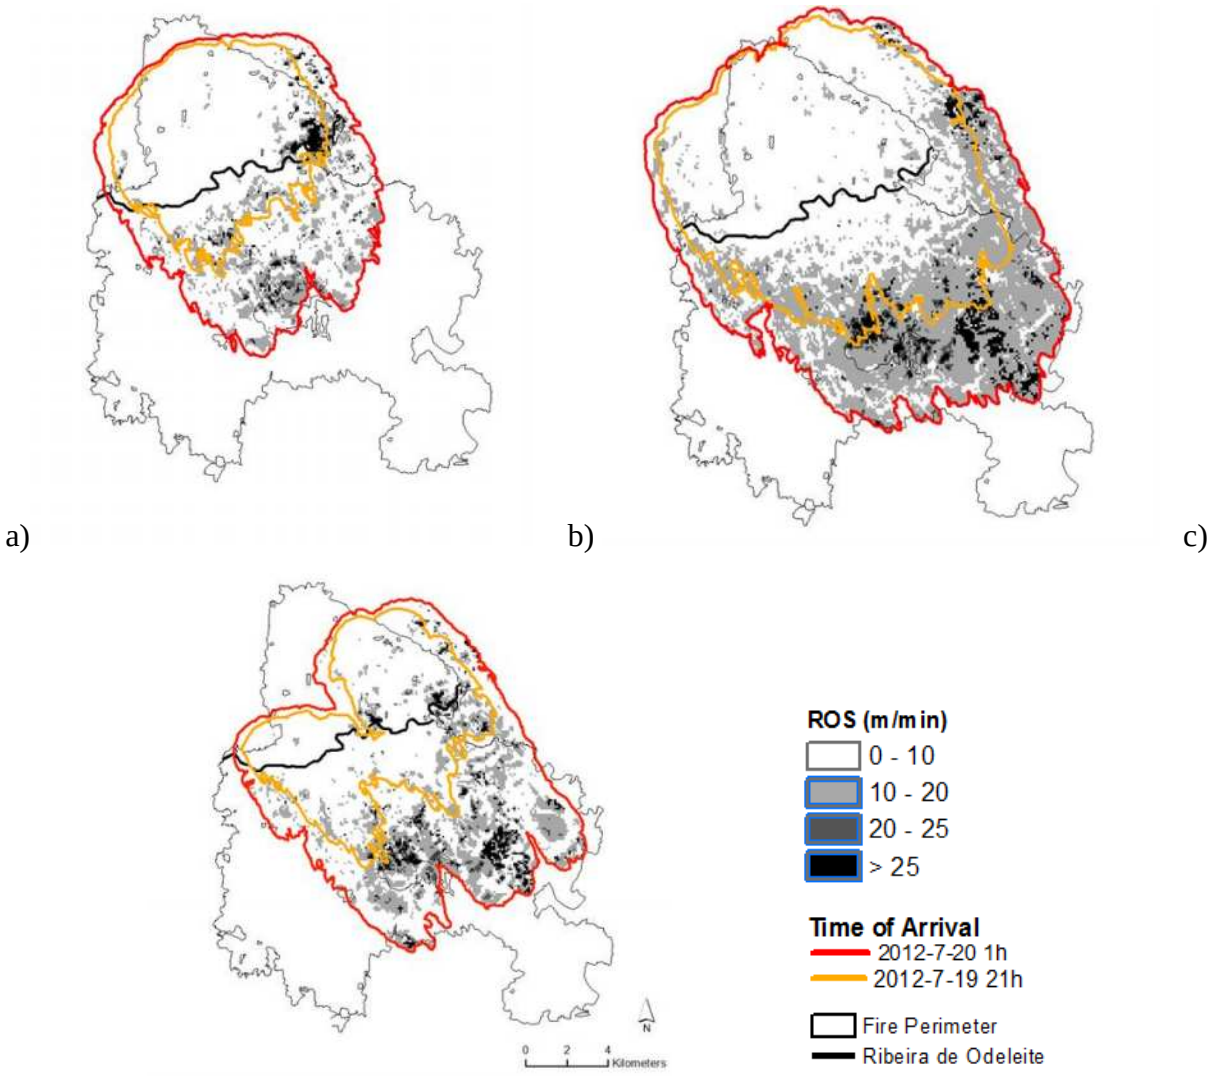

Figure 6. Spatial variation of rate of spread simulated using FARSITE. a) Simulation 1 - initialized at the reported ignition point (start: 2012-7-18 14h); b) Simulation 2 - initialized with satellite-derived active-fires ignition points (start: 2012-7-18 22h); c) Simulation 3 - initialized with satellite-derived active-fires ignition points (start: 2012-7-19 14h).

The Tavira wildfire blow-up behavior, once the fire passed Ribeira de Odeleite is apparent in all simulations, with FLI values simulated by FARSITE generally ranging from 350 to 1750 kW m^{-1} (Figure 7), meaning fires are too intense for direct attack on the head by persons using hand tools and equipment such as dozers, pumpers, and retardant aircraft can be effective.

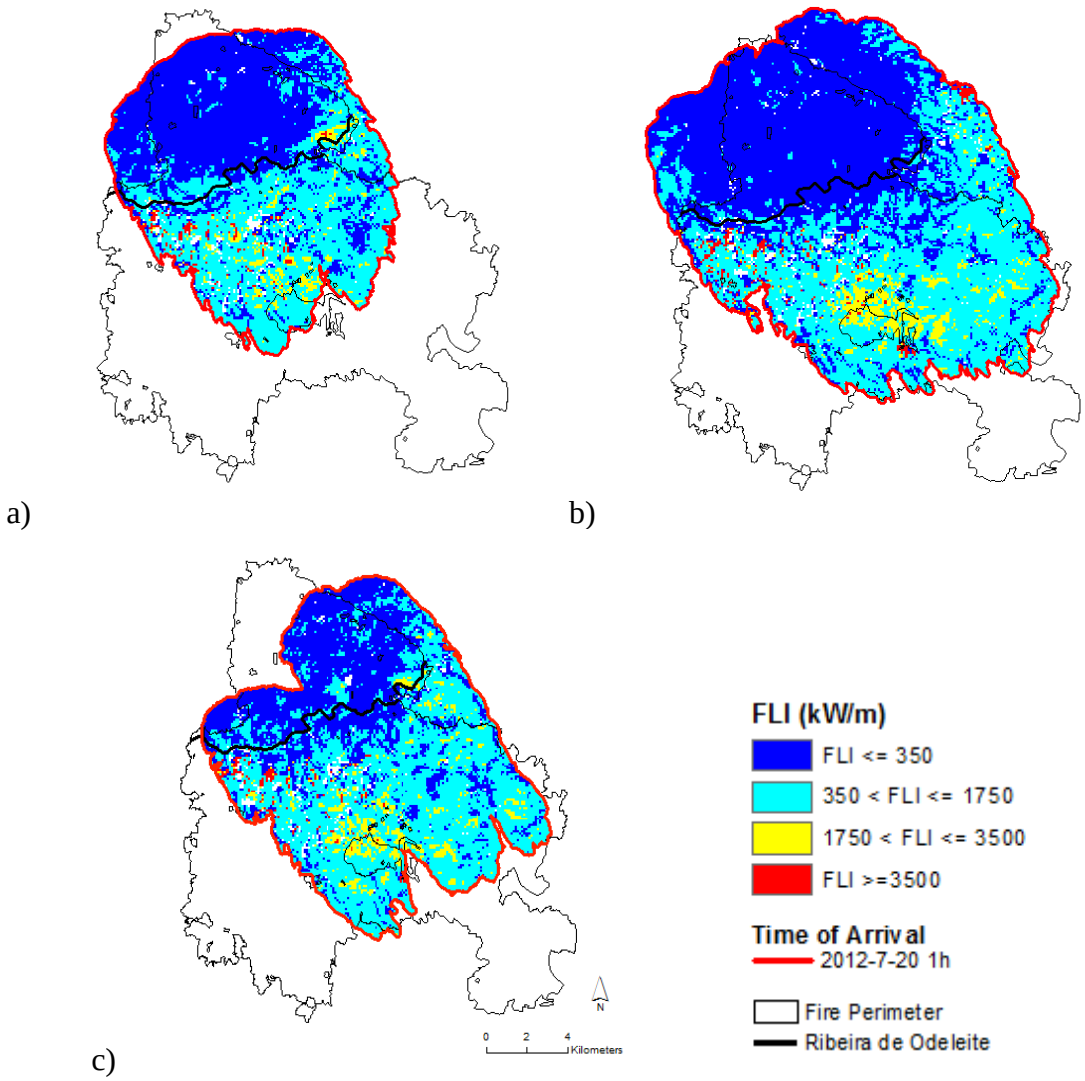

Figure 7. Spatial variation of fire line intensity simulated using FARSITE. a) Simulation 1 - initialized at the reported ignition point (start: 2012-7-18 14h); b) Simulation 2 - initialized with satellite-derived active-fires ignition points (start: 2012-7-18 22h; c) Simulation 3 - initialized with satellite-derived active-fires ignition points (start: 2012-7-19 14h).

Conclusions

In this paper we evaluated the capability of two landscape fire spread models, FARSITE and HFire, to forecast the development of the Tavira wildfire event. A first assessment of the combination of fire spread modelling and MODIS satellite derived active-fires was also performed.

Both fire spread models showed similar estimates regarding fire spread direction and shape. FARSITE produced better time of arrival estimates, i.e. for a given time step, the spatial distribution of the fire front (observed vs. simulated) were similar. HFire presented better Sørensen coefficient values and was also better able to cope with heterogeneity in fuels, reaching additional areas of fuel not burned during FARSITE simulations. However, FARSITE incorporates several other modules other than surface fire spread, taking into account phenomena (crowning and spotting) that play an important role in fire growth during extreme wildfire conditions. It also outputs important fire behavior descriptors

other than time of arrival and burned area. FARSITE was capable of anticipating abrupt changes in rate of spread and fire-line intensity, useful to identify opportunity windows for fire control.
Combining fire spread simulations with satellite-derived active-fires allows splitting a single simulation for the entire duration of the event, into as many simulations as the number of satellite passages, attenuating the errors that propagate throughout a single simulation, since simulations are updated in time and space at each satellite passage. We conclude that this combination improved time of arrival estimates and Sørensen coefficient values for some time steps, presenting great potential for use in near-real time fire spread forecasts.
FARSITE and HFire show good capability to forecast fire spread. The combination of fire spread models with satellite data improves fire growth and behavior predictions, providing valuable supplementary information that can be used in fire management and decision support during large wildfire events.

Abstract
In France, the clearing distance between buildings and forest edge is 50 m, to allow fire fighters to protect those buildings. Current building recommendations in the wildland-urban interface derive from fire-safety tests on building materials using heat exposures (duration and magnitude) that are expected to be different from those produced by wildfires. Beyond a few experimental data released after the International Crown Fire Modelling Experiment, there is a lack of characterisation of the physical environment of a building or human target within a cleared area, that receives hot gases and radiant fluxes from a crown fire. In the present study, we evaluate FIRETEC's ability to simulate heat fluxes based on some available experimental data and subsequently use it to characterize the radiant fluxes, gas temperatures and velocities around a human or building target.
Simulations have been performed in a mature Aleppo pine forest within a 600 by 400 m domain. The conditions of the fire spread were severe (30°C, wind up to 50 km/h, slope until 30%). Radiant fluxes and gas temperatures were computed for several distances between the forest tailing edge and a target that represents either a building or a fire fighter.
Peak radiant heat flux magnitudes decreased by about 80% when the target was at 50 m compared to a target at 10 m. This is between 90 and 95% reduction o0f radiant flux reduction observed at 50 m compared to the forest edge. For the purpose of comparison with reference acceptable thresholds for both materials and fire fighters, the peak values of the average over one minute of the instantaneous radiant fluxes and gas temperatures were computed. These values support the notion that a clearing distance of 50 m is appropriate in the tested conditions for both thermal radiation and gas temperature, even if radiant fluxes remain high is the sloped case.
This study shows a new type of application for physics-based models such as FIRETEC. Simulations demonstrate the interest of clearing around buildings and can help provide recommendations about the appropriate clearing distance. It can also be used for building material specifications.

Keywords: WUI, clearing, radiant flux, gas temperature, building, FIRETEC

Introduction

In France, the clearing distance between buildings and forest edge is 50 m. The aim of this recommendation is to limit fire effects on building, but also to offer safe conditions for fire fighters protecting the building. Current building recommendations in the wildland-urban interface have been derived from fire safety tests on building materials using heat exposures (duration and magnitude) that are of different ranges from those produced by wildfires. Beyond the experimental data released after the International Crown Fire Experiment (Cohen 2004), there is a lack of characterisation of the thermal exposure of a building within a cleared area receiving hot gases and radiant fluxes from a crown fire. Modeling radiatives fluxes is challenging because of its extreme sensitivity to, among other parameters, gas temperature due to the fourth-power dependence of temperature of the emissive power. An error of 20 % on temperature induces an error of 100% on radiative flux. Most of the modelling approaches used up to now assume a value for gas temperature and a shape for the source (Ellis 2000, Billaud *et al*. 2011). In physics-based models such as FIRETEC (Linn & Cunningham, 2005), the local values of gas and solid temperatures and absorption coefficients are computed in 3D by the model itself. These types of models resolve gas transport and combustion equations, coupling heat transfer, transport and combustion. Because of the physical basis of such a model, a satisfactory evaluation over some specific experimental data can give some confidence in the prediction within a slightly broader context. For instance, Linn *et al*. (2012) show some first results demonstrating a reasonable agreement

between the model and the crown fire experiment, even if large uncertainties in wind conditions were complicating the validation process.
In the present study, we evaluate FIRETEC's ability to simulate radiant heat flux using data collected during the International Crown Fire Experiment (Cohen *et al*. 2004). We thus used the model to characterize the radiant fluxes, gas temperatures and velocities to a human or building target. For an evaluation of FIRETEC's predictions of gas temperature and velocities in front and above a fire, the interested reader can refer to Dupuy *et al*. (2014).

Methods

Model evaluation: ability to simulate a radiant heat flux on a vertical target

Following the work of Linn *et al*. (2012), fire behaviour was simulated on four different plots of the International Crown Fire Experiments. Plot 1, 4, 6 and 9 were selected because of the relatively uniform fire behaviour observed during the experiment (Taylor *et al*. 2004, see figure 4). Cohen *et al*. (2004) provided information concerning radiant heat fluxes to a target at 10, 20 and 30 m from the trailing edge: figure 6 shows the temporal variation in incident heat flux for Plot 4 and 9 and table 2 the peak total incident heat ($kW.m^{-2}$) for plot 1, 4, 6 and 9 (except at 10 m for plot 1 and 20 m for plot 6).
The experimental fuels were simulated using the Fuel Manager (Rigolot *et al*. 2010), that provides an explicit representation of each individual tree, based on ICFME data inventory (Alexander *et al*. 2004). Canopy load maps are plotted on Figure 1.

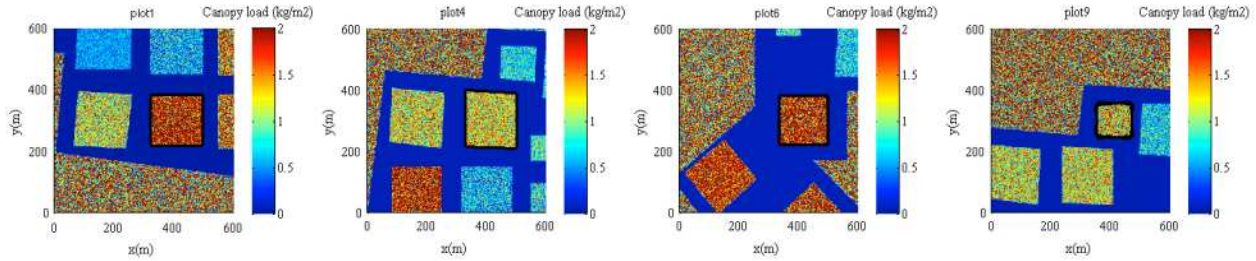

Figure 1. Canopy load maps for the four plots of the ICFME used for the model evaluation. The reference plot is circled in black. On these plots, the wind comes from the left side.

The ambient wind were precomputed using the large scale pressure gradient forcing described in Pimont *et al*. (2014) over homogeneous canopies and were used as boundary conditions for each fire run in order to match the order of magnitude of the reference value in the open (respectively 2.8 m/s, 4.1 m/s, 4.8 m/s, 6.9 m/s at 10 m for plot 1, 4, 6 and 9). Fire was ignited using a "terratorch" procedure, similar to the one used by Linn *et al*. (2012) to reproduce the progressive linear ignition used during those experiments.
FIRETEC uses a Monte-Carlo approach to compute the radiative transfer from any computational voxel of gas and fuel to another one. More details can be found in Dupuy *et al*. (2011). To compute radiative flux toward a vertical target, the number of photons that crosses the vertical cell faces corresponding to target positions were counted. Another specificity of this application is that it required a good accuracy of radiant heat fluxes "far from the flame", whereas what really matters for fire propagation is a good accuracy of radiant heat fluxes "close to the flame". To reach a better accuracy on targets at up to 30 m from the flame, we increased the number of photons thrown by the Monte-Carlo code.
The simulated fires had spread rates of respectively 0.7, 0.65, 0.8 and 1.06 m/s for plot 1, 4, 6 and 9. The experimental spread rates were 0.6, 0.74, 0.6, 1.16 m/s for the same plots. It should be noticed that these experimental fires were performed in a wide range of wind conditions, temperature and fuel

characteristics. Considering the uncertainties associated to wind field description in the experiment and the sensitivity of the model to wind fields (Linn *et al*. 2012), the agreement between experimental and modelled spread rates was found satisfactory.

Using data provided by Cohen *et al*. (2004), FIRETEC's radiant fluxes to targets were plotted against experimental data on Figure 2 for plot 4 and 9. For each distance to the trailing edge (10, 20 and 30 m), data was collected from FIRETEC simulations were at three different lateral positions (centered, 10 m right and 10 m left from the central axis parallel to wind direction) in order to illustrate the spatial variability of the simulated data. For plot 4, the agreement with the experiment was found to be satisfactory: the abrupt rise was very well captured by the model, as well as satisfactory values of peak. The decline occurs quicker in the model than in observations, which can be attributed to the fact that fuels thicker than 6 mm are not accounted for in the model and might play a significant role after the fire front has passed. Radiant heat flux peaks were underestimated on plot 9 by about 30 %. However, it should be noticed that the model rendered the fact that the peak was significantly higher in plot 9 than in plot 1, 4 and 6. Among the reasons that could help to understand the discrepancy, we noted that the modelled spread rate was underestimated (1.06 instead of 1.16 m/s) and Figure 3 illustrates that the modelled fire was more tilted and not as straight as the experimental fire. This might explain why the radiant heat flux was underestimated in this context.

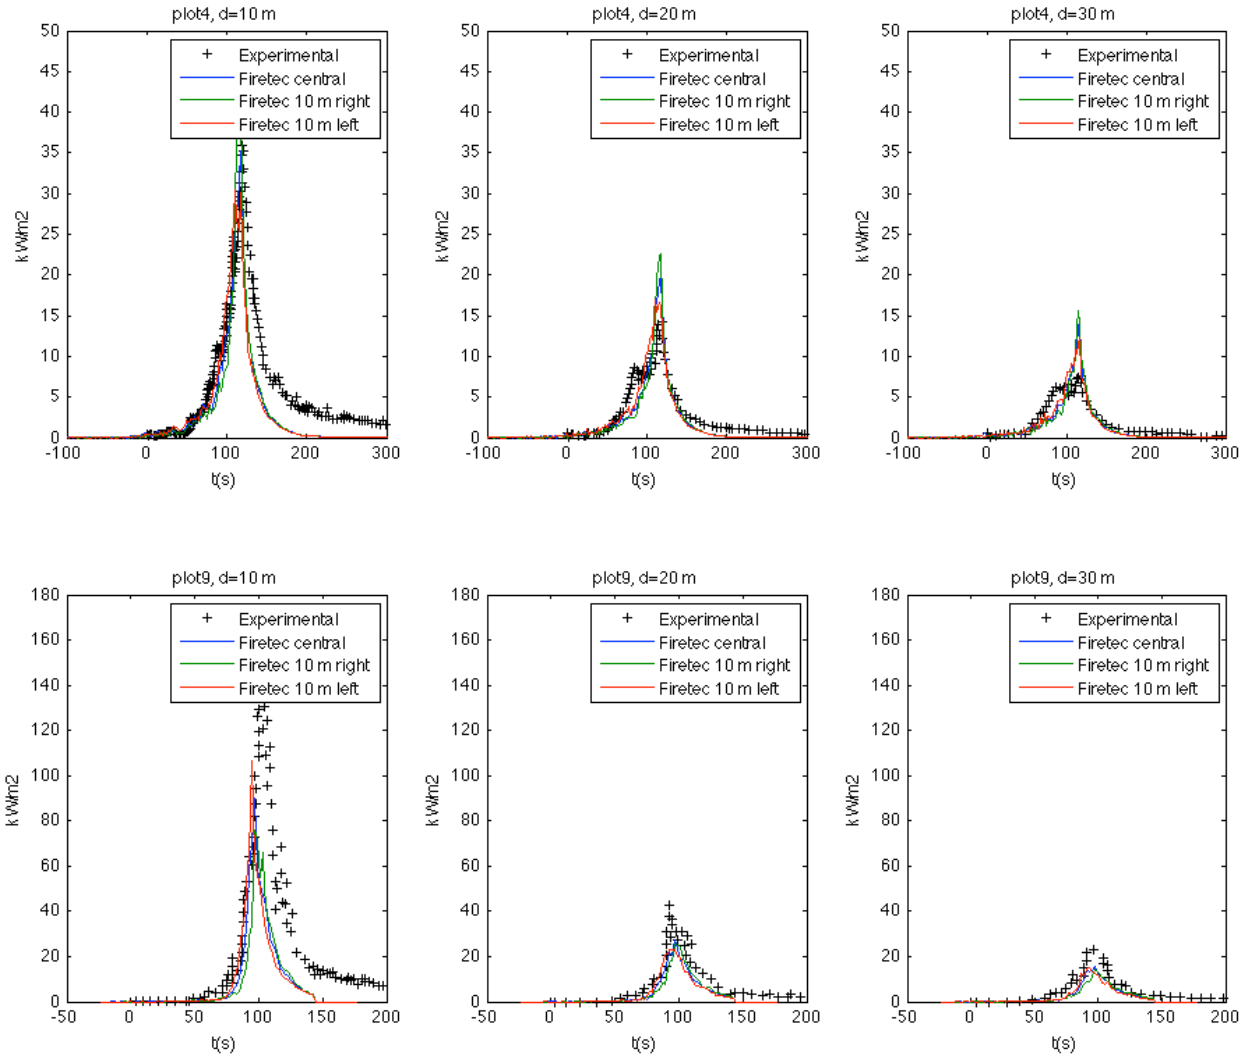

Figure 2. Simulated radiant heat flux at a target at d=10, 20 and 30 m downwind of the trailing edge of plot 4 and 9. Experimental data were taken from Cohen et al. (2004)

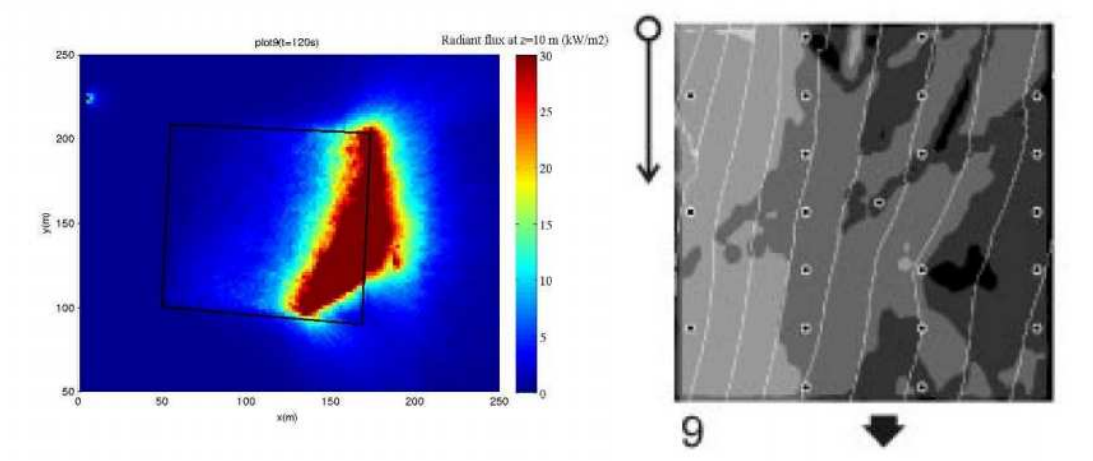

a) Radiant heat flux at z=10 m b) Experimental isochrons for plot 9, taken in Taylor et al. (2004)

Figure 3. Simulated peak radiant heat flux at a target at d=10, 20 and 30 m downwind for plot 1, 4, 6 and 9

Cohen *et al*. (2004) also provided radiant heat flux peak values for plot 1, 4, 6 and 9. **Figure 4** represents the simulated peak values against the experimental ones (FIRETEC's center value was chosen here). A log scale was chosen because of the wide range of radiant fluxes among cases and distances. Again, the agreement was satisfactory.

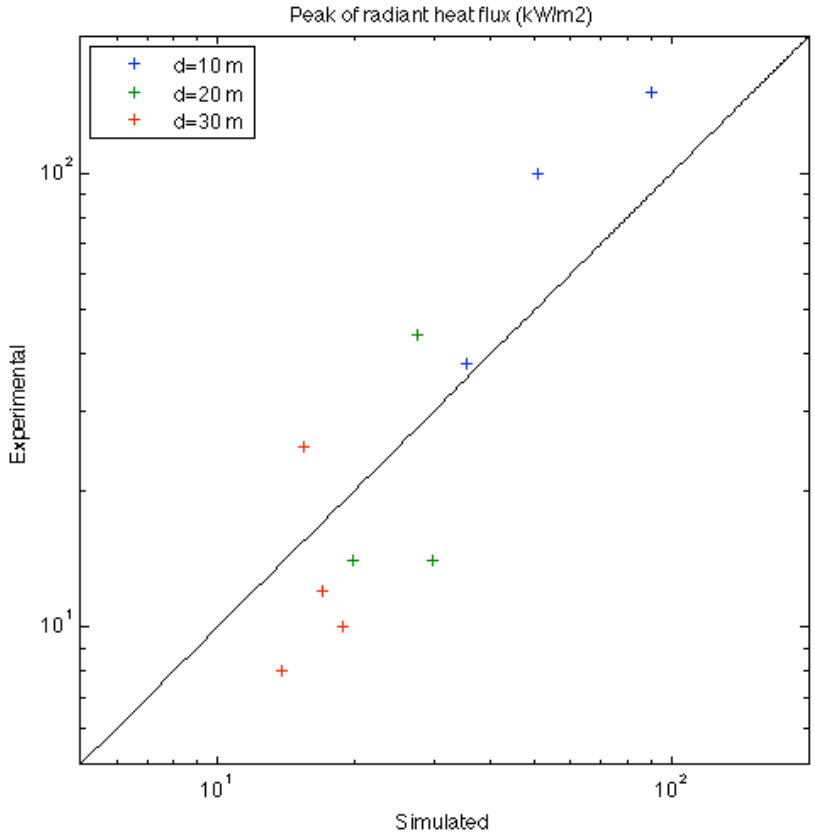

Figure 4. Simulated peak radiant heat flux at a target at d=10, 20 and 30 m downwind for plot 1, 4, 6 and 9.
NB: d=10 m is missing for plot 1 and d=20 m is missing for plot 6

Radiant fluxes in Aleppo pine stand

Four simulations were carried in a mature Aleppo pine forest over a 600 by 400 m domain (Table 1, Figure 5). The forested area is a 40 year old Aleppo pine stand of medium fertility class (corresponding to a dominant height at 50 year old of 12 m) with 1100 stems per ha. The understory is a mixed oak shrubland of 40 year old and has a cover fraction of 80 %. The fuel scene was simulated with the Fuel Manager (Rigolot *et al*. 2010) and can be seen on Figure 5. The simulated fuel scene has a pine/oak cover fraction of 88 % and a fuel load of 1.35 kg/m2, whereas the oak understorey has fuel load of 0.72 kg/m2.

Two different options were tested in the cleared area (see Table 1). Run1 and run2 have some remaining Aleppo pines on the first 20 m of the cleared area, but those pines were thinned so that distances between tree crowns are everywhere greater than 3 m. In the second scenario (run 3 and run4), all the pine trees and oaks were removed. We assumed that there was no ground fuel in the cleared area. Even if this assumption might be found restrictive in such a study, the mesh size of FIRETEC (2 m) is not really appropriate to deal with propagation of a fire in heterogeneous resprouts or patchy fuel at a scale much smaller than grid size. For that reason, this study focuses on the fire effects of the main fire front, spreading from the untreated region (and through thinned trees in the first 20 m of the cleared area when pine trees were only thinned at 3 m between crowns). The reader must be aware that the effect of the fuel recovery in the cleared area is not accounted for. The consequences of this assumption will be discussed in section 4.

The conditions of the fire spread were severe: the air temperature was 30 °C, with a wind speed of 50 km/h (at 10 m in the open that is upwind to the forest), the slope can reach 30 % and the fuel moistures were dry (100 % for Aleppo pine needles, 70 % for live understorey fuel and dead fuel moisture of 10 %). In addition, the cleared area is reached frontally by a crown fire with a wide firefront (about 100 m, when if reaches the cleared area).

Table 1. Description of the four Aleppo pine simulations

	Wind at 10 m in the open	Slope (%)	Presence of trees in the first 20 m of the cleared area
Run1	50 km/h	0 %	Yes
Run2	50 km/h	30 %	Yes
Run3	50 km/h	0 %	No
Run4	50 km/h	30 %	No

The fluxes and gas temperatures were computed at several distances (d=10, 30 and 50 m) downwind of the full-forest trailing edge including a 10 m height target that represents a building (Figure 5). To account for spatial variability, ten different virtual targets were used at each of the three reference distances. As in the evaluation procedure described in section 2.1, the number of photons used in the MonteCarlo scheme was increased to increase long distance accuracy. It should be noticed that the target is virtual here, so that no computation of the flow motion around the building or fire fighter is done, which might affect the gas temperatures, but not the radiant fluxes.

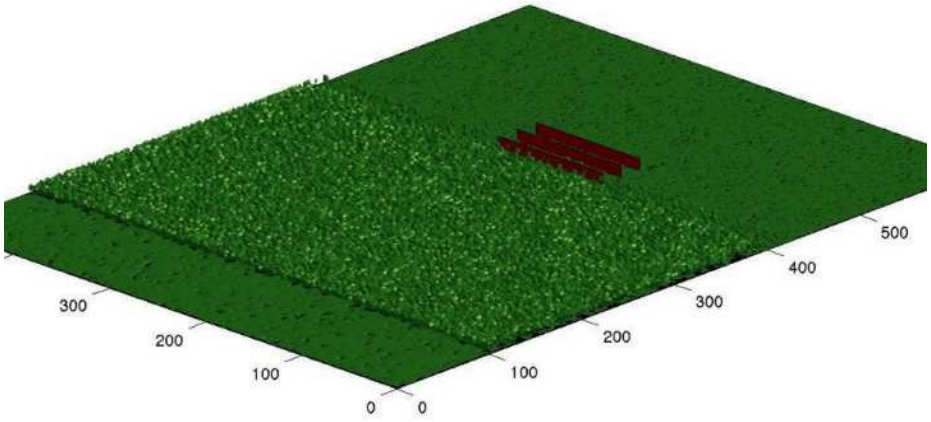

Figure 5. Schematic view of the numerical experiment in the no-slope scenario with tree thinning on the first 20 m of the cleaned area. The three red planes represent target location at respectively 10, 30 and 50 m from the forest edge.

In addition to the instantaneous radiant fluxes and temperatures similar to Figure 2, the peaks of 1 min-averaged radiant fluxes and temperatures where computed at 30 different locations in order to compare them to some known thresholds. The 30 different locations (10 for each distance *d*=10, 30 and 50 m) were then used to compute a maximum and mean value of peak time-averaged quantities over space.

Results

Fire behaviour

The fire behaviour computed by FIRETEC in the scenario described above was always an active crown fire (Figure 6), with computed spread rates of 1.05 m/s for the no slope scenarios (run1 and run3) and of 1.30 m/s for the 30 % slope scenarios (run2 and run4). For the no slope scenarios, the fire intensities reached 27000 kW/m at the head of the fire with a residence time of about 70 s. For the 30 % slope scenarios, the head-fire intensity reached 36500 kW/m with a residence time of about 100 s. Even if the fuel types are different, those values can be compared to the most documented crown fire experiments to date (ICFME, see above, Taylor *et al*. 2004), in which spread rates of more than 1.1 m/s were experimented with wind of less than 25 km/h on similar fire fronts without slope. Residence times between 63 and 94 s were reported at the ground and close to 30 s in the canopy.

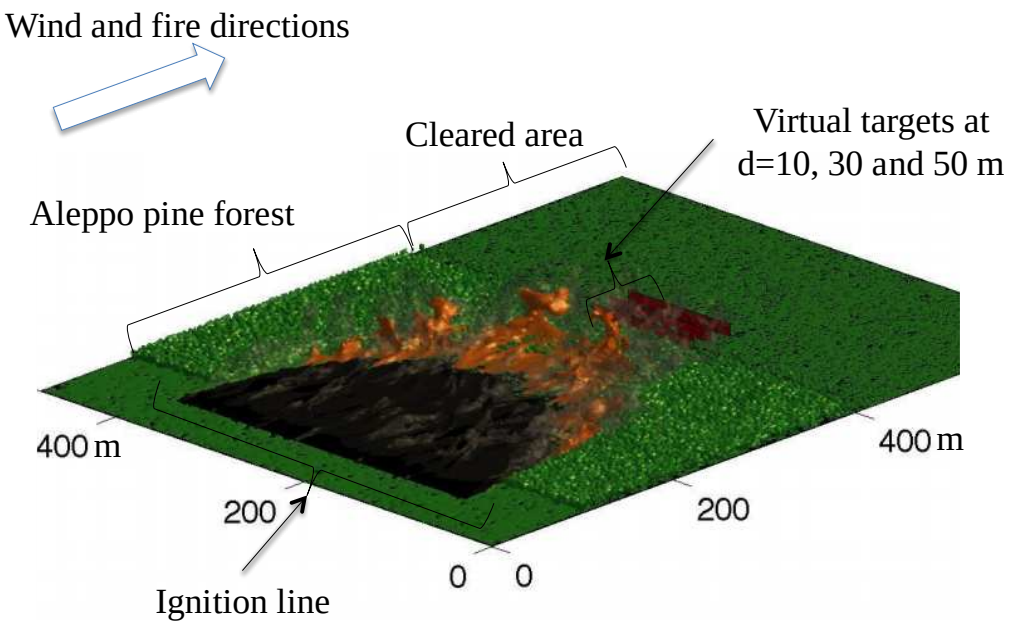

Figure 6. Fire propagation on the forest zone in the no-slope case

Instantaneous and time-averaged radiant heat fluxes

Figure 7 shows how the radiant heat flux decreased of approximately 80 % when the target was 50 m from the forest compared to a target at 10 m. This is up to 90 to 95 % of radiant flux reduction at 50 m compared to the values at the forest edge, that reach 200 kW/m^2. In Table 2, the mean and maximum (in brackets) value corresponds to spatial mean and max among virtual targets of the peak values of time-averaged fluxes. Mean peak average fluxes at 50 m were about 5 kW/m for the no slope cases and of 8 kW/m for the 30 % slope cases. The decrease associated with distance from forest edge was slightly lower for time-averaged quantities than for instantaneous quantities, with a reduction about of about 75% between 10 and 50 m data. The presence of thinned trees in the first 20 m of the cleared area (with distance between crowns of 3 m in run1 and run3) generally induced a small decrease of radiant heat fluxes for distances higher than 10 m (about 4 %), suggesting that those trees are not strong shelter for the targets. However, at 10 m the ignition of those trees can result in a 10 % increase of heat flux.

The standard deviation of the peak of 1 min-averaged fluxes among the targets at various crosswind positions was limited (not shown), suggesting that spatial variability was limited with a wide and homogeneous fire front. The maximum of the peak averaged flux was about 10 % higher than the mean value. It should be noticed that the maximum value for run4 at 10 m was 20 % higher than the mean value, illustrating that variability could be higher close to the forest edge with slope.

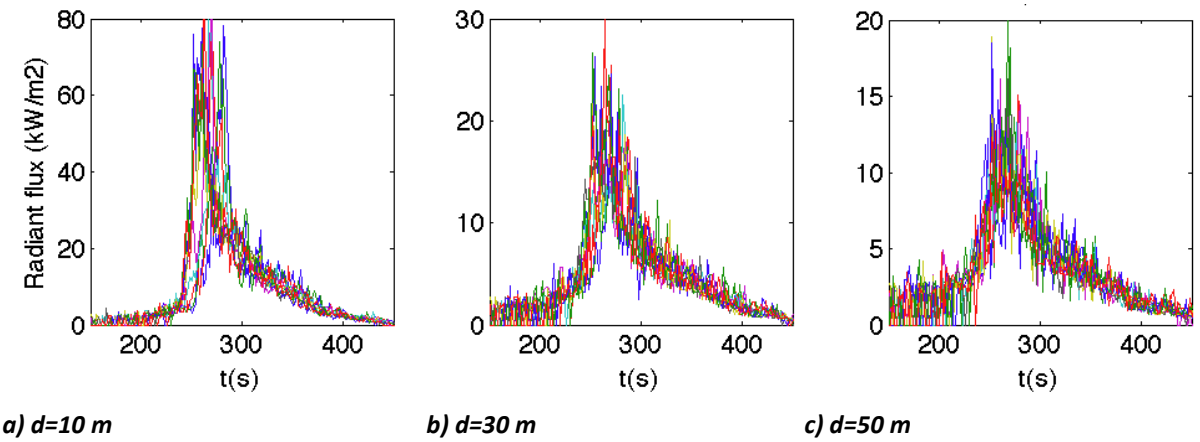

Figure 7. Radiant fluxes to targets at 10, 30 and 50 m from the forest edge in the 30% slope case

Table 2. Spatial mean (max) as a function of distance d of the peak of 1 min-averaged radiant heat flux (kW/m2)

	d=10 m	d=30 m	d=50 m
Run1 (no slope, trees)	24.6 (27.8)	8.6 (9.2)	5.5 (5.9)
Run2 (30 % slope, trees)	31.1 (34.6)	12.2 (13.2)	8.4 (9.1)
Run3 (no slope, no trees)	22.0 (25.8)	8.3 (8.8)	5.4 (5.9)
Run4 (30 % slope, trees)	30.0 (38.8)	11.8 (13.1)	8.0 (8.9)

3.3. Instantaneous and time-averaged temperatures

Figure 8 illustrates how the distance to the edge affects gas temperatures on the 10 m height target. The instantaneous values were much smaller than inside the forest, where they could reach 1000-1100 °C. Peak duration was always shorter than 2 minutes. Due to the large fluctuations associated with instantaneous data in the plume (Dupuy *et al*. 2014), the peak values of the 1 min-average were computed for each of the 30 targets, so that mean and max peak average temperature were computed in Table 3. The peak 1 min-averaged temperature decreased significantly with clearing distance to reach values significantly lower than 90°C, with can be considered as a reasonable threshold for fire fighters. One interesting result is that peak 1 min-averaged temperatures could be 10 % lower in the slope cases, than in the flat cases at 50 m, whereas there were very significantly higher at 10 m (+15-25 %). The stronger plume associated with the more intense fire in the sloped cases could result in their plumes being less tilted from vertical, with lower temperatures at long distances (50 m), whereas they are higher at short distances (10 m) close to the more intense plume and due to the slope effect. Lower gas temperatures in front of higher intensity fires have already been observed by Pimont *et al*. (2011), in the context of fuel treatment.

Figure 8. Gas temperature fluxes around targets at 10, 30 and 50 m from the forest edge in the 30% slope case

Table 3. Spatial mean (max) as a function of distance d of the peak of 1 min-averaged temperature (°C)

	d=10 m	d=30 m	d=50 m
Run1 (no slope, trees)	287 (323)	105 (111)	71 (78)
Run2 (30 % slope, trees)	329 (404)	110 (130)	59 (70)
Run3 (no slope, no trees)	280 (336)	108 (120)	68 (75)
Run4 (30 % slope, trees)	345 (422)	113 (143)	63 (70)

Discussion and conclusion

The evaluation of the fire behaviour and radiant flux predictions against the ICFME, as well as the results presented by Dupuy *et al*. (2014) suggest that FIRETEC is able to reproduce the main trends associated with physical variables with the right orders of magnitude. This evaluation is limited for the moment, but we can expect to evaluate the model in a wider range of conditions in the future, thanks to new field experiment campaigns. However, no model deficiency was identified in these first comparisons, so that the model can be used with some degree of confidence to contribute to the evaluation of the effects of various clearing distance or to investigate how wind, slope and fuel treatment can affect radiant heat fluxes and gas temperatures. Certainly such modelling results should be used in a complementary fashion with additional more detailed experiments.

The results of the present study confirm that a significant clearing distance around houses can have a huge impact to enable the intervention of fire fighters. For instance, the clearing distance of 50 m induced a decrease of 90 to 95 % of the peak radiant flux, as well as a reduction of 80 % of the peak 1 min-averaged heat flux. The peak 1 min-averaged temperatures below 90°C. It should be noticed that with the 30 % slope and severe conditions, a clearing distance of 30 m was not sufficient to allow defensibility, mainly because of the radiant fluxes.

Concerning building protection, the heat fluxes show that a clearing distance of 10 m is clearly insufficient to avoid direct ignition of woody materials, whereas a clearing distance of 50 m would be enough to limit the risk of direct ignition. In the present study, the cleared area was assumed to contain no burnable fuel, with the exception of low cover of pines trees in the first 20 m of the cleared area in run1 and run2. It should be noticed that even when the cleared area has been cleared very recently, some fuels and remaining litter can spread the fire to the building. And because the treatment are not done every year, the law allows the owner to have a phytovolume that can reach 5000 m3/ha, which can represent a fuel load 0.3 to 0.5 kg/m^2. FIRETEC is not the most appropriate model to deal with fire spread in area that has been cleared very recently, with sparse fuel or duff that will carry low intensity fire. The presence of fire fighters or house inhabitants is in general sufficient to avoid house ignition due to these low intensity fires associated with sparse fuels. However, the scenario of a

significant accumulation of phytovolume (5000 m^3/ha) would worth to be simulating: the model is appropriate to do it, if the fuel is relatively homogeneous, as in a low garrigue and the presence of those fuel is likely to significantly modify the heat fluxes and temperatures. Such simulations will be done in the future and could be used to advise prescriptions concerning the fuel accumulation allowed on cleared area around houses.

This study shows a new type of application for physics-based models such as FIRETEC. Simulations demonstrate the value of clearing around house and can help provide recommendations about the appropriate clearing distance. It can also be used for building material specifications such as those released by the French Scientific and Technical Building Center (CSTB).

Abstract
The problem of forest fires in the Wildland Urban Interface (WUI) areas is increasing in all countries that have problems with forest fires. This phenomenon is well known and studied in USA, Canada or Australia.
In European countries the problem is identified and studied. In the last 50 years Portugal experienced an unprecedented rural exodus in all its history. Rural areas faced the decreasing of population every year on the one hand emigration, on the other hand young people moved to urban areas. This led to difficulties of management and increased problems related with combat of wildland fires.
The problem of WUI is growing so fast in Portugal in last decade, mainly as a result of the events occurred in 2003, 2005, recently 2012 and 2013. This problems of WUI were identified as a priority, immediately afterwards to personal safety.
Given the importance of spot fires in the context of WUI fires the Centre of Forest Fire Studies (CEIF) developed several studies to increase the knowledge on this problem.
A study of the probability of penetration of firebrands in typical Portuguese house roofs was carried out. Studies on ember aerodynamic transport and on new ignitions inside houses caused by embers. In particularly this second work about ignitions inside houses is being developed with test that involves the generation of embers in a special device designed to create embers, similar to the ones generated in a real forest fire that can transpose structural gaps of the models tested and start a new fire inside of the structure.
In order to carry out this study program a firebrand generator similar to the Baby Dragon developed at NIST by Suzuki and Manzello in 2011 was built. The original device was used in 2013 by Manzello for a similar study.

Keywords*: wildland-urban interface, spot fire, firebrand generator, firebrand particles, burning particles.*

Introduction

The problems of forest fires in the Wildland Urban Interface (WUI) areas are increasing in all the countries that have problems with forest fires (Ribeiro *et al*, 2010). This phenomenon is well known and study in USA (Cohen, 2010), Canada (Cohen *et al*, 2004, 2008) or Australia (Harrap, 2004). In European countries the problem has been identified and studied (Caballero *et al*, 2007).
In the last 50 years Portugal experienced as well other Mediterranean territories an unprecedented rural exodus in all its history (Freire, 2006). Rural areas faced the decreasing of population every year on the one hand emigration, on the other hand young people moved to urban areas. This led to difficulties of management and increased problems related with combat of wildland fires. The problem of WUI is growing so fast in Portugal in last decade, mainly as a result of the events occurred in 2003 and 2005 (Ribeiro *et al*, 2010) and recently in 2012 in the south region of Portugal in Algarve (Viegas *et al*, 2012), and 2013 in Alfândega-da-Fé, Bragança district in the northeast region of Portugal (Viegas *et al*, 2013), as consequence the WUI problem was identified as a priority, immediately afterwards to personal safety (Viegas, 2008).
The situation in Portugal and Mediterranean areas and countries is quite different from the point of view of structures that could be burned. Structures are made of bricks that are not combustible and so in terms of fire the houses of this type of construction are much more resistant although they could be affected if they were not well maintained or have some weakness of constructions as gaps in windows,

doors, roofs and ventilation systems.. In the other hand many places such as USA, Canada have different types of constructions based on wood that are greatly affected by the occurrence of forest fires, despite of this they have some particularities that made is construction attractive as the low price of construction and quick time of construction or reconstruction after a fire.
It is also remarkable that despite of less construction on wood structures is not a synonym of lees problems in an occurrence of a fire many new fuels could appear in a forest fire context as the wastes drooped in the forests.
Given the importance of spot fires in the context of WUI fires the Center of Forest Fire Studies (CEIF) developed several studies to increase the knowledge on this problem. A study of the probability of penetration of firebrands in typical Portuguese house roofs was carried out (Viegas *et al*, 2008). It is not correct believe that wildfires ignite homes by the direct contact of flames on flammable surfaces, Mediterranean structures are not. It is very unusual to have a home ignition this way because of the non flammable nature of the materials.
Studies on ember aerodynamic transport and on new ignitions inside houses caused by embers transposing gaps are being developed. In order to carry out this study program a firebrand generator similar to the *Dragon* developed at NIST by (Suzuki and Manzello, 2011) was built at CEIF by Freitas (Fig.1). The original device was used in Manzello *et al.* (2013) for a similar study.

Figure 1. Firebrand Generator Device

Methodology and Results

An extensive experimental program to calibrate the equipment and to develop a methodology of test was established by Freitas (2013) for the study we have mentioned before.
The fuel particles used to generate the burning embers were pellets. Pellets were chosen because of their known characteristics of calorific value (not important in these tests), dimensions of weight and volume and their facility to burn and generate large amount of particles. Using this type of initial fuel is the best way to reach a repeatable experiment.
The device was manually fed with given amounts of fuel with initial mass (m_i). The tested quantity was considered at 300g of pellets. Greater amounts of pellets were not reflected in more number of generated particles by the device.

Other test control parameters are the gas burner pressure (p), the flow velocity that is linearly related to the radial fan velocity or frequency (Hz) and different opening gaps. Calibration tests to determine the flow of burning particles mass flow rate dm/dt for various sets of control parameters were performed.

A variation on the opening sizes sample results of the mass flow rate for different values of m_i performed with gas pressure equal to 0.3 bar and fan frequency of 50 hz are shown in figure 2.

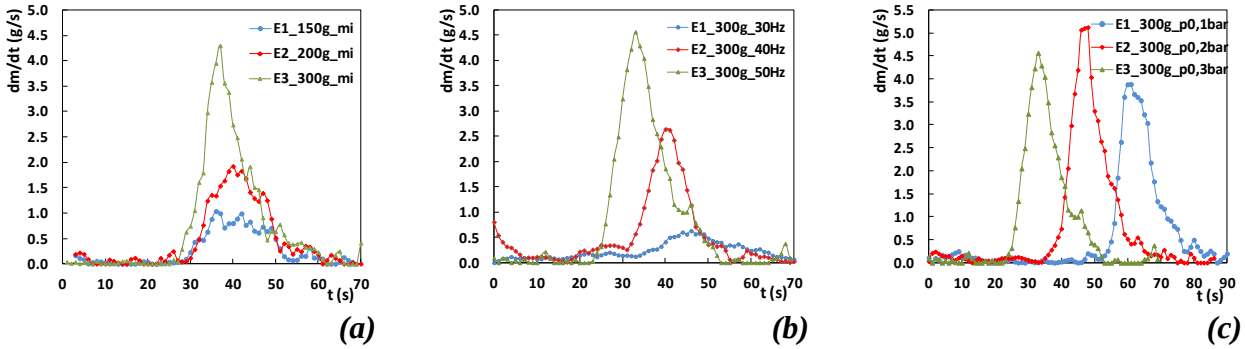

Figure 2. Plot of the rate of ember production dm/dt (g/s) as a function of time t(s). a) varying initial mass; b) varying flow velocity; c) varying gas pressure.

According to figure 2a) the duration of the shower of embers does not depend on the value of $\boldsymbol{m_i}$ but the peak value of *dm/dt* increases with $\boldsymbol{m_i}$. Figure 2b) shows that the maximum value of *dm/dt* increases with flow velocity and occurs earlier in the test. Figure 2c) show that the peak value of *dm/dt* is larger for gas pressure equal to 0.2bar and it decreases for larger or smaller values of ***p***.

In order to analyze the flow of embers through the gap created by a partially closed window or door simulating an opening in a house or building, a special structure that is shown in figure 1 was built specially for this experiment. The results of mass collected in five series of tests with vertical gap values set manually between 0 and 5 cm are shown in figure 3. The reason of choosing 5 cm is the consideration of a small but sufficient size opening to permit a burning particles cross inside the structure. The points corresponding to ***h***=80 cm Standard dimensions of a completely opened window are not shown in the figure but they are very similar to those obtained for h=5 cm A small side opening but wide enough, to the pass of particles. We consider 5 cm as a maximum threshold.

In these tests the following control parameters were kept fixed: *p*=0.3bar, $\boldsymbol{m_i}$ =100g and Frequency=50Hz. During the test the particle generator was placed always in the same position in relation to basis of the gap (from 5 to 80 cm openings). During the ember shower the particles that passed in the gap were collected in a wet surface that would quench immediately the burning particles in order to conserve their mass. After the test these particles were carefully collected and weighted. After that remaining water was eliminated by an oven process drying. The complete evaporating process of water particles took a 24 hours period. The results obtained of completely dried particles in a series of tests in which the gap height ***h*** was varied between 0.5 (almost closed) and 80 cm (completely opened) are shown in figure 3. These results show that the mass of particles collected inside the gap increases sharply for relatively small values of ***h***. For 0<***h***<3 cm the collected mass increases in average from 0 to 7g while for 3<***h***<80 cm it increases in average only to 8g.

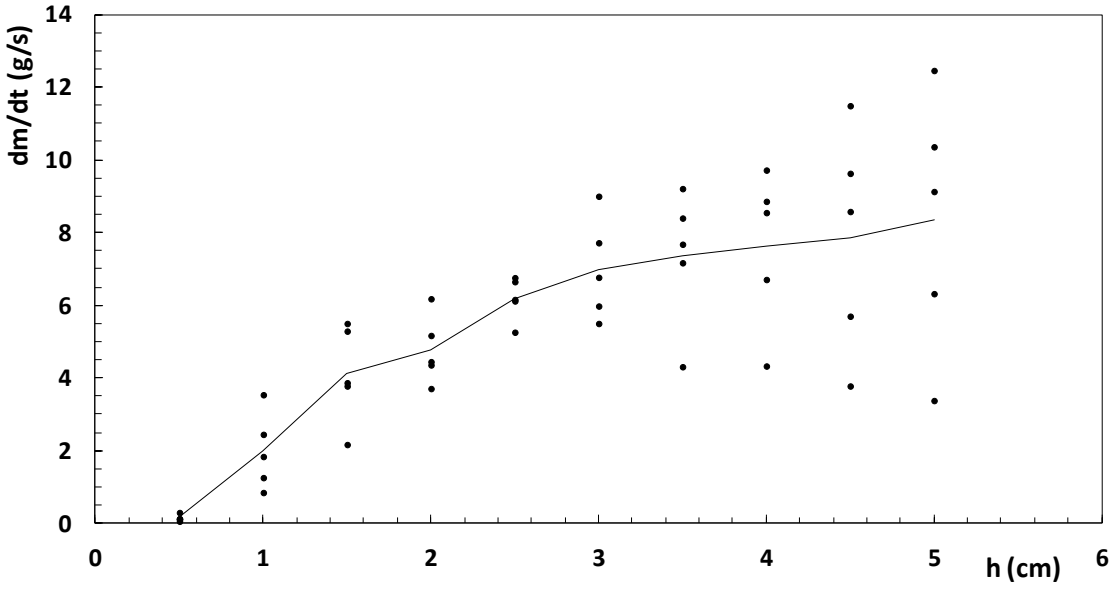

Figure 3. Mass of embers that transposed the gap as function of gap height h (cm). The continuous line is the average of five tests.

Further work

It is expected to extend the analysis for other particle sizes different of the ones represented in figure 4.

Figure 4. An example of firebrand dimensions obtained in the tests are showed in a 3 mm x 3 mm grid

To characterize the generated embers as a function of the feed particles properties could be used a new technique applied to the forest fires called PIV that are being used in CEIF laboratory to the study of firebrands generated by the burning of trees as showed in figure 5

Figure 5. An example of firebrand generated by the burning of trees

Particles position inside the structure can be studied as a limit parameter of an Inside Home Ignition Zone (IHIZ), the inside home fuels (curtains, armchairs, carpets) that an ember could find next to an opening like a window or a door and burn them.
We intend also to continue the experiments submitting different real structures to the tests with showers of firebrands like doors, windows and other structural weaknesses or openings that present in a real structure (figure 6).

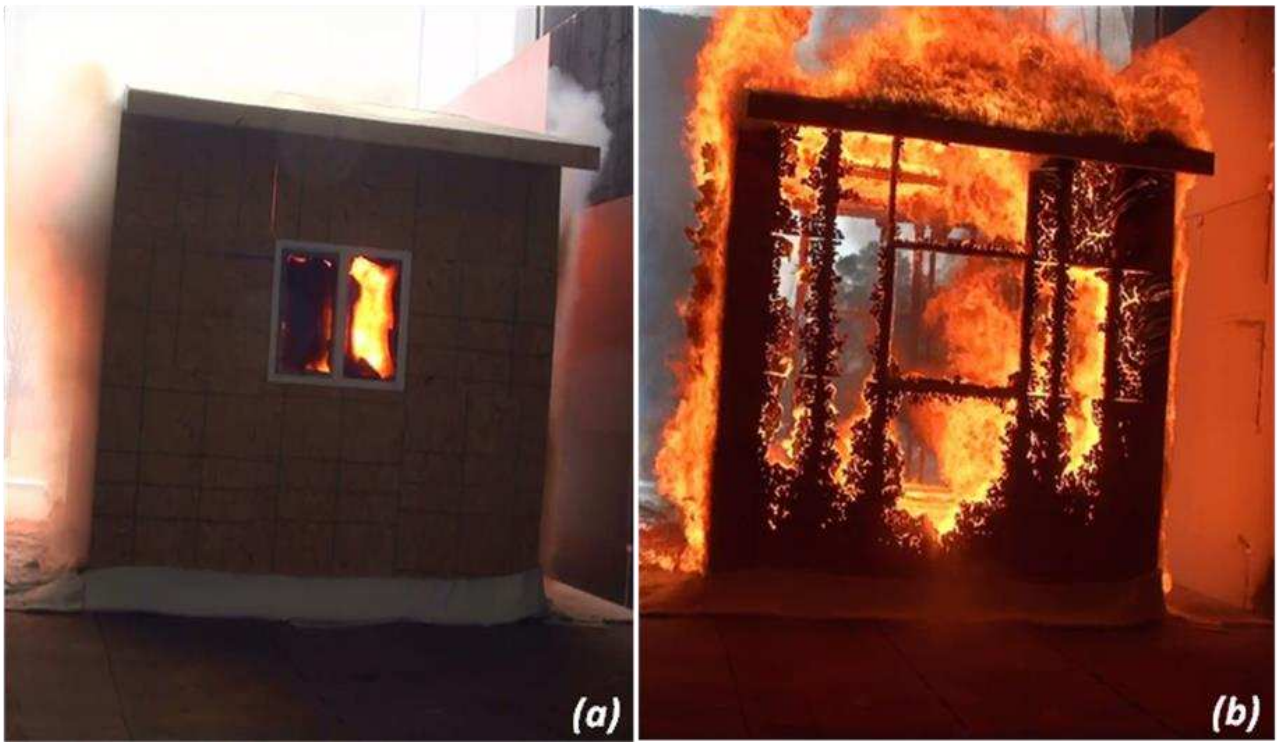

Figure 6. An example of real structures tested used in similar studies (a) after 4 minutes (b) the same structure after 10 minutes (source NIST, 2013)

Conclusions

This paper aims to contribute to a better understanding about the houses ignition by firebrands. Recent studies conducted in several countries that have serious problems of house ignition by firebrands allowed us to understanding the risks of houses ignitions in WUI areas.
The embers generator device installed at the CEIF laboratory allows us to lead several projects to propose mitigation measures to decrease the risk of home ignition in Mediterranean areas. This device working together with the PIV system could be a powerful tool to get reliable data about this problem such as the characterization of the generated embers as a function of the burned fuels and consequently the probability of the ignition as function of the type of the s released particle.
More studies should be effected whit the generator device to have more consistent results as gaps in doors or windows and whit real structures to testing different construction materiaisl to mitigate the problems in WUI areas.

Gaining benefits from adversity: the need for systems and frameworks to maximise the data obtained from wildfires

Abstract
The organisations that manage wildfires are expected to deliver scientifically defensible decisions. However, the limited availability of high quality data restricts the rate at which research can advance. The nature of wildfires contributes to this; they are infrequent, complex events and occur rapidly. While some information about wildfires is usually collected, it is often not of an appropriate standard for research. Valuable information may be discarded or not collected as it is not seen as operationally useful. The harmonisation of fire data management worldwide could increase the availability and quality of information for research. We propose a three tiered approach where agreements are created to standardise data quality, define the scope of information to be collected and establish access protocols for sharing. Standardisation of data collection would facilitate the aggregation of data throughout the world, providing leverage on data collected and reduce unnecessary duplication. If the scope of collection can be expanded, there are a wide range of research fields that stand to benefit. Appropriate data sharing between agencies would increase the value of the data and enable robust conclusions to be reached. It is imperative that the losses caused by severe fires are not in vain; losses should be offset by efforts to maximise the information obtained, helping to prevent a repeat of such events in the future.

Keywords*: bushfire, data, enquiry, experimental design, framework, investigation, observations*

Introduction

In the last decade there has been a high number of catastrophic wildfires throughout the world. In Australia alone, fires burning under extreme weather conditions have resulted in mass house loss in the state Victoria in 2009 (Cruz *et al.* 2012), Western Australia in 2011 and New South Wales and Tasmania in 2013 (Kepert *et al.* 2013). These fires have resulted in substantial social, economic and environmental impacts and recovery activities may take many years. In response to the increasing threat of fire, land managers in vulnerable jurisdictions have made substantial investments in mitigation, preparedness, response and recovery capabilities (McLoughlin 1985; Gebert and Black 2012). Due to the complexity of managing fires, it is not always clear how best to make investments to reduce fire impacts. As a consequence, there has recently been a rapid development of tools to aid decision support for landscape managers in fire prone environments. These include the development of systems that can evaluate complex information to optimise investment levels (Prestemon *et al.* 2008), resource placement (Chow and Regan 2011) or provide information on fire behaviour to aid suppression planning (Sullivan 2009). The development of systems that can support decisions for complex landscape scale events requires research that can differentiate the contributions of numerous interacting factors to an outcome. The analysis of such 'noisy' events requires large amounts of data in order for models to have adequate predictive power. However, the nature of wildfires means that obtaining such data is challenging.

Wildfires typically occur with limited notice, burning in heterogeneous natural landscapes driven by complex weather patterns (Cary *et al.* 2009). The behaviour of fires and their subsequent impacts are consequently the product of multiple interacting parameters and as a result, it can be difficult to quantify relationships and predict outcomes. While some research into wildfires has attempted to address this problem through the use of controlled experiments (Cheney *et al.* 2012), the need to safely manage trials has meant that it is prohibitive to use such experiments to evaluate emergent fire behaviour under extreme conditions. However these events are where losses are typically highest and are consequently of greatest interest to managers (Strauss *et al.* 1989). In addition, many elements of fire management need to be in a realistic landscape context to be relevant; activities such as evacuation or fire suppression are difficult to emulate experimentally.

As research into fields relating to extreme fire behaviour cannot be done experimentally, alternative sources of information are required to allow systematic management planning. The sole remaining way to source observations of fire dynamics is to collect information from fires as they occur. While up to date information is recognised as a critical need for managing 'going' fires, to date there has been a limited focus on collecting information during fires for post-fire analysis. Typically, post-fire investigations are driven by coronial or governmental requirements; it is rare for there to be a systematic process for collecting information during and after severe fires specifically for research purposes. Without such information, fire research and the development of subsequent decision support systems will stall. Case-study fires are commonly used in research; however there is currently no formal process for ensuring the data collected during and post-fire is appropriate for meeting research requirements.

While up to date information is recognised as a critical need for managing 'going' fires, to date there has been a limited focus on collecting information during fires for post-fire analysis. We contend that the collaborative development of a fire data management framework across multiple jurisdictions will have broad benefits for all involved. It has the potential to enhance cross border collaboration, increase the power of datasets and make research findings more internationally relevant.

1.1. The current state of data management

In jurisdictions where fires occur, it is typical that some information about wildfires is collected. This may be details of ignitions (Penman *et al.* 2013), severity (Harris *et al.* 2012) or economic impact (Donovan and Noordijk 2005). However there is currently no unified set of standards or methodologies that define a) what information needs to be collected and b) when collected, what data standards are appropriate. Furthermore there is no standardised system for sharing information that has been collected. As a result, the information that is generated during a fire may not be of an appropriate standard for research, it may be discarded if it is not seen as operationally useful or it may not be seen as important and it may not be collected at all (Figure 1).

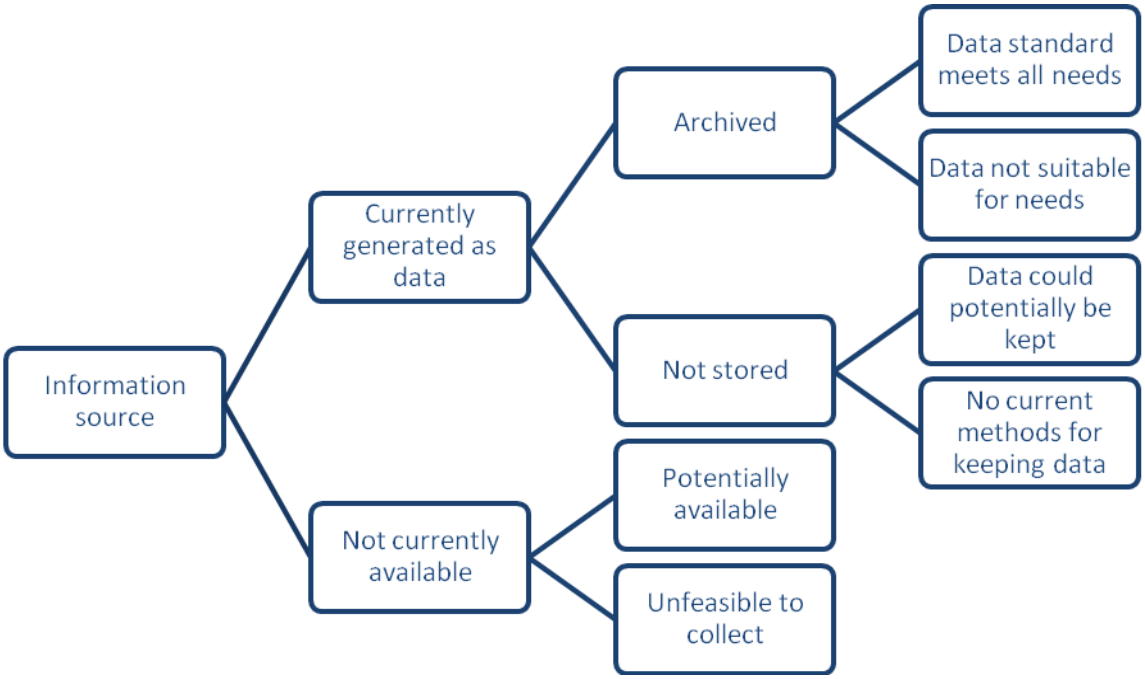

Figure 1. Data hierarchy for information generated at a fire incident

Proposed methods

Determining the breadth of information requirements

Experimental emulation of the most extreme fire conditions is not possible, particularly as many elements of fire management need to be in a real landscape context to be relevant; activities such as evacuation or fire suppression are difficult to emulate experimentally. At the moment, any agency managing a fire incident has specific information requirements to meet its daily operational and planning needs. While meeting these needs has been the priority for managers, there are potentially other needs that are not being met. These may be the needs of external groups (such as university researchers), other intra-governmental agencies (such as the police), inter-governmental agencies (such as the fire management agencies of other jurisdictions or states) or future needs within departments. In addition, at small scales (such as in relation to a single fire) some forms of information may not seem informative. However, when pooled, sample size and consequent model power is increased and the information may then be much more valuable. Without consistent data collection and management protocols, fire information may be useful only within the jurisdiction in which it is collected. Consequently to get the maximum value from information, discussions should be held at the highest level possible – the ultimate benefit would result if data could be effectively pooled across international borders, regions and continents. To do this agreement must be reached on three broad areas; ***scope***- what to collect, ***standards*** – how to collect, and ***access*** – how to share.

Scope: It would be necessary to obtain agreement on the scope of data to be collected. While there is typically a focus on fire behaviour and fuel, information regarding suppression strategies, logistics and command structures are often overlooked. Such information is invaluable for operational research. To optimise the scope of data collected, fire management agencies would need to look more broadly than within their organisations. Other interested parties include other emergency services, utilities, administration bodies and universities.

Standards: Data will need to be standardised, with quality controls on types, units, resolutions, formats and metadata. Standardised methodologies would greatly enhance cross jurisdiction collaboration and allow for broader, more widely applicable studies.
Access: In addition to data collection protocols, for value to be extracted it is important to ensure that contributing agencies are able to access the information provided by others. This is likely to require licensing agreements and the establishment of repositories. There is the potential for privacy issues to manifest, so limitation of access for some datasets may be a consideration.

The degree of difference in fire data collection protocols within a single country can be demonstrated with a search of the Australian public geospatial data directories using the term 'fire'. Table 1 indicates that there are orders of magnitude in difference between the numbers of records available for each state. Wildfires occur within all states of Australia.

Table 1. Number of spatial records discoverable using the term 'fire' on the 5/2/2014 in Australian state based spatial data directories

State	Records available
Australian Capital Territory	48
New South Wales	42
Northern Territory	2
Queensland	65
South Australia	4
Tasmania	11
Victoria	169
Western Australia	149

The three areas of fire information that need to be unified are described briefly below.

Data standards

Of the information typically stored by land managers in relation to fire, a large proportion of the data relates to infrastructure and other relatively invariant landscape attributes. There are a number of datasets that are in common between various states (for example fire history and ignition location), however metadata indicates that there is potentially substantial variation in the collection standards both within and between agencies (Walsh *et al.* 2007). While there are some barriers to the complete standardisation of data collection due to scale, access and technological issues, the degree of difference between the state data collection methodologies means there are likely to be interpretation issues when attempting inter-state investigations. In addition, while many agencies collect information on fire perimeters, for it to be of practical use to science, accessory data such as fuel details, topography, local weather observations, assets at risk and infrastructure must also be made available. Inconsistencies between jurisdictions in accessory data can further compound errors due to inconsistent fire data. For example, while approaches to evaluating fuel have been converging, there is still no system that is consistently applied or is suitable for all jurisdictions and vegetation types in Australia (Gould and Cruz 2012).
Inconsistencies in data can result in severe issues with regards to its access. Differing scales, units and margins of error can make it difficult to determine equivalence between datasets and can confound analysis. As there is much in common in the vegetation, weather and fire behaviour between states in Australia, it would be expected that many of the findings in one jurisdiction would also be appropriate in another. However with differing information, cross-border collaboration and model application is constrained. A common issue with fire science is that due to the complexity, rapidity and infrequent

nature of wildfire incidents it is difficult to collect enough observational data to provide suitable replication for statistical analysis. Standardisation of data collection will facilitate the aggregation of data throughout not only Australia, but the world, providing leverage on data collected, reduce unnecessary duplication and allow robust conclusions to be reached sooner and with less expense.

2.3. Scope of data

Considering Australia as a case study, there are a small number of data sets that are consistently collected by the majority of states despite the fact that wildfires are an issue to varying degrees in them all (Walsh *et al.* 2007). We believe that of the data available, only a small portion of data relevant to fire research is currently being archived as 'fire data' and made available for future needs. While it is common to collect information on impacts such as final perimeters and the locations of house losses, other information pertaining to fire spread predictions, firefighter accomodation and suppression deployments is not available. Table 2 provides an indication of potential information that may be generated; however this list is not exhaustive. Very few of the information sources listed are routinely collected.

Table 2. Information sources potentially available for typical fire incidents. Information is grouped by research group and incident management system category (AIIMS ICS 2013)

Research Potential	Information source	AIIMS ICS category	Routinely available?
Management / Social Science	Incident type	Incident Control	
	Escalation / de-escalation	Incident Control

A secondary issue relating to data scope relates to the type of fires that are evaluated in detail. Due to the coronial and reactive nature of large fire investigations, there is a greater likelihood of data being available for extreme events. Data that is consistently collected at these fires includes maps of the final fire perimeter, headfire rates of spread, post-fire aerial imagery, weather conditions, fuel properties and the locations of house losses and deaths. However for more minor fires, the quality of information is generally much poorer. While it may be argued that larger fires are more important to study due their disproportionate impact, a strong counter argument is that some of the smaller fires may have had the potential to be catastrophic but effective preparedness or response measures prevented that from eventuating. Correspondingly it could be argued that smaller fires that occur under severe weather conditions deserve greater attention rather than less.

As it stands currently, a bias of data collection towards particular fire types has the potential to confound research and lead to incorrect conclusions. For example, evidence suggests that the predominant mechanism of house loss under the most extreme fire conditions differs to that under less severe but more common conditions. In addition, fire suppression and fuel reduction are less likely to be seen to be effective under extreme conditions; however they have clear value in preventing incidents from escalating under less severe conditions.

An additional issue is information decay. While information from some sources is robust, providing for simple post-fire collation, other forms are more transient. Highly temporally specific data is common in fires –it is important to be able to track and understand fast moving fire fronts. However if detailed information is not recorded at the time of the fire, information is easily lost and there may be limited opportunity to reconstruct occurrences post fire. This means that management agencies need to develop pro-active data policies. There need to be processes in place to actively target and record information while it is available and before its quality decays. While there is likely to be some overhead cost to this information gathering, such data can lead to improved decision support tools which reduce the overall overheads of fire management. Examples of information that can be transient include the location and rate of spread of fire fronts, the location, number and activity of suppression resources, and the behaviour and activity of civilians in the fire zone. After a fire event, there is greater luxury to collect data from some sources at a slower rate, however it remains important to actively target and record information before it is lost.

The scope of information being collected during and after fires is currently very limited. If information collection can be expanded, there are a wide range of research fields that stand to benefit. While the nature of Australian Eucalyptus forests mean that embers can play a disproportionate role in fire spread than in other forest types throughout the world (Cruz *et al.* 2012), fire remains a physical process. As such, standardisation of the scope and quality of data would be of greater benefit if it could be on an international scale, enabling research projects to be more expansive and enabling conclusions to be more broadly applicable.

2.4. Availability of data

Even if data is of high quality and correctly scoped, fire research may still be hindered by lack of access. This results from two primary issues. The first is that can be difficult for anyone (both internal and external to management agencies) to determine what data is being stored and is available. While spatial data directories have made substantial progress towards transparency of fire information in some jurisdictions, not all information that is collected is formally stored in a manner that is discoverable through such systems (e.g. Table 2). Much of the information gathered during a fire by a

managing agency would be stored in some manner, however only a small proportion is centralised and can be accessed using a query focused on a particular fire. The discovery of such information can require substantial resources; coronial reconstructions of fires take significant time and money to reconstruct particular events, even though much of the necessary information would be generated and available at the time of the event. Currently, the data recorded during fires shows limited consideration to the likely post-fire reconstruction information needs.

A second issue relates to data infrastructure. States, and within states; agencies, currently independently manage their own information. Obtaining data for a large geographic area is likely to mean that access must be negotiated from a number of different bodies. Once data is available, variability in formats and resolutions mean that further processing is typically required to ensure information from various sources is compatible and equivalent. Both obtaining data access and data processing can pose a significant time burden on users. The development of tools to access shared information is a necessary step towards effective cooperation and collaboration on informational needs. One issue that would need to be overcome in relation to information sharing is what limits would need to be applied. Many countries and states now have legislated privacy laws. Some of the information collected during fires may full under the jurisdiction of such laws – undeniably information relating to fatalities and events at particular residences is going to be sensitive and require some limitations on sharing under specific circumstances.

More broadly, the development of systems to recognise, tag, store and share fire related information could greatly reduce data discoverability issues. Furthermore, appropriate data sharing between agencies would create economies of scale, and more comprehensive data would enable more robust conclusions to be reached. If methods, scope and storage of fire data were standardised, substantial benefits may be realised, including greater success in preventing impacts from major fires in the future.

Proposed process

The development of a fire information system is expected to be a complex process as it would require the commitment and collaboration of a large number of emergency service agencies in disparate jurisdictions. It would be necessary to develop any new framework as a multi-stage project.

- Phase one would be to audit the ‘status quo’ and determine in detail how information is being managed within agencies.
- Phase two would be to undertake a needs analysis, evaluating informational requirements of both agencies and scientists. This would need to be carefully planned to ensure that findings are broadly applicable and not merely convenient for a single country.
- Phase three would be to analyse information sources and end-user needs to address data ‘gaps’, making recommendations on data standards, scope and storage mechanisms. This must also include the potential for the recognition of new needs and the inclusion of novel information sources. As technology is continually improving, the future improvement of information collection standards and the inclusion of new sources must remain an option even when a data framework is operating.
- Phase four would focus on the establishing compatible systems between agencies with an overarching aim to develop a centralised system for discovering and accessing data. This would require some reciprocal understanding in relation to data access, licensing, privacy and public availability.

To be effective, this process should be cooperative. While a considered analysis of informational needs will have immediate tangible benefits for a single agency, the greatest benefit overall would be the potential for cross border cooperation and increased research leverage.

We suggest that initial steps towards establishing an effective fire information system should be:

- The allocation of a unique code to each reported fire ignition. Any information pertaining to a particular ignition should be associated with this code. To avoid the risk of duplicates, a composite code could be used such as *country/state/year/fire_number*. Such a code would assist in the development of databases for the archiving of data.
- The existing fire command and control system should be used as a template for structuring and storing fire information. This will ensure that all relevant aspects of a fire are considered. Each function group (i.e Planning, Intelligence etc.) should be responsible for ensuring that information is collected at a suitable standard (Australasian Fire and Emergency Service Authorities Council 2013).

Following this it will be necessary for substantial communication between agencies. This would need to be a forum style process, where views and perspectives can be shared to ensure the proposed procedures and policies best meet the needs of all involved.

The development of any new standards and processes requires careful consideration. Poorly designed standards can 'lock in' unsatisfactory methods or result in competing standards where the interested parties have not come to full agreement (Monroe 2011).

Summary

A common issue with fire science is that due to the complexity, rapidity and rarity of fire incidents it is difficult to collect enough observational data to provide suitable replication for statistical analysis. Standardisation of data collection will facilitate the aggregation of data throughout the world, providing leverage on data collected, reduce unnecessary duplication and allow robust conclusions to be reached sooner and with less expense.
Land and emergency response organisations are increasingly being expected to deliver scientifically defendable decisions and to demonstrate continuous improvement in management and resource use. The limited availability of high quality data restricts the rate at which research can advance and predictive capacity can improve. It is imperative that the losses caused by severe fires are not in vain; losses should be offset by efforts to maximise the information obtained, helping to prevent a repeat of such events in the future.

Global burned area maps from MERIS

Itziar Alonso-Canas, Emilio Chuvieco

Environmental Remote Sensing Research Group, Universidad de Alcalá, Colegios 2, Alcalá de Henares, Spain; e-mail: itziar.alonsoc@uah.es, emilio.chuvieco@uah.es

Abstract
Biomass burning is a global scale phenomenon that affects annually around 3.5 million Km2. This phenomenon has a very critical relevance for vegetation dynamics, atmospheric emissions and carbon budgets, increasingly affecting human lives and property, particularly in catastrophic conditions (heat waves, drought, strong winds). Properly characterizing burned areas on a global scale has become a relevant factor when studying these processes. The Fire CCI project, in the framework of the ESA's Climate Change Initiative, aims at providing consistent time series of burned areas (BA) globally, over the period 1995 to 2009. Global BA products are obtained by merging information from three sensors: the ATSR series, VEGETATION and MERIS. In this case, the algorithm developed to obtain burned areas from the MERIS sensor will be presented. The MERIS BA algorithm is based on MERIS reflectance bands, spectral indices and both post-fire and multi-temporal analysis controlled by HS locations. BA detection is performed in a two phase process: the first one aims to detect seed pixels while the second one will develop contextual criteria around these seed pixels. Global BA maps have been obtained with the MERIS algorithm for years 2006 to 2008.

***Keywords**: Burned Area, Climate Change, MERIS*

Introduction

Fire is a key component of the carbon cycle affecting greenhouse gases and aerosols emissions to the atmosphere (Andreae and Merlet 2001; van der Werf, Randerson *et al.* 2010), as well as global vegetation dynamics (Kloster, Mahowald *et al.* 2012; Thonicke, Spessa *et al.* 2010). Therefore, it becomes highly critical to monitor fires on a global scale and to estimate their impacts through global climate model simulations, biogeochemical models and dynamic global vegetation models.
Monitoring areas affected by biomass burning has been performed over the last decades using a wide variety of sensors, including very high-spatial resolution such as Ikonos for fine scales (Kachmar and Sanchez-Azofeifa 2006), high spatial resolution sensors such as Landsat-TM/ETM+ or SPOT-HRV for regional areas (Bastarrika, Chuvieco *et al.* 2011b; Pu and Gong 2004) and medium resolution sensors for continental to global studies (Chang and Song 2009; Chuvieco, Opazo *et al.* 2008; Giglio, Randerson *et al.* 2010; Roy, Boschetti *et al.* 2008; Tansey, Grégoire *et al.* 2008).
In the context of the fire_cci project, the goal of this work is to present a global BA algorithm specifically designed for the ENVISAT MERIS sensor. MERIS was mainly designed for ocean colour applications, as it provides high spectral resolution in the range of the blue to the near infrared regions (Gower and Borstad 2004). The application of MERIS data to fire applications is scarce: identification of smoke plumes (Huang and Siegert 2004), discrimination of burn severity (De Santis and Chuvieco 2007; Roldan-Zamarron, Merino-De-Miguel *et al.* 2006). Mapping BA with MERIS has only been performed at regional level (Oliva, Martin *et al.* 2011) using different vegetation indices while (González-Alonso 2009) combined fire hotspots from MODIS and NIR reflectance values from MODIS and MERIS imagery.
The potentials of MERIS for improving current information of BA rely on its greater spatial resolution, complementing other existing global BA products, particularly in areas where under or overestimations have been shown (Chang and Song 2009), thus reducing the uncertainty of current collections. Furthermore, this sensor has a follow up version on the OLCI (Ocean and Land Colour

Instrument) on board Sentinel 3, scheduled for launch in 2015 as part of the EC Copernicus programme.

Methods

The design of a global BA algorithm requires considering the great diversity of biomass burning conditions worldwide. The most extended approaches for mapping BA can be classified in two groups: those that use the thermal contrast of active fires (hot spots, HS) from the surrounding background (Giglio, van der Werf *et al.* 2005), and those based on reflectance changes caused by burning effects (changing of leaf and soil colour, leaf losses, char, etc) (Bastarrika, Chuvieco *et al.* 2011a; Roy, Jin *et al.* 2005). The former approach is more reliable because thermal radiance increases exponentially with temperature, while reflectance changes are more subtle. However, thermal signal lasts very shortly (minutes to hours), while the fires are active, where as post-fire reflectance changes are more lastly (days to years). In addition, BA mapping based on active fires only implies a sample of the total area burned (what is burning when the satellite observes the area), while reflectance changes cover the whole area affected by the fire.

Considering the pros and cons of each approach, several authors have proposed hybrid algorithms, where HS information is used to guide somehow the analysis of reflectance changes in the discrimination of BA, particularly to avoid commission errors (i.e. reflectance changes caused by non-fire causes, such as crop harvest, seasonal flooding, or topographic shade). After analyzing the spectral and temporal characteristics of MERIS, it was decided to follow a similar approach for developing the global BA algorithm, using a synergetic use of HS information derived from MODIS thermal data and temporal trends of MERIS reflectance bands. The hypothesis is that (Kaufman and Justice 1998) the combination of spectral reflectance information with active fires to identify BA should provide a more reliable discrimination of BA. In order to consider a proper balance between omission and commission errors, the algorithm includes two different phases (Chuvieco, Englefield *et al.* 2008): seed identification, which aims to minimize commission errors by selecting only those pixels more clearly burned, and contextual analysis, which applies region growing analysis to improve the delimitation of burned patches.

The algorithm was developed and tested in 10 different study sites, which were selected to take into account the diversity of burning conditions worldwide, including different biomes and fire regimes (Figure 1). (Olson, E. Dinerstein *et al.* 2001)

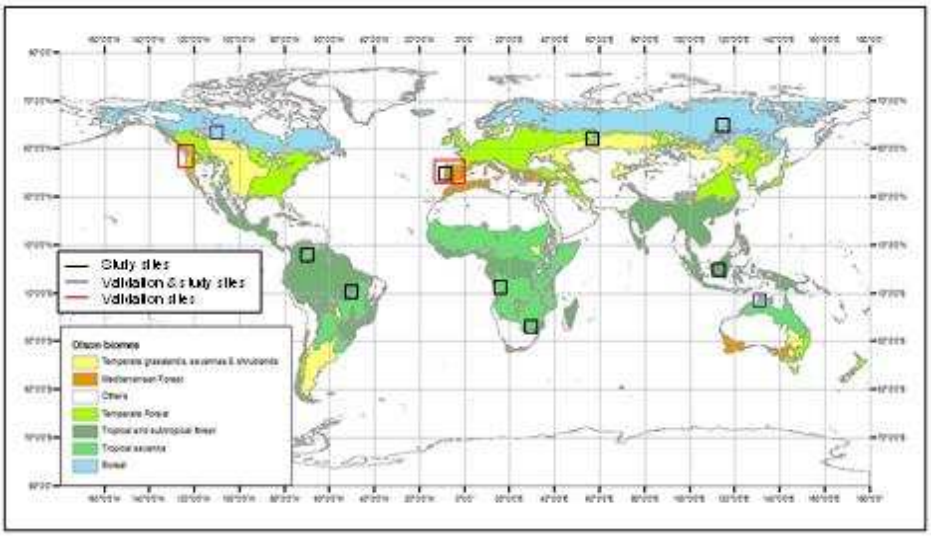

Figure 1. Study sites selection

Generation of corrected reflectances and spectral indices

Corrected MERIS reflectances were received from Brockman Consult. The pre-processing chain was based on the one developed for the Land CCI project with modifications to obtain daily reflectances instead of weekly composites as was required by this project. Geometric correction is obtained through the AMORGOS (Accurate MERIS Ortho Rectified Geo-location Operational Software), improving MERIS FR geolocation better than 70 RMS. Calibration and smile correction are also performed, as well as land water delineation, cloud screening and atmospheric correction. More details of these processes can be found in the ATBD from the Land CCI project (http://www.esa-landcover-cci.org/). The surface directional reflectances are floats between 0 and 1.0. As an output from the pre-processing, additional information layers are included with the MERIS images. Standard error associated to each band is provided. The angles are taken from the respective MERIS L1B input, sun and zenith viewing angles and sun and azimuth angles are provided in degrees. Also, a status layer is provided, with values 1 (clear land), 3 (snow/ice), or 0 (i.e. water, cloud, no observation).

In order to improve performance of the algorithm, the corrected reflectances were gridded into 10x10 degrees tiles (3600x3600 pixels at MERIS spatial resolution). These tiles were the input files for all processes of the BA algorithm.

The NIR region was selected as main input for the MERIS algorithm, since this spectral band has been shown to be highly sensitive to recent burns, especially when pre-fire fuel loadings are high and combustion produces large amounts of charcoal that are deposited on the ground (Pereira, Sa *et al.* 1999). Both green and dry vegetation have substantially higher reflectance than recent burns in the NIR. The suitability of this band to detect burned areas has been shown in previous studies (Chuvieco, Martín *et al.* 2002; Koutsias and Karteris 2000; Trigg and Flasse 2001).

In addition to the NIR band, we computed the Global Environmental Monitoring Index (GEMI) (Pinty and Verstraete 1992), which was proven the best performing to detect burned areas among the spectral indices based on the red-NIR space (Barbosa, Stroppiana *et al.* 1999; Chuvieco 2002; Chuvieco, Englefield *et al.* 2008; Martín, Gómez *et al.* 2005; Pereira, Sa *et al.* 1999). GEMI was computed as follows:

$$GEMI = \frac{\eta(1-0.25\eta)-(\rho_R-0.125)}{(1-\rho_R)}$$

$$\eta = \frac{2(\rho_{NIR}{}^2-\rho_R{}^2)+1.5\rho_{NIR}+0.5\rho_R}{(\rho_R+\rho_{NIR}+0.5)},$$

where ρ_{NIR} is the reflectance in the NIR (MERIS Band 10) and ρ_R is the reflectance in the Red (MERIS Band 8).

The selection of MERIS Bands 8 (673.75 nm to 688.75 nm), and 10 (746.25 nm to 761.25 nm), was based on the results from (Oliva, Martin *et al.* 2011), which showed a better sensitivity of the short NIR bands (bands 9 to 12) over the long NIR bands (bands 13 to 15) to discriminate BA areas. Following their conclusions, band 10 was used for the NIR region and bands 8 and 10 for computing the GEMI index.

Generation of composites

Temporal resolution of input data is quite relevant to build a global BA algorithm, since the analysis of post-fire reflectance may be easily contaminated by clouds or be affected by quick vegetation recovery. Therefore, the number of observations is a limiting factor for detecting fires in areas where images are not available for long periods of time. In order to improve spatial coherence of areas with low temporal continuity, monthly composites of near infrared reflectance (NIR) were generated. These composites were the basis for the two phases of BA detection. Composites were built for each month by selecting NIR information from a bi-monthly time space. This helps ensuring continuity in fire detection and is particularly relevant when a fire occurs in the final dates of a month.

The criteria for generating the monthly NIR-GEMI composites were chosen as to emphasize the sensitivity of the outputs to the burned signal. Two criteria were used: maximize the contiguity to fire dates and minimize the NIR signal. Since HS provide a very accurate estimation of burning dates (Boschetti, Roy *et al.* 2010), we first generated the composites selecting for each location the closest date to the closest HS. For doing so, a Thiessen matrix was created for each period, computing for each pixel the closest HS coordinates and labelling it with the date of that HS. For the Thiessen matrix we also considered HS located within a buffer of 0.5 degrees around the edges of each tile. This option mitigated potential continuity problems between tiles, when for instance a fire was in the edge between tiles.
The second compositing criteria selected minimum NIR reflectance values of the temporal series. However, since low NIR can be caused also for other reasons (cloud or topographic shadows, for instance), instead of selecting the minimum NIR of the 60 day period, we chose the first minimum after the date stored in the Thiessen HS matrix , as this would select a more immediate value to the post-fire burn reflectance. If no minima exist after that date, then the second minimum was chosen.
In addition to the monthly post-fire composites, an annual reference composite was created to help the contextual phase of the algorithm. This annual composite was obtained as the per pixel difference between the annual maximum GEMI value per year and the monthly GEMI composite. The former was created to obtain an estimation of the maximum annual greenness of each pixel time series. The expected change between that maximum value and the post-fire value (the GEMI monthly composite) should be the highest, which should emphasize post-fire spectral changes.

2.3. Seed selection

The first part of the seed selection focused on generating statistics of burned and unburned areas for each tile, based on the composite NIR values and HS distribution. Since burned conditions may be very diverse worldwide, we tried to obtain regional-oriented NIR thresholds, which could be tailored to different post-fire reflectance conditions. Cumulative distribution functions (CDF) were created to establish discrimination thresholds of NIR values that would be better adapted regionally to separate between burned and unburned categories.
The burned pixels to obtain the CDF of BA were obtained from the information provided by the MODIS HS to select the minimum NIR values. Since HS have an original resolution of 1000x1000 m, instead of assuming that all MERIS pixels covered by the HS are active fires, we assumed that the potential active fire (PAF) was more likely located where the MERIS NIR value was lowest in the 3x3 window around the HS. To avoid commission errors, we introduced an additional temporal change constrain, and accepted only those PAF where NIR values were lower than in the previous period. Otherwise, the minimum NIR values were not considered PAF to build the CDF of the burned category. The CDF of the unburned category was generated from the values of those pixels that did not have any HS in a 64x64 pixel matrix and were not detected by the BA algorithm in the previous months.
Specific discrimination thresholds were established for each tile and month. In order to compute them, the NIR threshold value of the burned category (TB) was defined as the decile of the burned pixels CDF that intersected the first decile of the CDF of unburned pixels (NIR values of burned pixels were expected to be lower than those of unburned ones) (fig 2). The more separated the CDFs between burned and unburned categories are, the higher the decile to define the burned category, as there are less chances of confusion with unburned category. On the opposite, the closer the CDFs the more pixel values are shared by the burned and unburned distributions, and therefore a more restrictive condition was chosen. It was considered a good discrimination between burned and unburned CDF when the threshold was established at 7 or more decile value, and bad discrimination otherwise. This classification was later used for phase 2 of the algorithm.

Seed pixels of burned category were selected based on three criteria:

a) The NIR value was lower than the TB for each tile and period.

b) At least one PAF should be found in a neighbour 9x9 matrix;

c) NIR value for month n should be lower than NIR of month n-1.

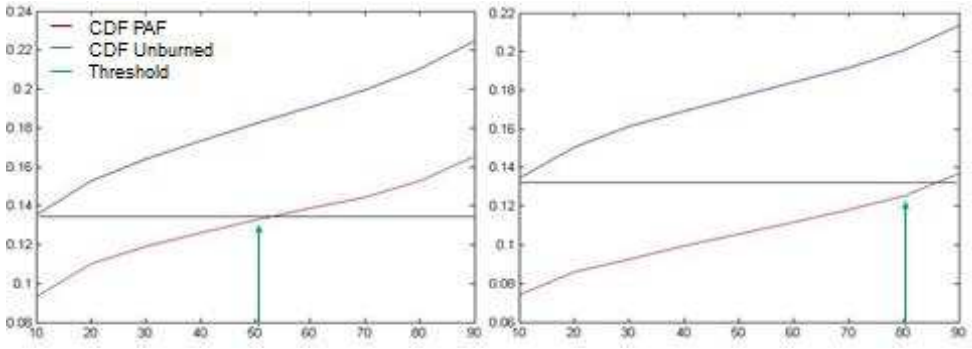

Figure 2. Threshold based on decile 10 of the unburned for a case with worse (left) and better (right) separation between classes for the Australian study site, correspondent to July & October 2005 respectively

2.4. Region growing

Contextual algorithms have been previously used for BA mapping (Bastarrika, Chuvieco *et al.* 2011b; Pu, Li *et al.* 2007). The goal of these algorithms is to reduce omission errors from the seed phase, while avoiding increasing commission errors. One of the critical issues to obtain a good performance of these algorithms for BA mapping relies on obtaining a sound method to stop the region growing process (Zhang, Pavlic *et al.* 2005).

Once the seeds were obtained, a region growing mechanism was applied to refine the characterization of burned patches. Only pixels surrounding the BA seeds were analyzed. This second phase of the BA algorithm included three conditions. These three conditions tried to account for a proper balance between extending the burned patches and avoiding commission errors. They were analyzed recursively around each seed pixel until their neighbour pixels did not meet them, which implied the end of the region growing process. If the criteria were met, the pixel will be included as seed and also its surrounding pixels will be studied. These criteria were:

a) The NIR threshold values were reviewed for this phase. If the TB was based on decile 6 or lower, it was assumed that the discrimination between categories is not good enough to increase the threshold. In this case the value was kept as it was for the seed phase. Otherwise, we assumed a better discrimination of burned and unburned categories and therefore, the NIR thresholds were increased for the region growing process up to the TB found at decile 9.

b) The decrease in NIR in burned pixels should be more negative than the threshold NIR decrease of unburned pixels. To define this new threshold we only considered those pixels more clearly unburned. We selected the first decile of the unburned CDF that has a higher value than decile 9 of the burned curve. For all pixels that satisfy this condition the difference with the composite from the previous month was computed. A new curve is built with these values. The minimum drop is defined as the percentile 90 of this curve.

c) Finally, the third condition was based on detecting the vegetation loss as a result of fire, based on the differences in GEMI values between the target monthly composite and the annual GEMI composites. This criterion was defined as 0.9 times the difference found in the GEMI value between the target pixel and those labelled as burned (either seeds or neighbour detected burns).

Results and validation

Three years of MERIS data (2006 to 2008) were processed with the described algorithm. Global BA obtained for years 2006, 2007 and 2008 was 3650268, 3772086 and 362327 km2 respectively. Figure 3 shows the BA obtained for year 2008.

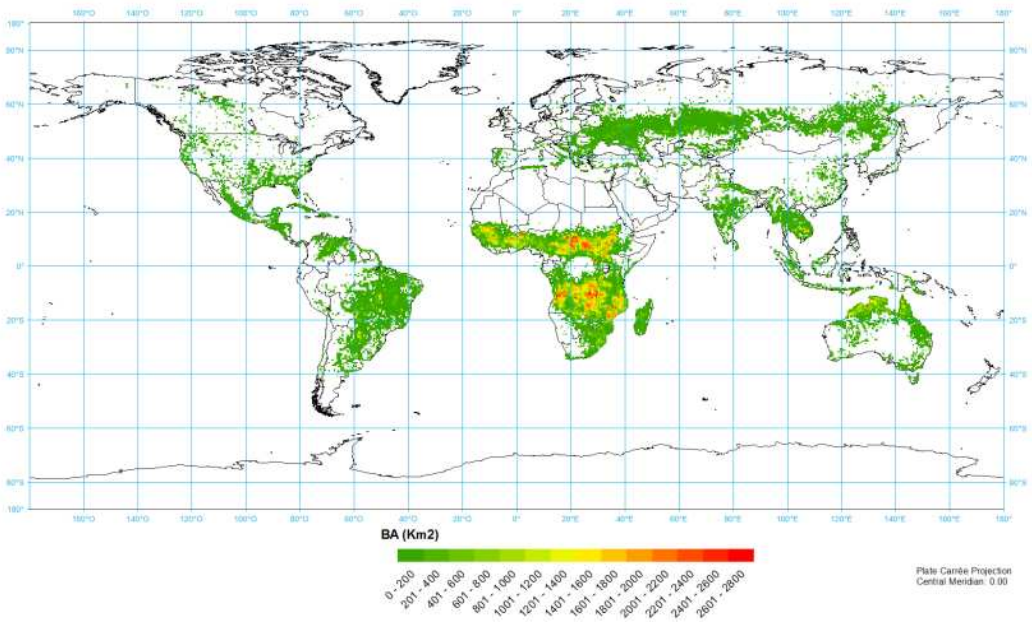

Figure 3. Global BA from MERIS in 2008

A complete global and temporal validation strategy has been developed within the Fire-CCI project. In this framework, a validation of the MERIS BA product performed with a LANDSAT validation dataset was performed. Results can be found in Padilla *et al*, 2014 (in preparation). The validation presented here is based on the use of perimeters obtained from different agencies and aims at validating the product in larger areas. The validation was performed for the 3 years where MERIS BA product is currently available (2006 to 2008).

Four areas were chosen:

- Canada: perimeters were downloaded from the Canadian Wildland Fire information System (cwfis.cfs.nrcan.gc.ca/ha/nfdb/). The Canadian National Fire Databse (CNFDB) is a collection of forest fire data from various sources, provided by Canadian fire management agencies (provinces, territories, and Parks Canada). The area designed to perform the validation is the Canadian study site (Figure 1). MERIS BA product and perimeters from the fire information system were reprojected to UTM.
- Australia: the Australian perimeters were downloaded from the North Australian Fire Information database (www.firenorth.org.au/nafi2/). Also the study site area was chosen to perform the validation (Figure 1). Both MERIS and perimeter databases were projected to UTM. Fire scars are sourced from the Darwin Centre for bushfires research at Charles Darwin University (for NT and northern WA fire scars) and Cape York Peninsula sustainable futures (for Queensland). They are obtained from 250 m MODIS imagery. Two images are used to map the affected areas, by using segmentation and visual interpretation (http://www.firenorth.org.au/nafi2/about/faq.pdf).

- The Californian perimeters were downloaded from the Fire and Resource Assessment program (FRAP) webpage (frap.fire.ca.gov). Fire perimeters information is obtained by several agencies. The validation site chosen covers an area of 572000km2 (Figure 1). MERIS data were reprojected to the perimeters database projection (alberts_conic_equal_area).
- Iberian Peninsula Perimeters were obtained from the European Forest Fire Information System (EFFIS). EFFIS makes use of satellite imagery acquired with MODIS. The area was selected to include the Iberian Peninsula, as shown in Figure 1. MERIS data were reprojected to the perimeters projection, standard European spatial reference system ETRS-LAEA, ETRS89, Lambert azimuthal equal area.

Validation results are shown in Table 1 for the 4 areas under study. Through the years same tendencies and range of commission and omission errors are identified. Overall there is a tendency towards omission for the 3 years. Australia shows higher omission errors. The Californian validation site shows a higher balance between omission and commission except for year 2008. The Canadian area has higher omission values, where as in the Iberian Peninsula the MERIS BA algorithm tends to overestimate the BA leading to higher commission errors.

Figure 4 shows cumulative distribution curves that relate the number of fires detected per fire size for both the validation dataset (dotted line) and the MERIS one (black line) for year 2008. In the case of the validation datasets, perimeters are already identified by a number that differs for each perimeter. In the case of MERIS, perimeters were obtained by assuming that the pixels burned are part of the same perimeter when the dates between neighbour pixels do not differ in more than 15 days. In the Australian site, both NAFI and MERIS show the same tendency. Omission errors found in the validation exercise are shown by the fact that the MERIS line follows under the NAFI one for all fire sizes. For the other 3 validation sites the number of fires detected by MERIS is higher for small fire sizes where as it becomes lower for bigger size patches. This trend is especially clear for the Canadian site. Similar results and behaviour were obtained for years 2007 and 2006.

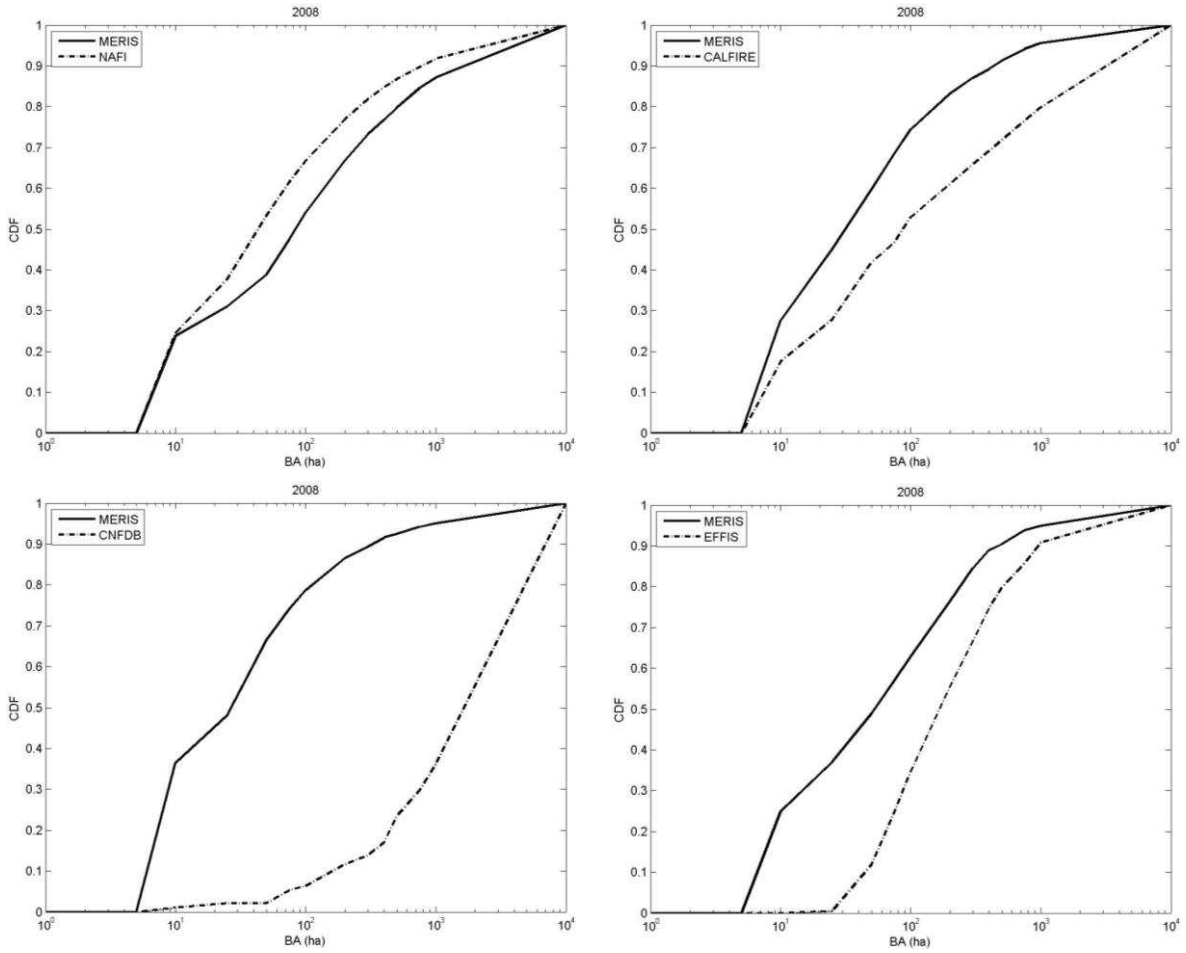

Figure 4. Fire size classification for 2008

We separated the BA by ecosystem, following the classification defined in (Giglio, Loboda *et al.* 2009). Results are shown in Table 2. The areas with higher fire activity are AUS, BOAS, CEAS, NHAF, SHAF, SHSA showing similar tendencies for the 3 years. When comparing the product globally to the MDC 64 (Table 2) results show that MERIS estimates more BA than MCD64 for the 3 years where the comparison has been performed, having the largest difference in 2008. Results are consistent in the order of magnitude for all regions. For 9 regions (CEAM, CEAS, EURO, NHAF, NHSA, SEAS, SHAF, SHSA, TENA) MERIS estimates are higher or in the same order as the GFED ones. In these cases, the trend is consistent between years, i.e. if a BA value increases from one year to the next in the MERIS case, the same behaviour occurs in the GFED. In another 3 regions (AUS, BONA and MIDE) BA MERIS estimates are lower or in the same order than GFED. There are only 2 regions where results are less consistent between the two products (BOAS and EQAS). In BOAS, 2006 has an order of magnitude higher in MERIS estimates, where as 2007 is higher than GFED but in the same range and 2006 is lower than GFED but in the same order. In EQAS 2006 has lower estimates than GFED, where as 2007 and 2008 have higher values.

Discussion and conclusion

MERIS BA estimates are higher than the ones obtained by other collections such as GFED for the 3 years that have been processed, but remain in the same range. In 2 of these areas (AUS, BONA) validation was performed and results showed a tendency towards omission for the 3 years tested. More detailed identification of omission and commission errors will be available soon in Padilla *et al*, 2014. but from this preliminary study there seems to be an underestimation of BA in certain regions. There are 2 possible reasons for this:

- Omission inherent to the HS: as shown in (Hantson, Padilla *et al.* 2013), commission errors in the MOD14 product tend to be small, but omission errors can be significant, especially for some areas (South Africa, Colombia, Australia).
- Conditions too restrictive in both seed and growing phases. In the seed phase the algorithm does not consider all HS as seeds, pixels that do not satisfy the conditions detailed in the previous sections will not be classified as seeds. Filtering out some of the HS should not be a significant problem for large fires, since pixels around the detected PAFs will also be studied. Nevertheless, excessive filtering can become relevant for smaller fires, or in areas where there are less HS, as all HS could be filtered out in the seed phase, leading to non detection of the fire. In the growing phase conditions could be too restrictive particularly for some regions. In this case, larger fires will be considered smaller, and if there are several seeds for the fire this will probably lead to fragmentation of fires. This will lead to an over estimation of smaller number of perimeters in cases where the same fire is fragmented. This could explain the results shown in Figure 4, where smaller fires were more abundant that in the database due to the fact that the fire might be fragmented, and it was considered as more than one perimeter. Although when designing the algorithm the aim was to make it tailored for each region, the growing conditions might not be optimal for all types of land cover and ecosystems.

An algorithm to estimate burned areas on a global scale for the MERIS sensor has been presented. It is an hybrid algorithm that makes use of thermal and spectral information to detect fire scars. It is based on a two steps process: seed and growing phases. Results have been obtained for 3 years of data, and show consistency with other BA collections such as GFED. According to preliminary validation

results, there is a tendency towards omission. Future versions of the algorithm will consider these findings to refine the BA estimates.

Global mapping of burned areas from European satellites: the fire_cci project

Emilio Chuvieco, Itziar Alonso-Canas, Marc Padilla and Ruben Ramo

Environmental Remote Sensing Research Group, Universidad de Alcalá, Colegios 2, Alcalá de Henares, Spain; emilio.chuvieco@uah.es

Abstract
This paper presents the results of phase 1 of the fire_cci project. This project is part of the Climate Change Initiative of the European Space Agency, and aims to generate global, long-term burned area maps from European sensors (VEGETATION and MERIS). This information is intended to help modelling efforts of climate and atmospheric and carbon scientists, by adjusting to their needs in terms of product specifications. The project has done an extensive effort of validation and error characterization of the results. Intercomparison with other existing datasets has also been carried out.

***Keywords**: Burned area, Remote Sensing, Climate Change Initiative, GCOS, Earth Observation*

Introduction

The European Space Agency (ESA) Climate Change Initiative (CCI) is part of the European contribution to the Global Climate Observing System (GCOS) program. The CCI aims to produce consistent and accurate time series of Essential Climate Variables (ECV), which may be used by climate, atmospheric and ecosystem scientists for their modelling efforts Plummer 2009. The CCI stresses the importance of improving scientific impact of data acquired by ESA sensors, while maintain close links with key science bodies and other agencies currently generating ECV data. The first call of the CCI program has included 13 ECVs covering atmospheric products (ozone, greenhouse gasses, aerosols andclouds), oceanic variables (ocean colour, sea ice, ocean height and temperature), and terrestrial (fire, glaciers, ice sheets, soil moisture and land cover): http://www.esa-cci.org/.
Biomass burning is widely recognized as one of the critical factors affecting vegetation succession and carbon budgets worldwide (Chuvieco 2008; Thonicke *et al.* 2010). At regional and local scale, fires have also important socio-economic implications, both affecting lives and structures (Chuvieco *et al.* 2010). At a global scale, the effects of fire on the atmospheric chemistry, both in terms of CO2 and aerosols emissions are very relevant (Bowman *et al.* 2009; van der Werf *et al.* 2010). The most recent studies estimate that an average area of 3.5 million km2 is burned every year (Giglio *et al.* 2010; Tansey *et al.* 2008), mostly in the Tropical savannahs, temperate grasslands and boreal forests. Other impacts of fire on the global climate are still poorly understood, such as the direct and indirect role of aerosols, their impact on land use change and surface albedo, the relation with tropospheric ozone and the deposition of black carbon on soils (Bowman *et al.* 2009).
The fire_cci project aims to improve mapping of burned areas (BA), including proper validation and error characterization, as well as the use of BA information in global vegetation and atmospheric models. The fire-cci project has been developed by a consortium of ten teams from five different European countries: University of Alcalá, CIFOR-INIA and GMV (Spain); GAF, DLR and Julich (Germany), IRD and LSCE-CEA (France), ISA (Portugal), and University of Leicester (UK). These groups cover the different specialities required for the project: Earth Observation scientists, Climate-atmospheric-vegetation modellers and System engineers.

Methods

Figure 1 includes the general flowchart of the fire_cci project. The project started with the definition of user requirements, which guided the generation of product specifications. The Burned Area (BA) product was initially based on the analysis of ERS and ENVISAT-ATSR, SPOT VEGETATION (VGT) and ENVISAT MERIS sensors, although finally the ATSR datasets were discarded as they did not provide significant improvement over VGT data. The project included geometric and radiometric corrections, masks, BA and merging algorithms (to fuse BA results from VGT and MERIS sensors), as well as validation and intercomparison analysis.

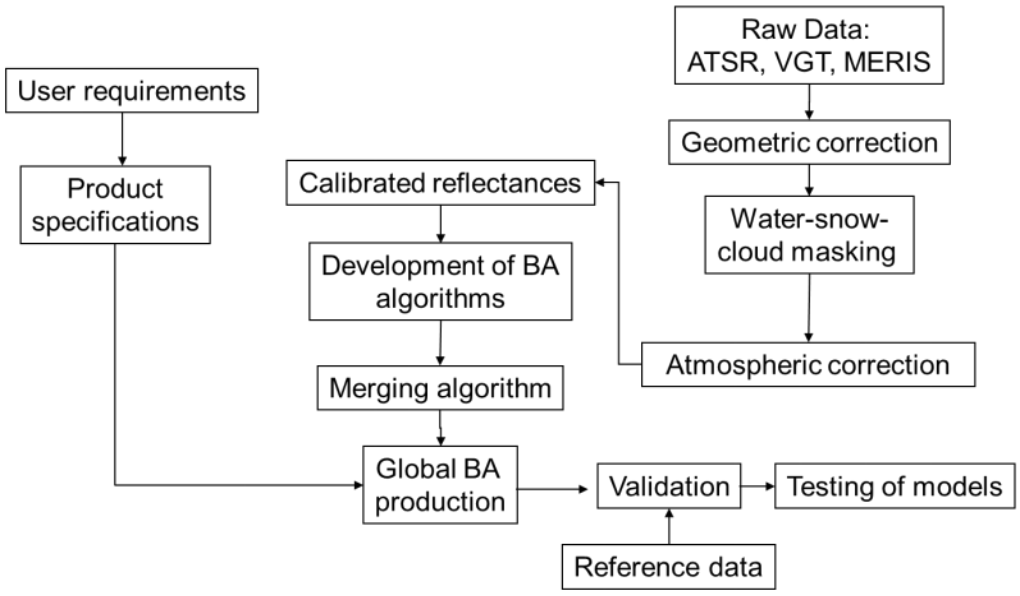

Figure 1. Fire_cci project flowchart

User requirements and product specifications

A proper understanding of user requirements of any product is a critical step to assure that the product will benefit the target community. In the case of the CCI program, the definition of user requirements was part of the program strategy. For the fire_cci project, a detailed questionnaire was addressed to potential users. Forty seven scientists from different fire-related communities (modellers, remote sensing experts, natural hazards, forestry sector...) provided their answers. They were complemented by an extensive literature review on past and present uses of available burned area (BA) products (Mouillot *et al.* 2014).

From this analysis, the product specifications (PSD) were generated. The fire_cci project includes two BA products, one at pixel level at 300 m resolution, and the other one at grid level at 0.5 degree resolution, following the most standard climate grid modelling (CGM) size). The pixel product includes four variables: day of burned detection, confidence level, sensor detecting the burn, and burned land cover. It will be distributed in monthly Geotiff format files, dividing the world in six tiles to make files more manageable (Figure 2). These tiles were agreed with the landcover_cci project to facilitate across-product consistency. The grid product includes 22 layers: sum of BA for each cell, standard error, fraction of observed area in the period, number of burn patches and burned area of each land cover (derived from globcover2005:Arino *et al.* 2007). These grid BA files are produced for 15-day periods in NetCDF format. Both pixel and grid products use the Plate Carré projection and geographical coordinates.

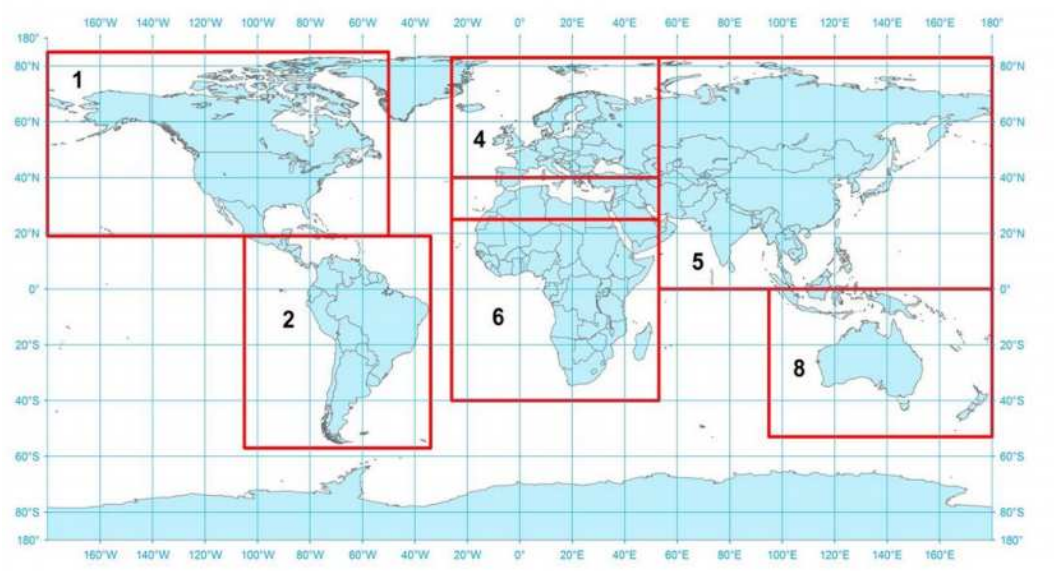

Figure 2. Tiles for the fire_cci pixel project

Pre-processing

The pre-processing, the BA products of the fire_cci project was based on level-1B and level-2 calibrated radiances from VEGETATION and MERIS. To derive corrected level 2 products, advanced image geometrical matching was applied to all sensors. Atmospheric correction was initially based on the ATCOR algorithm (Brazile *et al.* 2008) for ATSR and MERIS, by adapting the wide field of view of both sensors for this project. However, the final version of the processing chain was based on simpler atmospheric correction to improve process performance. Water, cloud snow and cloud shadow masks were developed to reduce the potential confusions in the BA algorithms, since these covers may present similar spectral characteristics to BA. Particularly challenging was the water mask, since water bodies may be seasonal (flooded areas), and the low radiances of water may be easily mixed up with post-fire char.

2.3. BA algorithms

Burned area algorithms were developed based on ten study sites selected from the main ecosystems affected by fire. These algorithms were adapted to VGT and MERIS sensors. Global BA algorithms are particularly challenging, as fire detection is affected by a wide range of factors: pre-fire conditions, burn severity, burn size and regeneration capacity of affected ecosystems (Bastarrika *et al.* 2011a; Giglio *et al.* 2009). The VGT algorithm was developed by the Instituto Superior de Agronomía (Pereira *et al.* 2014) and it is based on multitemporal trend analysis of near infrared reflectance. The process applies robust temporal filters to reduce the impact of instability of the time series, and provides scores of automatically detected changes to select those most likely connected to actual burnings. Initially the algorithm was also tested with ATSR data, but since the temporal resolution of this sensor is lower than VGT, the quality of outputs was considerably lower, and therefore it was decided to focus the global processing on VGT datasets.

The MERIS algorithm was developed from a hybrid two-phase approach, and took into account temporal changes of near infrared reflectance, as well as active fire detections from MODIS thermal channels. The algorithm is regionally adapted, as it estimates threshold values from cumulative distribution functions for both the seed and the region-growing phase (Alonso-Canas and Chuvieco 2014).

The final step was the merging of VGT and MERIS results into a single BA product. This merging was based on confidence levels derived from each sensor results, using a sample of the reference datasets.
A Round-Robin exercise was conducted between October, 2011 and January 2012, in which all available BA algorithms for VGT and MERIS images were tested. The results were compared using a set of statistical metrics. The goal of this exercise was to select the best performing algorithm for global production of burned area maps. The exercise was open to public participation. Once the final algorithms were selected, they were implemented in the global processing chain. For the current phase 1 of the fire_cci project, three global years have been processed (2006 to 2008).

2.4. Validation

Validation of the BA product was carried out by comparing BA outputs with reference fire perimeters generated from Landsat-TM/ETM+ multitemporal images. A standard protocol based on the CEOS LPV recommendations (http://lpvs.gsfc.nasa.gov). was generated and agreed between the internal validation teams to extract fire perimeters from Landsat data, based on a semi-automatic algorithm (Bastarrika *et al.* 2011b). Two samples of reference sites were obtained, one to measure the spatial variation of accuracy using 100 Landsat pairs acquired in 2008 (global validation), and the other one aiming to measure the temporal stability using a temporal series of Landsat scenes (one each year, whenever available in the Landsat archive) for ten representative study sites (temporal validation) (Figure 3). A total of 242 Landsat pairs were processed, including more than 147.000 burn patches and more than 126.000 km^2 of burned area.

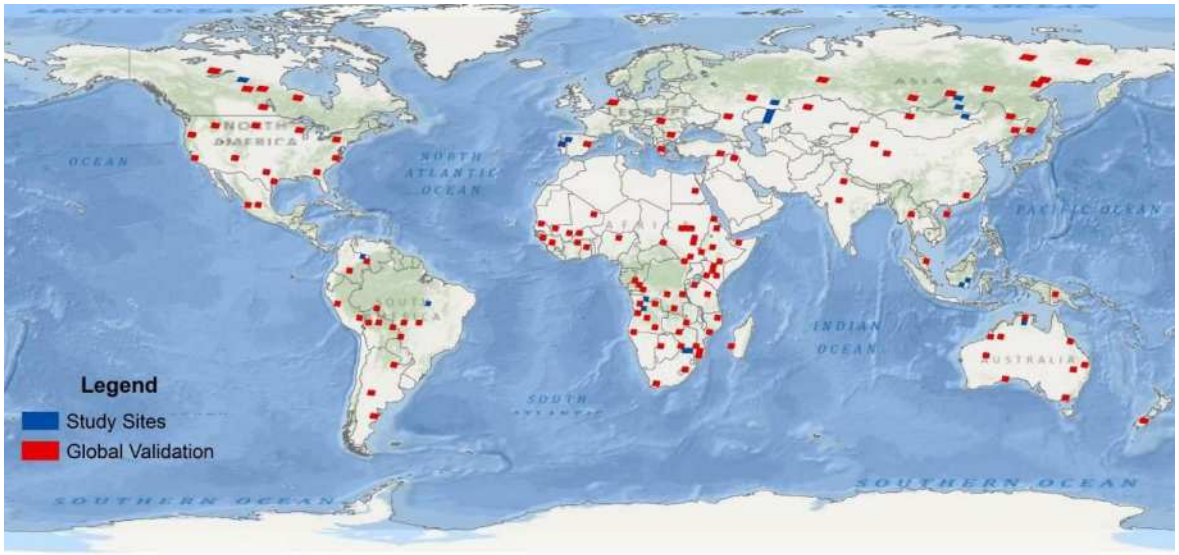

Figure 3. Location of validation sites for the fire_cci project

Validation was based on a fuzzy error matrix and covered three aspects: global accuracy (closeness to the true burned area), error balance (equilibrium between omission and commission errors) and temporal stability (temporal consistency of accuracy). Specific methods to tackle these three aspects were developed (Padilla *et al.* 2014a; Padilla *et al.* 2014b).

2.5. Intercomparison

The intercomparison analysis was based on comparing the total burned area for the fire_cci products and existing global BA products (Geoland, Globcarbon, GFED3 and MCD45) for each of the three years processed. Correlation analysis was also calculated between our results and existing products considering different ecoregions (those used by the GFED database: Giglio *et al.* 2010).

Results

Global datasets from 2006 to 2008 have been generated and are currently being assessed by climate modellers. In terms of sensors outputs, VGT identified less BA area than MERIS, particularly in tropical regions, as we can notice in Figure 4, and higher values in temperate regions, mainly in agricultural areas.
From preliminary validation, MERIS provides much higher accuracy than VGT, both when comparing with our validation sample and with existing BA products. The merged product showed an intermediate estimation of BA, higher than VGT but still lower than MERIS and other existing BA products (table 1).

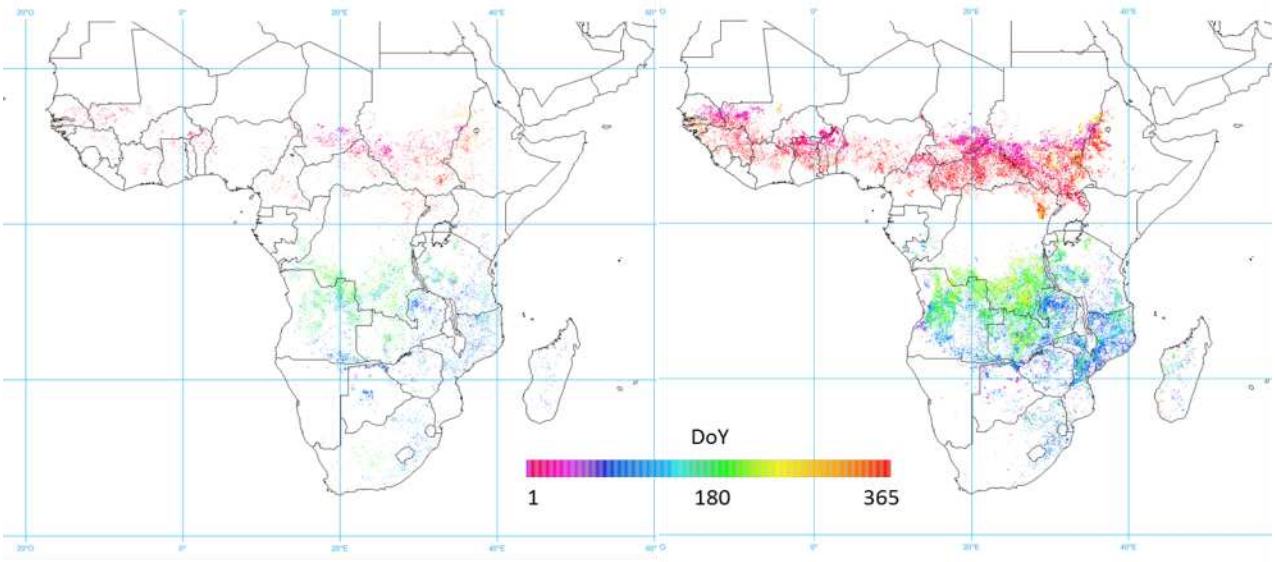

Figure 4. Date of Year (DoY) of Burned Detection from VGT (left) and MERIS (right) over the African continent (2008)

Table 1. Total Burned Area estimated by different global products (sq km)

	GFED	VGT	MERIS	MERGED	MCD45
2006	3418690	2374032	3650268	2853270	3372924
2007	3661888	2239012	3772086	2817410	3522453
2008	3296434	2228610	3623277	2687650	3307390

In terms of spatial variability, Figure 5 shows the estimated burned area from MERIS BA algorithm. The most extensive burnings occur in the Tropical regions, particularly in the African continent and, with less severity, in the Northern regions of Australia, Central Brazil, Venezuelan and Colombian Llanos, and SE Asia. A second belt of burned regions is noticeable in the temperate grasslands and croplands of central Asia, and SE USA. The boreal forest of Russia and Canada have also a substantial role in global biomass burnings.

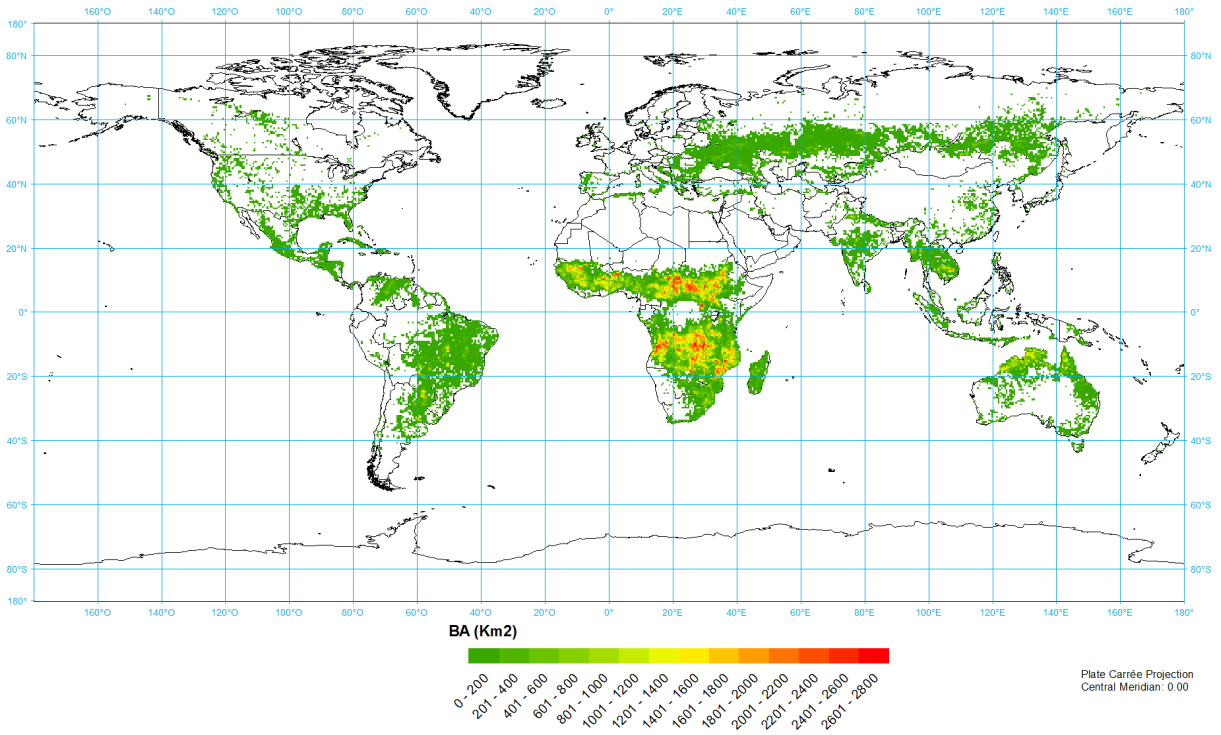

Figure 5. Burned Area estimated from MERIS (2008)

Finally, in terms of estimations produced by our product and other existing global BA products, Figure 6 includes scattergraphs that show the estimated BA in different ecoregions and products. The geographical units were defined by the Global Fire Emissions Database (GFED: Giglio *et al.* 2010), which is a widely-used information source for burned area information, based on MODIS data. Our MERIS product has very high correlations with GFED, with a tendency of around 10% to overestimation. Comparing with the standard MODIS BA product (MCD45), the results are similar in terms of trends, although in this case the tendency is towards underestimation.

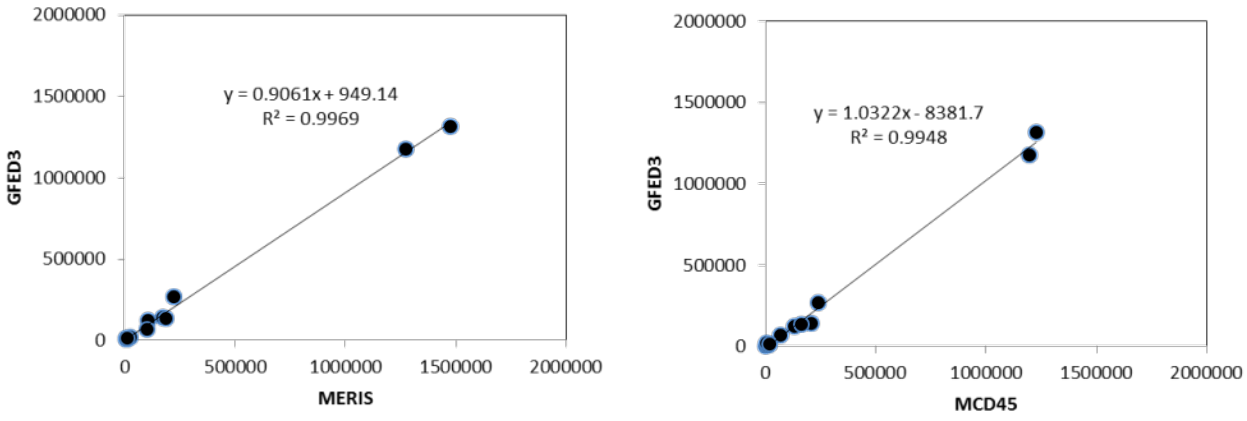

Figure 6. Correlations of BA estimations between MERIS, MCD45 and the GFED in different ecoregions (2008)

Conclusions

This paper has presented the first results of the fire_cci project, which aims to map global burned areas from European sensors. Results are currently in the validation stage, but preliminary assessments show good correspondence between our estimations and existing BA products. A climate assessment report to measure the performance of our product as input to existing carbon and atmospheric models is also under development.

Hardening structures to resist wildland-urban (WUI) fire exposures

Samuel L. Manzello

Fire Research Division, National Institute of Standards and Technology (NIST)
Gaithersburg, MD USA, samuelm@nist.gov

Abstract
Wildfires that spread into communities, referred to as Wildland-Urban Interface (WUI) fires, have destroyed communities throughout the world. In the USA, over 46 million homes in 70,000 communities are at risk of WUI fires [1]. Historically, fire safety science research has spent a great deal of effort to understand fire dynamics within buildings. Research into how to potentially mitigate the loss of structures in WUI fires is far behind other areas of fire safety science research. This is due to the fact that fire spread in the WUI is incredibly complex, involving the interaction of topography, weather, vegetation, and structures. Since the best way forward to address the WUI problem is the hardening of structures [2], the technical basis for improved test standards and fire and building codes are being developed. This paper provides a brief description of the NIST Dragon technology, recent application of the technology to various building assemblies and mulch, and closes with a series of research gaps that must be addressed to be able to design building components to resist firebrand ignition from WUI fire exposures.

***Keywords**: Wildland-Urban Interface (WUI), firebrands, ignition*

Introduction

Wildland-Urban Interface (WUI) fires continue to burn in the USA, and are rapidly getting worse, with attendant increased economic costs [1]. Some recent examples include the Bastrop Complex Fire in Texas in 2011, the Waldo Canyon Fire in Colorado in 2012, and fires in Arizona, Colorado, and California, in 2013. Firebrands are generated as vegetation and structures burn in these fires. While firebrand showers are responsible for a majority of structure ignitions in WUI fires (see any number of post-fire investigation reports over the past 60 years; for example Foote [3]), there exist no scientifically-based standard laboratory test methods to evaluate individual building component's resistance to ignition from wind-driven firebrand showers. Without standard laboratory test methods, it is impossible to evaluate and compare the performance of building elements ability to resist firebrand ignition. It cannot be overstated that current understanding of building component type to WUI exposure is still mainly predicated on *anecdotal* evidence. As a result, the limited WUI fire and building codes and standards in practice lack scientific rigor and, when implemented, it is not clear if these provide any benefit to structures in the path of hazardous WUI fires.

Before test standards are developed, full-scale experiments that systematically evaluate individual building component vulnerabilities to ignition to firebrand showers are required. It is critical to understand the full-scale assembly performance when exposed to wind-driven firebrand showers since weak points in a given assembly can be investigated. In turn, this will lead to determining the necessary scale of building component mock-ups that can be used in standard laboratory test methods. As wind is a critical component required to transport firebrand showers observed in actual WUI fires, and wind plays a major role in whether ignition is observed, full-scale experiments must be able to consider the influence of an applied wind field to understand such ignition vulnerabilities.

The Fire Research Division at NIST has embarked on research to begin to determine the vulnerabilities of structures to firebrand showers using the NIST Dragon coupled to a full-scale wind tunnel at the Building Research Institute (BRI). The BRI facility (Japan) has been used since it is the only facility

in the world to examine or study the behaviour of building component under wind-driven firebrand showers. Most recently, the NIST Dragon technology was improved to allow for the generation of continuous firebrand showers, as opposed to the original batch-feed Dragon (as described below). With this technology, it is now possible to systematically ascertain building component vulnerability to wind-driven firebrand showers of any duration [4-6]. The Dragon technology directly feeds into the NIST developed WUI Hazard Scale [7]. While beyond the scope of this paper, the WUI Hazard Scale attempts to provide a framework to quantify expected WUI fire exposure, and assign severity scales, for a given parcel and community. The vision is to establish a basis for the levels of hardening (ignition resistance) needed for buildings and communities to protect against exposure from WUI fires. As a result, with the Dragon technology, it will be possible to expose any type of building assembly to different levels of (radiative and convective) heat transfer and firebrand flux, thus enabling design of structures by tailoring fire resistance to the fire exposure and the hazard.

This paper provides an overview of the NIST Dragon technology, recent application of the technology to various building assemblies and mulch, and identifies a series of applied and fundamental research gaps that must be addressed to be able to begin to design building components to resist firebrand ignition from WUI fire exposures.

NIST Dragon Technology

The NIST full-scale Continuous Feed Firebrand Generator (NIST Dragon) consists of two parts: the main body and continuous feed component (**see Figure 1**). A brief overview is provided of the device; the interested reader is referred to recent review articles [5-6]. The feed system is connected to the main body and is equipped with two gates to prevent fire spread from ignition chamber back to the wood supply reservoir. A blower is connected to the main body and the purpose of the blower, described in more detail below, is to vary the combustion state of the generated firebrands from either glowing combustion or flaming combustion. The feed system consists of a pneumatic cylinder coupled to a cylindrical container where wood pieces, that will be ignited to produce firebrands, are stored. The pneumatic cylinder is contained inside a metal sleeve. Inside the metal sleeve, the sliding rod of the pneumatic cylinder is connected to a plate that allows the volume of wood contained within the sleeve to be varied. This volume can be set precisely to allow a specific mass of wood to fall into this volume. When the air pressure was applied, the sliding rod of the pneumatic cylinder moves forward, forcing the wood pieces that have fallen by gravity within the volume of the metal sleeve to the first gate, where they are then dropped into second gate that leads to the Dragon where they are ignited (see **Figure 1**). Douglas-fir wood pieces machined to dimensions of 7.9 mm (H) by 7.9 mm (W) by 12.7 mm (L) are used to produce firebrands. Firebrands generated from combustion of these wood pieces in the NIST Dragon have been shown to be consistent with sizes measured from full-scale burning trees, as well as size distributions obtained from actual WUI fires [6]. The number flux and mass flux of generated firebrands may be adjusted by varying the feeding rate of wood pieces into the device.

An operational parameter that is also varied is the blower speed. When the blower is set to provide an average velocity below 3.0 m/s measured at the exit of the Dragon when no wood pieces were loaded, insufficient air is supplied for combustion, and this results in a great deal of smoke being generated in addition to firebrands. At blower velocities above 3.0 m/s, smoke production is mitigated, and many of the firebrands are in a state of flaming combustion rather than glowing combustion. When firebrands contact ignitable fuel beds, they are typically in a state of glowing combustion, not open flaming. It is possible for firebrands to remain in a flaming state under an air flow, and it is reasonable to assume that some firebrands may still be in a state of flaming combustion upon impact. The purpose of this device is to simulate firebrand showers observed in long-range spotting and therefore firebrands in a

state of glowing combustion are desired. Yet, the NIST Dragon is also capable to generate showers of flaming firebrands as well.

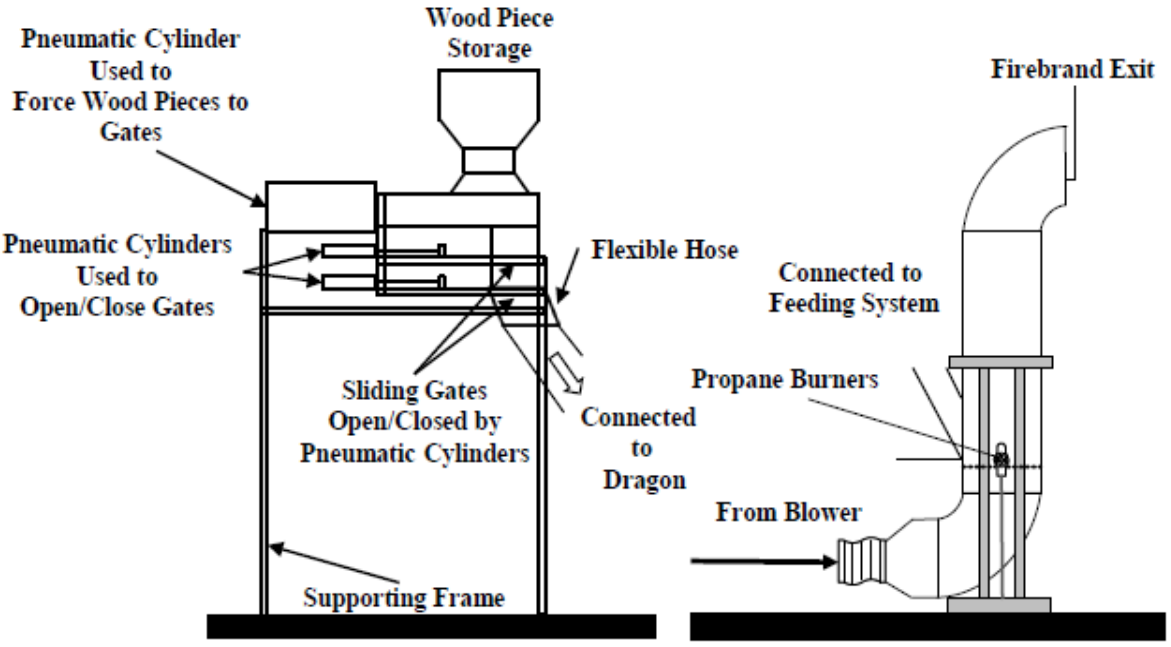

Figure 1Schematic of Full-Scale Continuous Feed Firebrand Generator

3. Current Knowledge Gaps – Applied Research Gaps

3.1. Decking Assemblies

In WUI fires, wood decking assemblies have been observed to be an ignition vulnerability based on post-fire damage surveys conducted by NIST and elsewhere. The California Office of the State Fire Marshal (OFSM) adopted the test method known as State Fire Marshal (SFM) STANDARD 12-7A-4 [8]. The SFM test method is intended to determine the response of decks to firebrand exposure and is very similar to the ASTM E108 [9] roofing test Namely, a firebrand is simulated by placing a burning wood crib (either Class A, B, or C firebrand) on top of a section of a deck assembly under an air flow. Class A is intended to represent the most severe firebrand exposure as it represents the largest crib size (30.48 cm x 30.48 cm x 5.715 cm). The dynamic process of multiple firebrands bombarding decking materials as a function of time is not taken into account in this standard test method. In addition to not simulating a dynamic firebrand attack, no attempt is made to relate the size and mass of the firebrand used in this standard to actual firebrands produced from burning vegetation and structures. There is no evidence to suggest that this test is a 'worst-case' firebrand exposure for decking assemblies.

Recent experiments using the NIST Dragon have demonstrated the dangers of the dynamic process of continual, wind-driven firebrand showers landing onto decking assemblies for the first time [9]. For each wood decking assembly type tested (cedar, Douglas-fir, and redwood), the accumulation of glowing firebrands resulted in flaming ignition of the deck boards. It was also observed that ignition of the deck boards produced smoldering ignition in the support members under the decking assembly (**see Figure 2-3**). Additional experiments must consider more wood types as well as composite (wood/plastic) decking assemblies to determine its performance when exposed to continuous wind-driven firebrand showers. These experiments should be compared to experiments using protocols outlined in SFM STANDARD 12-7A-4 [8]. Finally, it is important to determine whether decking

assemblies, once ignited, can result in a fire spreading to adjacent building components. Therefore, future full-scale experiments are required to address the questions:

- Is the current decking test method that uses Class A firebrand exposure adequate?
- If decking assemblies are ignited, are they capable to ignite adjacent building components?

Figure 2. Picture of the underside of the decking assembly (cedar); overall view [10].

Figure 3. Detail of the underside of the decking assembly (cedar). The ignition process was observed to spread to the wood supporting members [10].

Roofing Assemblies

As indicated above, the ASTM E108 [8] roofing test is used to evaluate ignition of roofs to firebrands by placing a burning wood crib on top of a section of a roof assembly under an air flow, yet, similar to decking assemblies, the dynamic process of multiple firebrands landing under ceramic tiles/gaps as a function of time is not taken into account [6]. Post-fire studies have identified a building ignition mechanism where small firebrands penetrate under non-combustible tile roof coverings [6]. Experiments conducted using the NIST Batch-Feed Dragon has provided experimental confirmation of this ignition mechanism for ceramic tile roofing assemblies (see **Figure 4** and [11] for more details).

Figure 4. ***Images of experiments conducted using oriented strand board/ceramic tile (OSB/CT) without bird stops installed [11]. Intense smoldering ignition (SI) was observed within the OSB base layer and eventually flaming ignition (FI) was observed. The wind tunnel speed was 7 m/s and the Firebrand Generator was located 2.0 m from the CT roofing assembly. The dimensions of the roof assembly were 122 cm by 122 cm.***

In addition, concrete tile roofing assemblies (flat and profiled tile; **see Figure 5**) as well as terracotta tile roofing assemblies (flat and profiled tile) commonly used in the USA, Australia, and elsewhere were exposed to wind-driven firebrand showers [12]. The purpose of these *scoping* experiments was to determine if firebrands were able to penetrate the roofing tile assemblies and melt the underlying sarking material. No sheathing layer was included in the roof support structure as these experiments were intended to replicate Australian construction details [12]. The results, however, are relevant to US construction since the same concrete (flat and profiled) and terracotta (flat and profiled) tiles are used in both countries. Underlayment or sarking, in the form of a layer of aluminium foil laminate bonded with a fire retardant adhesive to a polymer fabric, was placed under the tile battens. The results showed that firebrands penetrated the tile gaps and subsequently melted the sarking material for both types of concrete tile roofing assemblies (flat and profiled tile) and the profiled tile terracotta roofing assembly when exposed to wind-driven firebrand showers (**see Figure 6**). The flat tile terracotta roofing assembly appeared to perform better due to its interlocking design. For these tiles, the firebrands were observed to become trapped within the interlocking sections of the tiles and as a result, the firebrands were not able to penetrate past the tiles toward the sarking material. Based on the findings of these experiments, a potential cost-effective mitigation strategy might be to use a continuous underlayment of firebrand-resistant sarking [12].

Figure 5. Concrete Tile Roofing Assembly (profiled tile) Exposed to Wind-Driven Firebrand Showers. The dimensions of each tile were 420 mm long by 320 mm wide. The Height, from the Wind Tunnel Floor to the Base of the Gutter of Roof Deck was 1250 mm [12].

Figure 6. Images of Sarking Placed Under Concrete Tiles (profiled tile) Taken Immediately after the Experiment was Completed. The Tiles have been removed [12].

To further address the issue of wind-driven firebrands, the State of California in the USA mandated the use of a non-combustible mineral surfaced cap sheet under roof tiles [13]. These requirements have never been tested to wind-driven firebrand exposure. A series of open questions remain:

- All roofing assembly experiments conducted by NIST (described above) have made use of the batch feed NIST Dragon. What happens to roofing assembly performance when experiments are revisited with the improved continuous feed Dragon capable of longer firebrand exposures?
- Is the current requirement mandated in California [12] on the use of a non-combustible cap sheet under roof tiles adequate?
- Should the legacy ASTM E108 [9] roofing test be modified to consider continuous wind-driven firebrand exposure to roofing assemblies?

3.3. Mulch Located Adjacent to Structures

Buildings are often surrounded by vegetation that, when ignited, can produce intense, localized firebrand showers, and provide direct flame contact onto building elements, leading to ignition of buildings. The creation of defensible space around structures is a common mitigation strategy, yet in many areas the requirement for the creation of defensible space is either not popular due to resistance to modify the natural environment and landscaping around structures, or not practical due to limited lot/land parcel size. Of particular concern are wood landscape mulches located adjacent to buildings. While there have been some studies of mulch ignition in the literature, none of these studies have investigated the ignition of mulch installed in realistic building configurations exposed to wind-driven firebrand showers; conditions seen in real WUI fires.

Figure 7 displays a typical experiment to expose shredded hardwood mulch beds to continuous wind-driven firebrand showers. In this image, the wind tunnel speed was 6 m/s and the mulch bed moisture content (MC) was 11 % (dry basis). While full details of these results are beyond the scope of this paper (see [14] for full details, it is rather clear that continuous-wind driven firebrand showers are capable of rapidly igniting mulch beds (**see Fig.7**).

Figure 7. Image of 1.2 m by 1.2 m by 51 mm (depth) shredded hardwood mulch bed at 11 % MC exposed to continuous wind-driven firebrand showers. The re-entrant corner, with dimensions of 1.2 m by 1.2 m by 2.44 m high, was lined with gypsum board to investigate the ignition of the mulch bed itself; the ability of the mulch bed to ignite the wall assembly was not considered [14].

- Are wind-driven firebrand showers capable of igniting common wood mulches found in WUI communities?
    - Shredded hardwood mulch was observed to ignite. How about other common mulch types such as pine bark, pine bark nuggets, and pine straw?
- Once ignited, is the wood mulch bed capable of producing ignition of the structure itself?

3.4. Wood/Vinyl Fencing Assemblies

Post-fire studies conducted by NIST on the Waldo Canyon Fire in Colorado (2012) suggested that wood fencing assemblies are vulnerable to ignition from firebrand showers in WUI fires, but again there has never been any experimental verification of this ignition mechanism. Fencing assembly ignition has also been observed in Australia [15]. Presently, there is lack of understanding on fence assembly ignition vulnerabilities under wind-driven firebrand exposure. **Figure 8** displays results obtained when exposing redwood fencing to continuous firebrand showers. Redwood fencing assemblies were observed to produce their own firebrands.

- Do fence assemblies, if ignited by wind-driven firebrand showers, transfer or link the fire to the structure?
- Are certain fencing assembly types more amenable to firebrand generation?

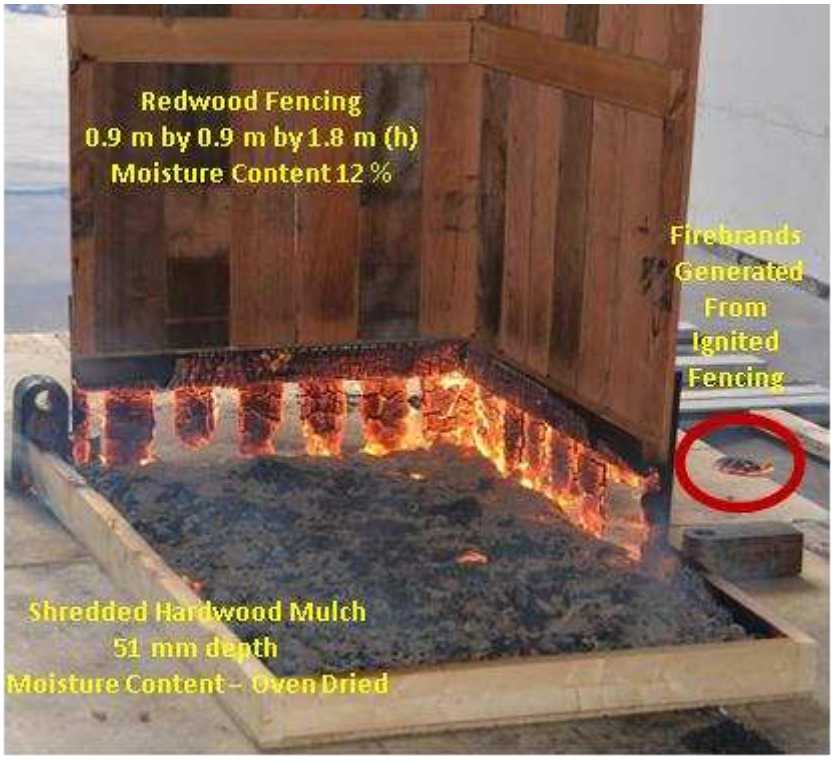

Figure 8 Redwood fencing (inside corner section), exposed to wind-driven firebrand showers at 8 m/s from the NIST Dragon. The firebrands produced smoldering ignition in the shredded hardwood mulch bed (foreground; depth 51mm), this transitioned to flaming ignition in the mulch, and the redwood fencing was subsequently ignited by the mulch. Shredded hardwood mulch was intended to represent various fuels that are adjacent to fencing in the Wildland-Urban (WUI). As the redwood fence continued to burn, firebrands were generated with large projected area and low mass, and were blown downstream (far right).

3.5. Different Wall Siding Types

Complete lack of understanding on wall ignition vulnerabilities under wind-driven firebrand exposure.

- Are test standards [16] that exist for direct flame impingement adequate?
- Once ignited, are certain combustible siding types more likely to generate firebrands?

Translating Full-Scale Experimental Results to Laboratory Test Standards

As needed physical understanding is being collected from the full-scale experiments, work is required to develop reduced-scale test methods that will be able to reproduce results of the full-scale experiments above. The specific exposure ranges (*e.g.* duration of firebrand flux) will be determined as further understanding of WUI fire exposure develops. It is important to understand that is a significant challenge.

As mentioned, a very important characteristic of the NIST Dragon is that the firebrand size and mass produced using the device can be tailored to those measured from full-scale tree burns [17-18], and actual WUI fires [19], which are in stark contrast with the size of firebrands referenced in existing test standards and wildfire protection building construction recommendations. In collaboration with the California Department of Forestry and Fire Protection (CALFIRE), NIST quantified firebrand distributions from a real WUI fire (2007 Angora Fire) [19]. Specifically, digital image analyses of burn patterns from materials exposed to the Angora Fire were conducted to determine firebrand size distributions. The firebrand size distributions reported were compared to firebrand size distributions from experimental firebrand generation using the NIST Dragon, as well as historical firebrand field studies. The most salient result reported in [19] was the documentation of the consistently small size of firebrands (<0.5 cm^2) and the close correlation of these results with the sizes of experimentally generated firebrands from the NIST Dragon. The Texas Forest Service has used this methodology to collect firebrand size distributions from the recent Texas Bastrop Complex fires in 2011, as well, and reported similar findings to the 2007 Angora fire; significant numbers of very small firebrands were produced [20].

- More information of this type is clearly needed from actual WUI fires - this is an important challenge for future WUI fire research.
- Other than the Angora Fire and Bastrop Fire data sets, which are limited, no other information on firebrand distributions from actual WUI fires is available.

Rapidly deployable instrumentation packages that can be placed in the path of WUI fires to collect information on firebrand fluxes generated in *actual* WUI fires are needed. The authors have developed such a system to quantity heat flux from WUI fires and the concept was vetted in prescribed fires, but this methodology must be extended to collect needed firebrand flux [21] from actual WUI fires. It is difficult to simulate the range of WUI fuels (*e.g.* structures) and wind speeds in prescribed fires, and as a result, using only firebrand data from prescribed fires will not give meaningful data from actual WUI events. Prescribed fires are, however, a useful place to test a conceptual firebrand flux instrument package.

Fundamental Research Needs

As indicated above, much applied research is needed to be able to begin to consider designing structures to resist firebrand ignition in WUI fires. Yet, it is important not to overlook fundamental research needs that are an integral part of this problem as well. Important fundamental needs also link WUI research to materials science research, as better fundamental ignition data will lead to enhanced, firebrand resistant materials. Specifically, these needs are:

- Fundamental understanding of ignition of building elements by firebrands, answering questions such as:
  - What is the mechanism of ignition of building elements by firebrands?
  - How does firebrand accumulation influence the heat flux applied to adjacent ignitable materials?
  - How does wind influence accumulation as well as the burning and heat transfer from accumulated firebrands to an ignitable material?
- Forensic analysis of firebrands collected from WUI fires, answering questions such as:
  - What are firebrands comprised of?
  - Is it possible to determine the source of firebrands from burned samples?
    What types of firebrand materials have a greater potential of igniting materials (vegetative and building elements)?

Summary

Research into WUI fires, and how to potentially mitigate the loss of structures in such fires, is far behind other areas of fire safety science research. This is due to the fact that fire spread in the WUI is incredibly complex, involving the interaction of structures with topography, weather, and vegetation, and other structures [6]. While WUI research is challenging, this paper attempts to delineate a series of current research gaps in order to be able to begin to harden structures to firebrand showers, an important aspect of WUI fire exposure.

Ignition of wood subjected to the dynamic radiant energy flux

Alexander Filkov, Kuznetsov V.T., Guk V.O

National Research Tomsk State University, 36 Lenin Ave., Tomsk, Russia, aifilkov@gmail.com

Abstract
In this paper we analyzed the ignition of the wood samples subjected to the dynamic heat flux. The experimental setup was created on the base of the optical wave "Uran-1" with a radiation source. The intensity of the heat flux was changed during the experiment by moving the test sample along the optical axis of the elliptic reflector in the setup. Pine wood was used as the test samples. We received the delay times for ignition of pine wood during heating under conditions of the decreasing and increasing heat flux. The received data were compared with the data for a static heat flux.

***Keywords**: wood, dynamic radiant energy flux, wood, ignition time*

Introduction

In [1] it is reported that the ignition process is essentially dependent on the type of heat flux, whether it is static or dynamic (when the ignition of fuels is initiated by time-dependent heat flux). At the same time, the ignition of fuels under dynamic conditions has been insufficiently studied. There are only some experimental work [2, 3], where the ignition of fuels was carried out under dynamic conditions of heat supply. Taking into consideration that the dynamic type of the heat flux dominates in the real conditions, the urgency of this problem is obvious.

Methods

In [1] the first results were received, in particular, it was developed an experimental technique. The radiant energy source was an Uran-1 optical wave with a DKsR-10000 (Figure 1).

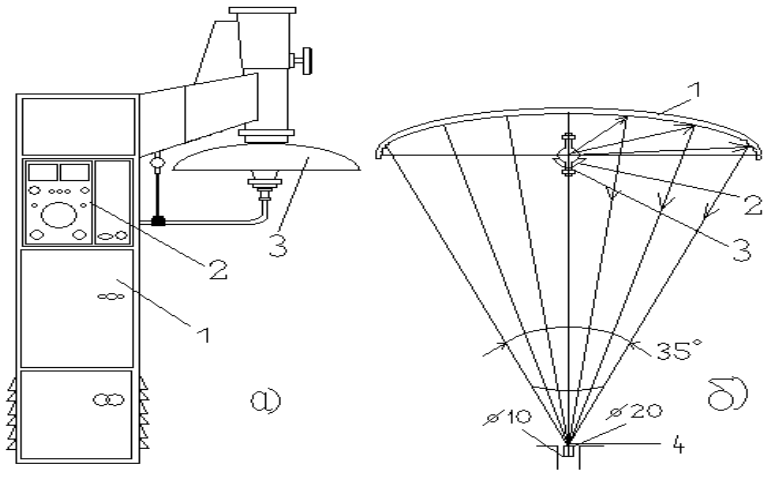

Figure 1. The scheme of experimental installation: a) optical furnace URAN-1: 1- power supply, 2 - control panel, 3 - radiator; b) optical radiator: 1 - reflector; 2 – counter reflector; 3 - lamp; 4 – action spot

Of the 10-kW power generated by the lamp, optical radiation accounted for only 5.5 kW. The radiation spectrum distribution was as follows: 0.5 kW (9%) was in the ultraviolet region, 2 kW (36%) in the visible region, and 3 kW (55%) in the infrared region. The setup provided not less than 95% stability of the radiation in time and not less than 87% uniformity of the radiant energy flux distribution in a

spot of diameter $2 \cdot 10^{-2}$ m. With a deviation of $2 \cdot 10^{-3}$ m from the focal plane along the optical axis, the change in the radiant flux density did not exceed 5%. The diameter of the focused flux was about $2 \cdot 10^{-2}$ m.

The recording unit provided measurements of the radiant flux density, exposure time, the onset of flame and controlled experimental conditions. It included a radiant flux density sensor, diodes, relays and N-117 light-beam oscillograph.

The density of a radiant energy flux in a focal spot was controlled by using radiation attenuators and a smooth change of electric power applied to the xenon lamp. The attenuators of the radiant energy flux were a metal grid that was placed perpendicularly to the optical axis at a distance of 0.3-0.4 m from the focal plane. The system of gates protects the test sample against heating by the radiant flux and dosed supply of energy radiation.

The dynamic flow was modeled by the movement of the sample along the optical axis. For the movement of the sample it was used the following installation (by the example of the decreasing flux of radiant energy, Figure 2).

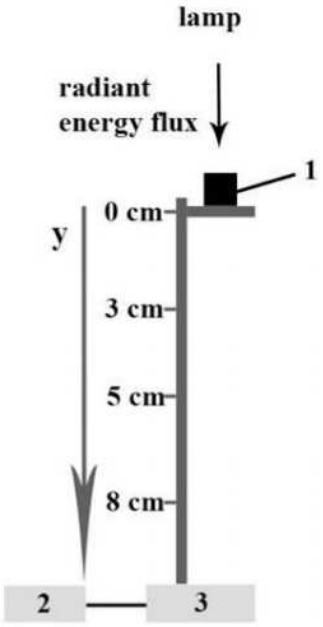

Figure 2. Installation for the movement of the sample: 1 is the sample, 2 is the remote control of motion platform with a sample; 3 is the mechanism that move the sample, y = 0 cm is the focal plane; 3, 5, 8 cm are the distances from the focal plane

Simultaneously with the opening of the gate, the transporter was turn on and the sample started moving with a constant speed of 0.117 m/s. The opening (closing) time of the gate was $4\ 10^{-2} \cdot$ sec.

The test procedure was as follows. The intensity of the radiant flux was measured by a calorimeter fixed to the holder at the upper and lower points of the optical axis. Then the test sample was located on the place of the calorimeter and tested. The registration unit recorded the opening time of the gate and the appearance of flame. Ignition of the condensed substance was determined by the appearance of flame on the sample surface.

The calorimeter was a copper disk 10^{-2} m in diameter and $3 \cdot 10^{-3}$ m thick with a thermocouple calked in the center of the disk to a depth of $1.7 \cdot 10^{-3}$ m. The thermocouple was obtained by contact welding of copper and constantan wires with a diameter of 100 microns.The receiving surface of the calorimeter was coated with lampblack. In the radiation spectrum of 0.36–1.1 μm, the reflection coefficient of the

blackened surface of the calorimeter was 1.5–2.0%. The measurement error of the radiation intensity did not exceed 10%. The heat flux density was measured in the range q = 20–110 W/cm^2.
To determine the density of radiant flux, we experimentally measured the heating rate of the copper disc subjected to radiation coming to the blackened surface. The radiant flux density was calculated by the formula:

$$q = \frac{mc}{(1-b)S} \cdot \frac{\Delta T}{\Delta t} \tag{1}$$

where m is the mass of the disk; c is the specific heat; S is the area of the blackened surface of the disc; b is the reflection coefficient; $\frac{\Delta T}{\Delta t}$ is the rate of heating.
The delay time of ignition was determined by a photoelectric method. The ignition time was taken as the time interval from the beginning of exposure to the radiant energy flux to the occurrence of flame over the surface of the sample. Radiation of flame was registered using photodiodes. The H-117/1 oscilloscope was used for recording electrical signals. In measurements of the ignition time from the occurrence of flame, the error is not more than 4% and is determined mainly by the physicochemical properties of the material studied.
Pine wood (Pinus Silvestris) was used as the test samples (Figure 3). The samples were cylinders $1.9 \cdot 10^{-2}$m in diameter and $1.5 \cdot 10^{-2}$m in height. The surface of the samples, absorbing radiation, was covered by lampblack.

Figure 3. Wood sample before (left) and after experiment (right)

The light radiation was incident on the sample perpendicularly to the wood fibers. The investigations were carried out in air at atmospheric pressure. The initial temperature of the samples corresponded to room temperature — 297 K. The moisture content of the samples was W≈1.8%. The absolutely dry state of wood was achieved by predrying in a drying box at 376 K for 48 hours. Unchangeable moisture content of the samples was provided by a desiccator filled with silica gel. The moisture content of the samples was determined with an accuracy of 0.01% using a A&D MX-50 moisture content analyzer.

3. Results and discussion

To compare the delay time of ignition under static and dynamic conditions, the heat flux was averaged under dynamic conditions. For this purpose, the following method was used. The intensity of the radiant energy flux was measured with a microcalorimeter at fixed distances from the focal plane of the reflector. Knowing the velocity of the sample along the optical axis of the elliptical reflector we

can turn from fixed values of the distance to the time. In this case, the dependence of the heat flux on time is well enough (correlation $R^2 = 0.997$) approximated by the function (Figure 4):

$$q = ae^{\pm 0.7t} - 2, \quad (2)$$

where q is the heat flux, W/cm^2; t is the time, s; a is the nondimensional coefficient, "+" – increasing heat flux; "-" – decreasing heat flux.

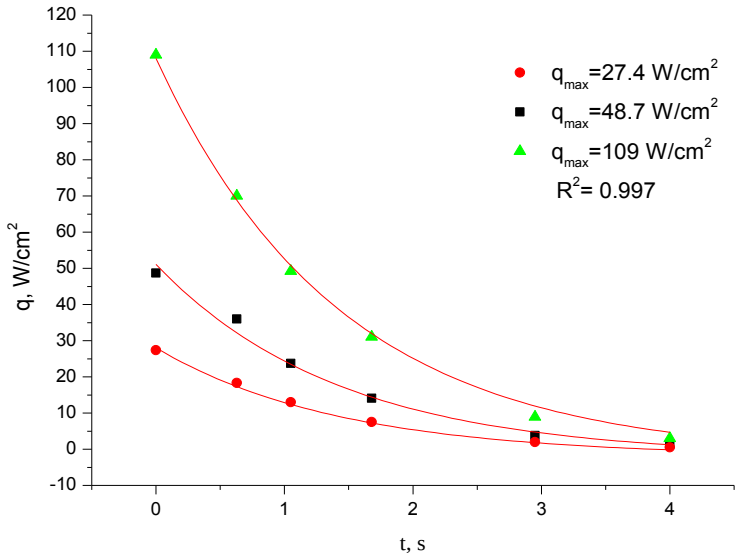

Figure 4. Heat flux versus time when the sample is moved from the focal plane

Thus, depending on the value of heat flux in the focal plane (t=0) we can determine a coefficient *a* and dynamic changes of the heat flux at the surface of the moving sample. The delay time of ignition was measured using a photodiode. Knowing the ignition delay time of the sample we can find a heat flux in the ignition point using a distribution curve q(t). Since the sample of pine ignites within one second in the tested range of the heat flux, then from Figure 4 it can be seen that the curve is quasilinear in this range. In this connection, the average heat flux was determined as the arithmetic mean value for dynamic conditions.

Figure 5 shows the ignition delay times of the pine samples under decreasing (q=f(t)) and static (q=const) heat flux.

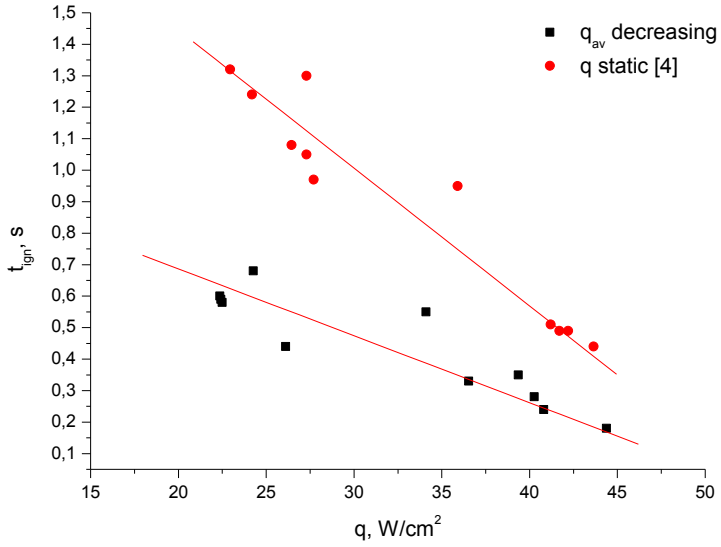

Figure 5. Ignition delay times of the pine samples versus heat flux for dynamic (decreasing heat flux) and static conditions

When the radiation flux decreases, the delay time for ignition of the pine samples is 2-2.5 times less than that for the constant radiation flux. At the same time, Figure 5 shows that the decrease in value of heat flux leads to the fact that the delay time of ignition increases faster under static conditions than under dynamic ones. These results do not contradict the paper [3], where it was experimentally shown that in the case when the heat flux increases, the delay time for ignition of nitrocellulose is greater than that for the constant heat flux.

In a similar way, according to the formula (2) the flux of radiant energy was determined at the moment of ignition for increasing flux. The average heat flux was determined using the method for determination of the average value for interval dynamic rows [5]. Figure 6 shows the delay time to ignite the pine samples for the increasing (q=f(t)) and static (q=const) radiant energy flux.

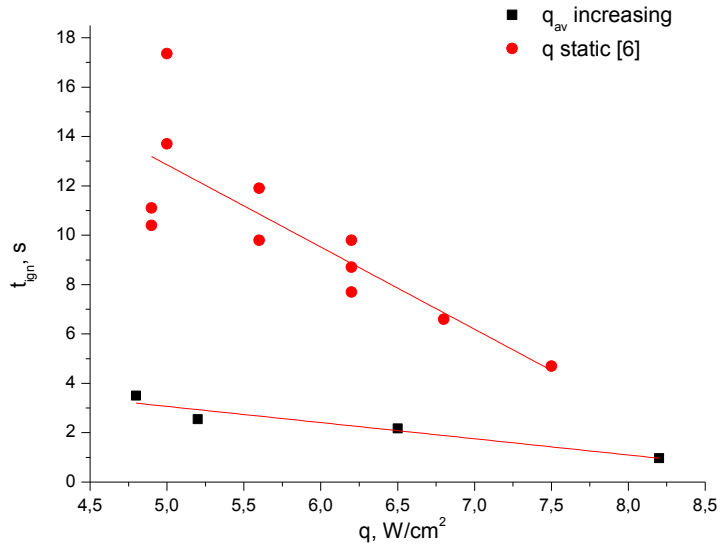

Figure 6. Ignition delay times of the pine samples versus heat flux for dynamic (increasing heat flux) and static conditions

The analysis of the curves in Figure 6 shows that the ignition delay time for the increasing flux of radiant energy is smaller than for a constant flux. The difference in time is from 2 to 3 times. For the decreasing flux (Figure 5), a similar pattern is observed. However, the ignition delay time for the increasing flux of radiant energy decreases slower than for the decreasing flux with the increase in time. The data obtained are in qualitative agreement with the results of mathematical modeling of dynamic conditions for heating of wood in [7].

At a result we have received the delay times for ignition of pine wood during heating under conditions of the decreasing and increasing heat flux. The received data were compared with the data for a static heat flux [4, 6].

The results obtained can be used to improve the prediction of dangerous zones for ignition of wood in wildland and anthropogenic fires.

Abstract

Wildfires are an important ecological disturbance in Mediterranean forests and have dramatic social, economic and environmental impacts. Portugal is already experiencing an increase in the number and extent of wildfires, with records of burnt extent exceeding 400,000ha and 300,000ha in 2003 and 2005, respectively. With the projected future increase in the frequency of large wildfires, those negative impacts and fire suppression difficulties will also likely increase.

Spatially explicit wildfire spread models (e.g. FARSITE) are one of the most effective tools to understand complex interactions among topography, vegetation fuel and weather conditions. These models can be used not only to study past fire events but also for forecasting fire spread and behavior. MODIS active fires have a large potential to provide relevant information regarding the spatio-temporal distribution of large wildfire events. When combined with fire spread models, they may provide crucial information to overcome the error propagation that arise when simulating large and long duration wildfire events, which is crucial for monitoring and forecasting fires in an operational fire-fighting context.

We investigated nine large wildfires (>=10,000ha) that occurred in Portugal between 2001 and 2012 in order to evaluate if combining fire growth simulations with active fire data improves the accuracy of fire spread predictions. To achieve this goal we propose to: 1) simulate fire growth using FARSITE model in combination with the time and spatial information of the MODIS active fires during the fire event propagation; and 2) assess the performance of fire spread simulations comparing them with the spatio-temporal distribution of the active fires. Additionally we performed a sensitivity analysis to evaluate the impact of key model parameters and variables on fire growth simulations, to understand the main sources of error and identify future work needed to improve the use of combined model-satellite approach in an operational context.

Results show that fire growth simulations are improved when satellite-derived active fires were used to reinitialize the simulation while the fires are occurring. Sørensen coefficients obtained for these simulations assisted by MODIS active fires were all above 0.5, showing a significant improvement over full fire growth event simulations. This innovative approach of combining satellite active fires data with fire spread simulations reduces the propagated errors of the large and long duration fire events and improves the forecasting ability of fire spread models.

Keywords*: Fire growth simulations, satellite active-fires, FARSITE, FIRE-MODSAT.*

Introduction

Large wildfires while infrequent are responsible for severe environmental, ecological and socio-economic impacts. In Portugal, wildfires have consumed an average of 140,000ha/year during the last decade (Sá and Pereira 2011). Portugal has been experiencing significant increments of both maximum and minimum temperature at annual and seasonal scales (Ramos *et al*. 2011) and all regional climate

models indicate an increased likelihood of future increases in the frequency and amplitude of summer heat waves (Barriopedro *et al*. 2011). Therefore, most climate change studies point to an increase in the number and extent of forest fires (Flannigan *et al*. 2013), thus the negative impacts of wildfires and fire suppression difficulties will also likely increase. Portugal is already experiencing this reality, with records of burnt extent exceeding 400,000ha and 350,000ha in 2003 and 2005, respectively (Oliveira *et al*. 2012), and several very large and catastrophic wildfires in the South and Centre of Portugal (Trigo *et al*. 2006).

The scientific community is becoming increasingly aware of the significance of large wildfires impacts, being essential to understand the complex interactions among the main drivers of wildfire spread and behaviour, such as topography, fuel and meteorology. Spatially explicit wildfire spread models are one of the most effective tools to understand such complex interactions and have been commonly used to simulate wildfire growth and behaviour (e.g. Arca *et al*. 2007). They can provide relevant descriptors directly related with fire suppression, such as the rate of spread and fireline intensity of the fire front (Finney 2004). However, fire spread models have been seldom used to monitor real wildfire events, particularly large wildfires (Arca *et al*. 2007, Kochanski *et al*. 2013).

Since large wildfires have extensive burn scars and are in general active for several days, some authors have recently explored the potential of using satellite data to monitor such events events in a quasi-continuous mode (Smith and Wooster 2005, Loboda and Csiszar 2007, Benali and Pereira 2013, Coen and Schroeder 2013). The MODerate Resolution Imaging Spectroradiometer (MODIS) detects active fires that are burning at the time of overpass up to four times per day (Giglio *et al*. 2003) and has been integrated in operational systems assisting fire managers to define strategic decisions regarding fire suppression resource allocation (e.g. Lee *et al*. 2002, USDA 2014).

Modelling and monitoring large wildfires is limited by the accuracy and availability of information about the spatio-temporal distribution of fire spread which is usually taken from subjective eye-witness interviews and limits the accuracy of model calibration and validation. The skill of forecasts in simulating future fire states is basically dependent on accurate weather forecasts, and therefore, both decrease significantly with time (Coen and Schroeder 2013, Lilly 1990). In this context, satellite active-fire data can provide detailed and objective information regarding the dynamics of those events improving the implementation of fire spread models. Both satellite data and fire spread models provide different types of information about the spatial and temporal distribution of large wildfires. However, they have not been combined in a manner that fully exploits their potential and minimizes their limitations. Remote sensing and modelling have been successfully combined to provide useful and accurate predictions in other earth sciences contexts, for instance in hydrological applications (Moradkhani 2008) but very few studies have explored this combination for wildfire applications (Lee *et al*. 2002). Combining active fires satellite data with fire-spread simulations may reduce error propagation during simulations of large, long duration wildfire events. To the best of our knowledge a single recent study moved towards this direction exploring the use of satellite active fires data to initialize and evaluate coupled weather-wildfire growth model simulations in a long lasting fire event (Coen and Schroeder 2013).

FIRE-MODSAT (Supporting FIRE-suppression strategies combining fire spread MODelling and SATellite data in an operational context in Portugal) is an one-year funded project by the Portuguese Foundation for the Science and Technology (FCT) that aims at providing crucial information to understand how large wildfire impacts can be minimized in the future, by combining fire spread simulations and satellite data to support fire management decisions in an operational context improving the efficiency of the fire suppression system.

The study presented here shows some preliminary results of the former project. We selected extreme wildfires (above 10,000ha) that occurred in Portugal between 2001 and 2012 to evaluate the potential of combining fire growth simulations with active fire data, and improve the accuracy of fire spread predictions. We propose to: 1) simulate fire growth using FARSITE (Fire Area Simulator, Finney 2004) model in combination with the temporal and spatial information of the MODIS active fires

during the fire event; 2) assess the performance of fire spread simulations comparing them with the spatio-temporal distribution of the active fires. Additionally we carry out a sensitivity analysis to evaluate the impact of key model parameters and variables on fire growth simulations, to understand the main sources of error. This will contribute to identify future work needed to improve this new approach, producing valuable information to be integrated in a fire-fighting operational context.

Data and Methods

Data

2.1.1. *Case studies*

Nine unusually large wildfires (larger than 10,000ha) which took place in the centre and south of mainland of Portugal between 2001 and 2012 were selected for analysis (Figure 1). Corresponding burnt area perimeters were extracted from the annual 35-years fire atlas of Portugal (1975-2009) (Sá and Pereira 2011) and were used as reference data.

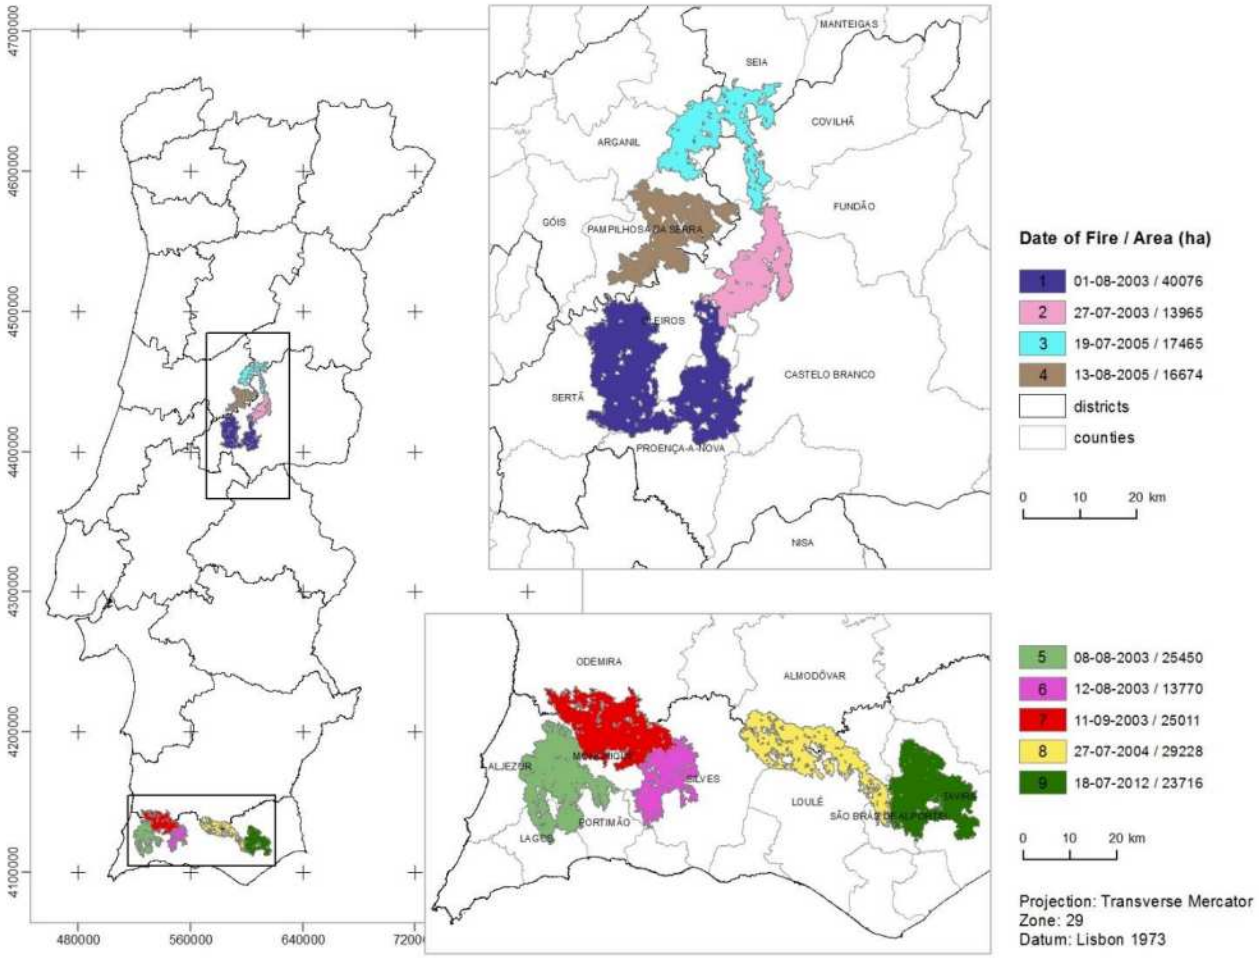

Figure 1. Case studies: nine very large fire events (larger than 10,000ha) that occurred in the mainland of Portugal between 2001 and 2012. Fire events are named as: (1) CasteloBranco1 (Cb1 2003); (2) CasteloBranco2 (Cb2 2003); (3) Covilhã1 (Cov1 2005); (4) Covilhã2 (Cov2 2005); (5) Monchique1 (Mcq1 2003); (6) Monchique2 (Mcq2 2003); (7) Monchique3 (Mcq3 2003); (8) Loulé (Lou 2004); and (9) Tavira (Tav 2012). In the legend we can see each fire date of ignition and the corresponding burnt area extent.

2.1.2. *Landscape and weather data*

Fire spread simulation requires spatial information of the landscapes, and on the weather conditions prevailing during the entire simulation period. Spatial data comprise fuels, weather, and topography. In the simulations, weather variables are input as streams of data, whereas fuels and topography are provided as GIS raster themes. Based on the input variables spatial resolution, and on the time-consuming resources of each simulation, the landscape cell-size spatial resolution was set equal to 100m, which provides an acceptable level of detail for heterogeneous landscapes.

Elevation was obtained from the Shuttle Radar Topography Mission (Farr *et al*. 2007). This dataset was also used to derive the slope and aspect variables.

Fuel maps as per the Northern Forest Fire Laboratory (NFFL) 13 fuel models (Anderson 1982) were provided by the Portuguese municipalities affected by the selected fire events. Some municipal fuels maps were not available for this study, so those maps were derived using a Classification Tree algorithm (Breiman *et al*. 1984) setting as predictor variable the Corine Land Cover (CLC, Caetano *et al*. 2009) class and the fuel class model as the response variable. Burnt areas up to two years before the date of the land cover map were updated to shrublands. The fires that occurred in the same fire season as the fire events were classified as non-burnable.

Tree cover was derived from the MODIS Vegetation Continuous Fields (MOD44B) at 250 m spatial resolution (DiMiceli *et al*. 2011). Stand and tree-based variables were set constant for the entire simulated landscapes (canopy height = 5m; crown base height = 2m and crown bulk density = 0.1 kg $/m^{-3}$).

FARSITE requires daily weather observations of minimum and maximum temperatures, humidity and precipitation at a specified elevation, and hourly observations of wind speed and direction. These data characterize the daily weather pattern and are used to calculate the dead fuel moisture contents. Spatially variable wind fields were modelled wind the WindNinja software to account for the effect of complex topography (Forthofer *et al*. 2009).

Weather (temperature, precipitation, insolation, relative humidity and wind speed and direction) hourly simulated data were derived from the 10km regional climate model (MM5), which is able to reproduce the main regional circulation patterns as well as the temporal variability of the wind series (Jerez *et al*. 2013a). This model was already applied to various applications that require reliable fine-scale meteorological fields (Jerez *et al*. 2013b, Jerez *et al*. 2010).

2.1.3. *MODIS active fires satellite data*

Satellite data has large potential to provide relevant and innovative information about the spread dynamics of large wildfire events, such as the direction and rate of fire spread (Benali and Pereira 2013). The MODIS active fire product detects fires in 1km pixels that are burning at the time of overpass under relatively cloud-free conditions up to four times per day (Giglio *et al*. 2003). MODIS active fires satellite data were aggregated in day and night time overpasses and, within each overpass, we identified the early and late active fires. Each overpass has a different viewing geometry and thus a different pixel size (Wolfe *et al*. 1998). The active fire *footprint* was defined based on the viewing zenith angle and on the azimuth of each MODIS overpass (Ichoku and Kaufman 2005).

MODIS active fires satellite data were coupled with fire growth models in four stages: 1) to initialize simulations from ignition points; 2) to define the start and end date of each wildfire event; 3) to restart fire spread simulations at each satellite overpass; and 4) to evaluate the accuracy of the simulated fire growth. Only the early overpass active fires were used to reinitialize the simulations to ensure a significant simulation time and capture the relevant fire spread periods. However, to evaluate model's performances both the late active fires of the previous overpass and the early active fires of the next overpass were used.

Wildfire simulation

We used FARSITE 4.0 (Fire Area Simulator, Finney 2004) fire growth model simulator, which incorporates existing models of surface fire spread, crown fire spread, spotting and fuel moisture. Fuel moisture (live and dead) has to be provided for each fuel model. Live fuel moistures (woody and herbaceous) were assumed constant during the simulations. Dead fuel moisture varies over time as a function of fuel particle size, weather conditions, and exposure to wind and sun (Finney 1998). Thus, FARSITE uses an initial fuel moisture condition and throughout the simulation it re-calculates dead fuel moisture contents for each time. Considering the weather conditions that usually prevail during the Portuguese fire season, fuel moisture contents were set based on the low scenarios (Table 1) of Scott and Burgan (2005).

Table 1. Dead (1-hr, 10-hr and 100-hr time-lag classes) and life (herbaceous and woody) fuel moisture contents (Scott and Burgan 2005).

Dead fuel moisture content (%)			Live fuel moisture content (%)	
1-hr	10-hr	100-hr	herbaceous	woody
6	7	8	60	90

The rate of spread adjustment factor is a fuel model specific parameter that adjusts the simulated rate of spread to match observed fire patterns. Thus, its value is dependent on the user expertise of fire behaviour in the local fuel complex. Changes in this parameter are based on limitations of the temporal/spatial scales of the simulations, or to adjust errors in fuel classification, inaccurate fuel moistures or improperly represented local winds (Finney 1998). We kept this parameter equal to 1 to keep the original fire spread rate.

Crown fires were simulated using the previously defined constant stand and tree-based variable values. Fire suppression activities were not considered during simulations. Fire growth simulations were performed for i) the full length of the wildfire event using as ignition points the first active fires detected within the reference burnt area perimeter (hereafter *Full simulation*) and, ii) the fire growth simulations were reinitialized at each MODIS overpass during the lifetime of each fire event (hereafter *Satellite simulation*). Thus, the satellite-assisted simulations used all the active fires derived from each satellite passage as ignition points to restart fire growth simulations until the next satellite passage.

2.3. Performance of the fire simulations

In order to assess the performance of fire growth simulations with and without combining actives fires detected from each satellite passage, we compared the simulated final burnt area perimeters with the respective reference burnt area perimeter extent. For this analysis of performance we used the Sørensen coefficient (SC, Sorensen 1948), which is widely used in ecology to compare the similarity of two samples (Eq. 1):

$$SC = \frac{2a}{(2a+b+c)} \quad \text{(Eq. 1)}$$

where, *a* is the intersection of the simulated burnt area extent values (from the full or the satellite combined simulations) with the reference burnt area extent, *b* is the area burned exclusively by the simulation, and *c* the area exclusively burned in the reference data. It ranges from 0 to 1, with the former value corresponding to a completely failed simulation and the latter indicating a perfect agreement between the fire growth simulations and the reference burnt area perimeter.

Additionally, for both the *full* and *satellite* simulations for each MODIS overpass we calculated the distance between the active fire footprint and the position of the nearest correspondent simulated burnt area pixel. This provided a measure of the spatial displacement error between simulations and the position of the fire front observed by the MODIS satellites during the length of each fire event.

2.4. Sensitivity analysis

Sensitivity analysis was performed to evaluate the impact that small changes of selected variables/parameters had on the simulated final burned area extent. Given the model complexity, a large number of variables and parameters affect simulated fire growth and behaviour. Therefore we limited the sensitivity analysis to the variables wind speed and direction, the rate of spread adjustment factor and the position of the ignition point. In order to restrict this analysis to a common fire lifetime period, we set a common simulation period of three days for all case studies.

Wind speed has a strong influence on fire spread and can be one of the most important factors shaping fires (Beer 1993). Changes in wind direction are also considered important because of its interaction with the topography, and also because this information may be used to define fire-fighting strategies. The rate of spread adjustment factor is usually defined empirically based on user's expertise and impacts on the simulated burnt area extent. Additionally, we also evaluated the impact of the uncertainty in the position of active fires within their footprint. The MODIS active fire product can identify a fire as small as 10% of the pixel's footprint, however the correct position of the actual fire within the latter is unknown. Thus, we varied the position of the ignition point in each quadrant of its footprint and varied its distance to the centroid in intervals of 20, 40, 60, 80 and 100% of the maximum distance between the centroid and the footprint's boundaries.

Table 2 shows the sensitivity analysis for the range of values of the selected variables/parameters. For each variable we performed 21 simulations, which resulted in a total of 672 simulations comprising the nine case study fire events. Within the simulations for each variable there is one that is the reference. In the case of the wind speed and direction reference values were those observed during the three-day simulation period. For the rate of spread adjustment factor the reference value is 1, meaning no adjustment. Active fires centroids were used as the ignition reference points.

Table 2. Variables used in sensitivity analysis, with respective interval unit change, with a total number of simulations of 21 each. Dmax is the maximum distance between a centroid of an active fire and its footprint borderline.

Variable	Interval range / (step)
Wind speed (km/h)	(-10; +10) / (1 km/h)
Wind direction (º)	(-50; +50) / (5º)
Rate of spread adjustment factor (adim.)	(0.25; 1.75) / (0.075)
Active fire position (% dmax, m)	(0; dmax) / (0.2)

Results and Discussion

3.1. Model performance

For each case study the fire event simulations performance was assessed using the Sørensen coefficient (Figure 2). Based on the coefficient values there is clear evidence that fire simulations are improved when they are coupled with active fires to reinitialize the simulations at each satellite aggregated overpass (with only one exception). These simulations had Sørensen coefficients above 0.5 (often higher than 0.6) indicating an accuracy improvement when compared with a full event simulation.

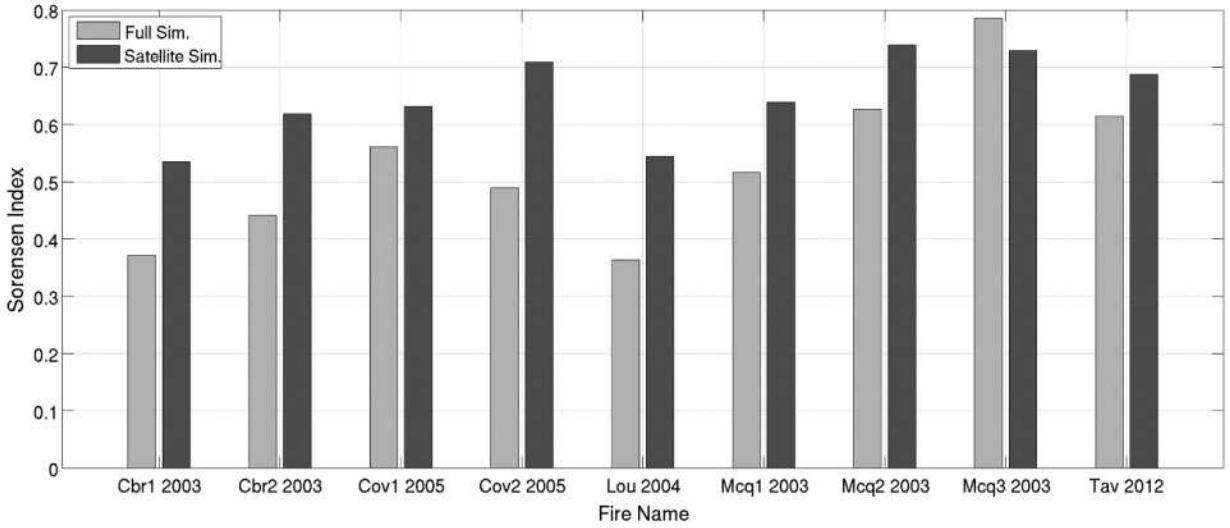

Figure 2. Assessment of the performance of the fire growth simulations using the Sørensen coefficient for: a) a full event lifetime simulation where the ignition points are derived from the first detected active fires satellite passage after the beginning of the event (grey bars); b) simulation of the fire event supported by the MODIS active fires satellite passages during the lifetime of the fire event (black bars).

Figure 3 shows the distribution of simulation accuracies along the duration of the fire events. Full simulations show that the error is almost always higher than the one derived from the satellite simulations and, propagates over time, with a maximum which is more than three times higher at 65% of the time of a fire event completed. The complex interactions between weather, fuels and topography are often difficult to reproduce with fire models producing inaccuracies on the fire spread that increase for long periods of simulations. Additionally, these errors have larger variance than the ones observed for the satellite simulations. Reinitializing simulations with the actual positions of the active fires reduces the propagation of these errors as well as its variability. For most of the time steps, the satellite-assisted simulations have a significantly lower error (around 1 km) than the full simulations.

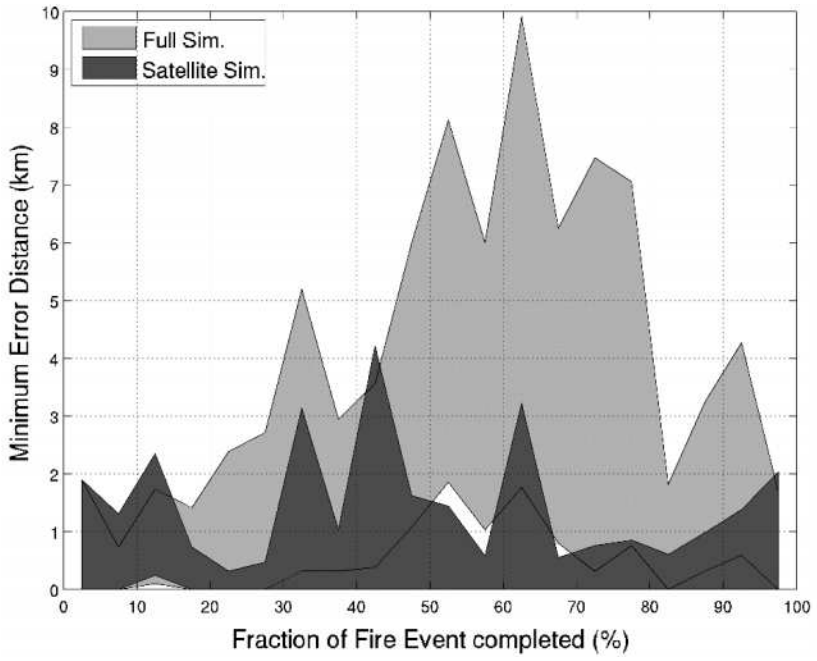

Figure 3. Interquartile range of the minimum error distance for the full and satellite simulations as a function of the fraction of the fire event completed.

Sensitivity analysis

Figure 4 shows the impact that wind speed and direction, rate of spread adjustment factor and the position of the ignition point have on the simulated burnt area (Figure 4, bottom left panel). As expected, wind speed has a large impact on the simulated burnt area extent. Positive wind speed increments produce more variation in the simulated burnt area extent than the negative increments. Two fire events cases are contributing to this wide variation: Lou 2004 and Mcq1 2003. The Loulé fire was more resilient to wind speed increments showing a simulated burnt area extent variation less than ~25% when compared with the simulation using the reference data. The reason for this may be the fact that prevailing wind speed during the simulation period was already quite high so additional increments did not have a significant impact on the new simulated burnt area extent (Figure 5). The length-to-breadth ratio of a fire increases with wind speed, implying that increasingly higher wind speeds will increase fire size at an increasingly lower rate (Alexander 1995). On the other hand, any small increase in wind speed in the Monchique1 fire event (which overall has a low length-to-breadth ratio) produced a large change on the burnt area extent because the reference wind speed values for this fire were low. Other reasons might be involved in the differences between fires, as fire spread rate as a non-linear function of wind speed varies with fuel characteristics (Rothermel 1972).

Changing the wind direction produces a lower extent of burnt area variations than introducing small changes on the wind speed (Figure 4, top right panel). The effect of wind direction increments over the variation of burnt area is more pronounced also on the Loulé fire event, but with an opposite response in terms of burnt area extent. This fire propagated under strong wind conditions with a prevailing direction (from North), thus any change from north to northeast direction will reduce the simulated burnt area extent. Negative increments (from north to northwest) have a smaller and positive effect on burnt area.

As expected, the impact of changing the rate of spread adjustment factor is also very high, with large positive values producing an increase in burnt area extent that can be four-fold larger than the no-adjustment reference value value (Figure 4, bottom left panel). Again, the Loulé fire showed more resilience in terms of burned area variation while CasteloBranco2 showed an opposite response. One explanation for this impact may be that ~40% of the fuels in this fire event are litter (NFFL fuel model 9) and they are concentrated around the area where the fire started. Fire propagation on this type of fuel bed is high and, increases in both wind speed and spread of rate, largely promote the increase in the simulated burnt area extent.

Another source of variation on fire growth simulations evaluated here is the location of the ignition point inside the footprint of MODIS active fire. Sensitivity analysis on this variable (Figure 4, bottom right panel) shows that increasing the distance of the ignition point from the centroid increases the variability on the output simulated burnt area extent. Several factors affect this measure namely the vegetation fuel map where the ignition point is located.

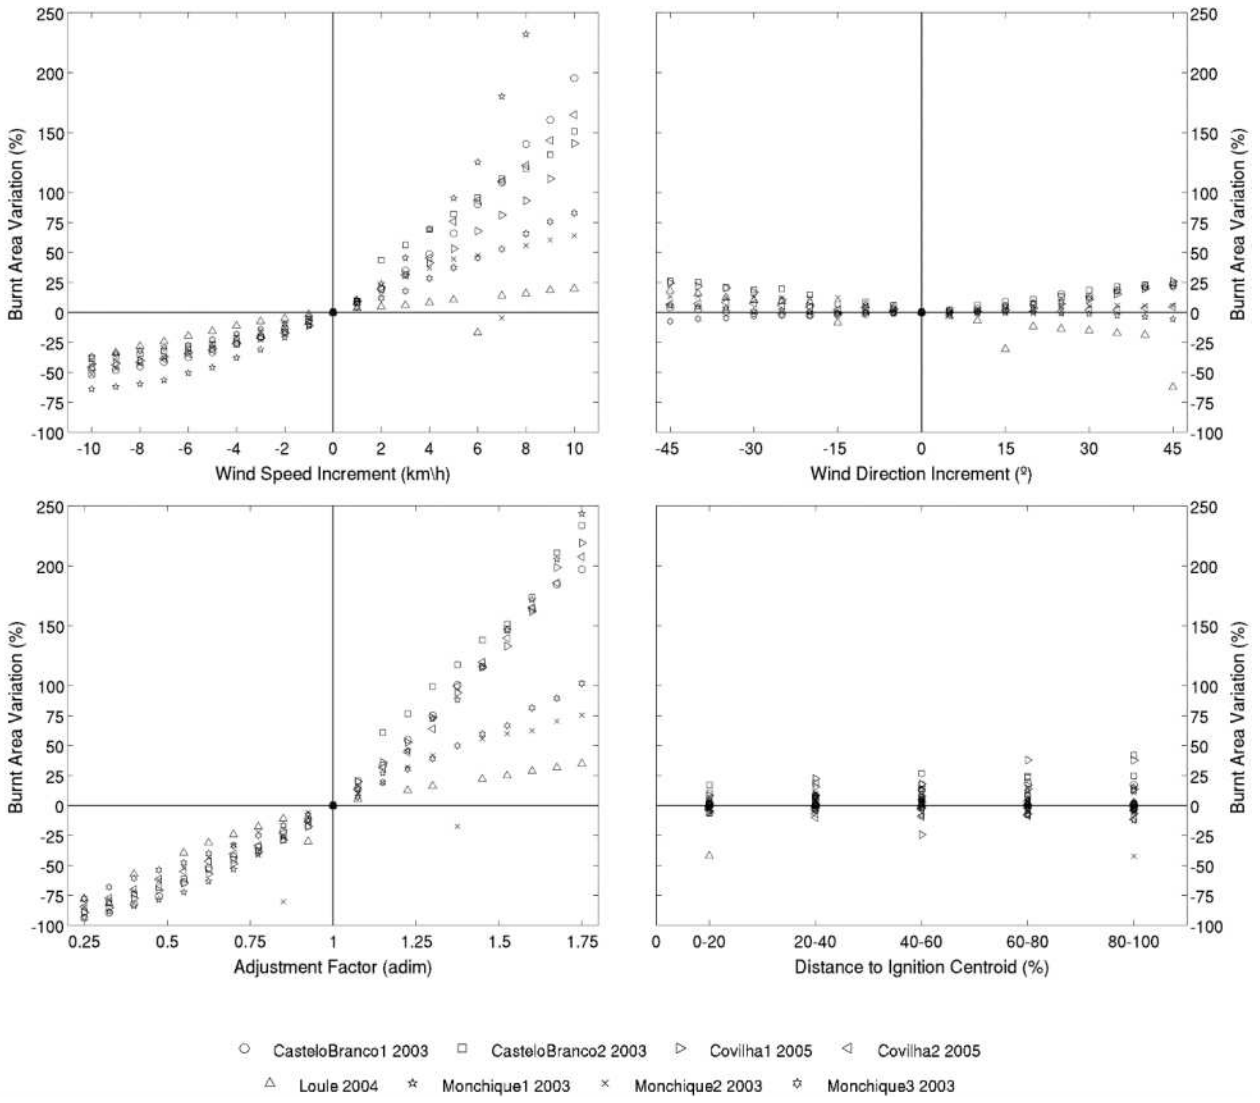

Figure 4. Sensitivity analysis for the wind speed and direction, rate of spread adjustment factor and distance to the ignition centroid variables. Analysis was based on the variation of the burnt area extent derived from introducing small increments of each variable and comparing it with the simulation derived using the corresponding variable reference values.

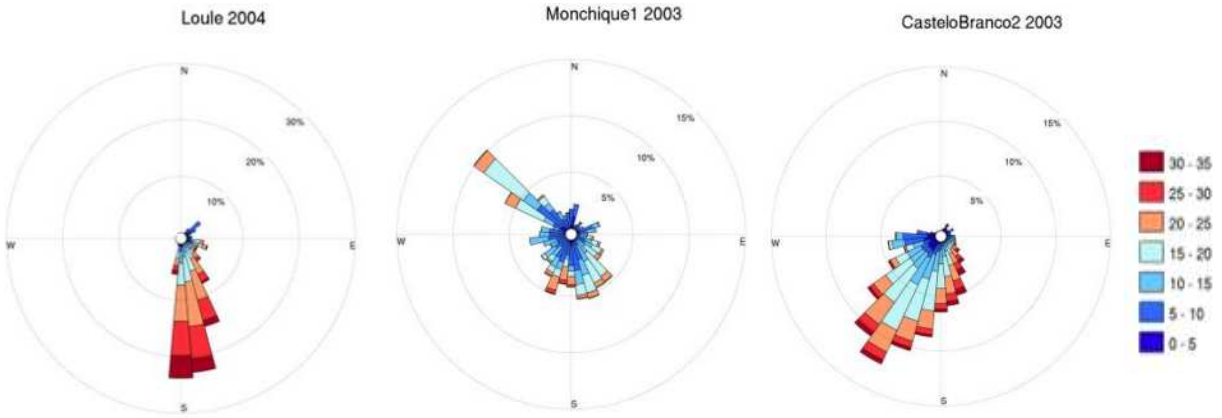

Figure 5. Wind speed (km/h) and direction (º)for the Loulé2004, Monchique1 and CasteloBranco2 fire events for the entire 3-day fire simulation period.

Conclusions

Fire-spread simulations can be improved using MODIS active fires satellite data for monitoring large and long duration wildfires. Estimated burnt area extent derived from fire growth simulations reinitialized with MODIS active fires detected at each overpass showed an improvement when compared with the single ignition point simulation for the entire fire duration.
We evaluated the impact of wind speed and direction, rate of spread adjustment factor and ignition point position, given the potential effect these variables have on fire propagation. As expected, small changes on the wind speed and on the rate of spread adjustment factor had a large impact on the simulated burnt area extent. This response enhances the importance of having accurate information on the wind variable when using fire spread models either for studying past fire events or for fire spread modelling in an operational context.
This innovative approach of combining satellite active fires data with fire spread simulations minimized the observed propagation error through the single fire event simulation. This improvement arises from reinitializing fire-spread simulations for each satellite aggregated overpass with updated maps of fire location for the next simulation.
Attempts to integrate fuel and weather data inaccuracies on the simulations may also improve the fire spread and behaviour simulations.
Future work will encompass uncertainties in fire spread and behaviour simulations using custom fuel models derived from other fuel classification systems (e.g.,Fernandes *et al*. 2009, Scott and Burgan 2005), changing some of its most influential parameters, namely live fuel moisture contents, weather-dependent variables, and stand level variables derived from the Portuguese National Forest Inventory. This information will be integrated in this innovative combination of fire spread and behaviour simulations assisted by MODIS active fires, in order to have a tool that will support decisions in a fire-fighting operational context.

Abstract
Wildfires cause irreversible damage to the environment, whether in the flora, fauna, people and large economic losses. Knowing the profile of forest fires, traced through different variables, it is essential to have guidelines to establish polices for protection planning. The statistics of occurrences are the main tools to know the profile of fires to planning the prevention and to control more efficiently, reducing costs, time and fight risk. This study used the coordinates of each of the 3,754 occurrences in the city of Juiz de Fora, MG, Brazil, for the period 01/01/2002 to 12/31/2011. The land aspect, the shape and the slope land of each event was determined in order to analyze the influence of the relief on the number of fire occurrence. According to the results, the relief influences directly the occurrence and fire spread. The northern aspect with greater slope and forms that facilitate the flow of water had a higher number of cases. The influence of relief is also confirmed by the relationship between wind direction and occurrences. Land exposures that directly receive the daily prevailing winds have a higher probability of occurrence of fire.

Keywords*: Relief, Fire, Susceptibility*

Introduction

The fires in vegetation are directly responsible, not only for environmental damage, but also economic and social losses whose dimensions often reach invaluable levels (Vosgerau *et al*., 2006).
There are two types of factors that determine the degree of fire danger: the constant factors, represented by the fuel type, which involves different types of vegetation and topography; and variable factors, represented by atmospheric conditions (Torres *et al*., 2011). Besides the listed factors it includes the land use and occupation.
The topography, according to Batista (2000), influences the climate and determines the type of fuel. Considering that fire behaviour is largely the result of the climate and fuel available, it can be said that the topography indirectly influence on the behaviour of the fire and the flames directly by the greater proximity the higher slope. So, we conclude that the relief is fundamental in establishing prevention and control plans.
To preserve the environment from the harmful effects of fires, it is essential that protectionist policies be appropriate to the characteristics of each region. It is necessary to know when and why the events occur. The statistics of occurrence are the main tools to trace its profile. With these data, the control can be planned more efficiently. The lack of this information can underestimate or overestimate the expenses relating to the protection of the environment, endangering the survival of forests and fighters (Santos, Soares and Batista, 2006). According to Vosgerau *et al*. (2006) in Brazil, there is a lack of effective plans for prevention and control. These plans can only be organized and put into practice by evaluating information to report precisely the characteristics of the occurrences of fires
To prioritize areas of greatest risk with intensive programs of protection and structure services of fire fight, in economically feasible limits, it is important to know the locations and the cause of occurrences and the factors of spread. Knowing the factors that contribute to the higher incidence of fire, it may

concentrate efforts and resources to fight it, because these systems are relatively expensive and would be impossible to keep them continuously in all locations.
The aim of this study was to analyse the influence of relief, such as the Sun aspect, The shape of the slopes, the inclination and its position in relation to the prevailing winds, on the occurrence of vegetation fires in the city of Juiz de Fora, Minas Gerais State, Brazil in order to trace the events, giving to the government tools to improve the prevention and fight policies.

Methods

The municipality of Juiz de Fora, with a population of 516,247 inhabitants (IBGE, 2010) and coordinates 21° 41' 20"S and 43° 20' 40"W, is located in the southeastern state of Minas Gerais, (Figure 1).,

Figure 1. Location of the study area

The area is extremely mountainous, reaching 1,000 meters of altitude at the highest point and 670-750 m in the valley bottom. The urban area falls entirely on the middle reaches of the Paraibuna River belonging to the Paraíba do Sul river basin (PJF, 1996).
The relief patterns show a strong tendency to a structural orientation. Their lithologies are characterized by having coverages of thick soils and rock exposures, mainly in the areas of occurrence of charnockitic rocks, to south of the city. In general geomorphological features tend to a convexity of slopes from the top, together with the formation of large number of amphitheatres and plains. The central core of the city, taking advantage of this natural condition, lodged in the enlarged section of the Paraibuna river valley, strangled by a sturdy bar, downstream (PJF, 1996).
The data of fires occurrences in vegetation were obtained in the 4th Battalion of Military Firefighters (4th BBM). We use 3,754 fire occurrences taking the nature, date, time and address for the period 01/01/2002 to 31/12/2011, within the urban area.
All places of occurrences were geocoded and tabulated. The exposures were grouped into strands North (315° to 45°), East (45° to 135°), South (135° to 225°) and West (225° to 315°), by using a compass. The shapes were got by visual interpretation, classified in concave and convex rectilinear. The slopes classes was determined with the Abney clinometer and grouped into classes from 0° to 10°, 10° to 20°, 20° to 30°, 30° to 40° and > 40°.

The preferred directions of the winds were recorded in Principal Climatological Station, located at the Federal University of Juiz de Fora (UFJF). Data were collected at 9:00, 15:00 and 21:00 UTC. From the readings of the three times, the preferred direction for each day of the series divided into North, Northeast, Northwest, West, East, South, Southeast and Southwest was determined.

Results and Discussion

Figure 2 shows that there was a significant influence of exposure of the slopes on events where most of the fires occurred in North aspect (N) followed by the West aspect (W), East aspect (E) and the lowest on the South aspect (S).

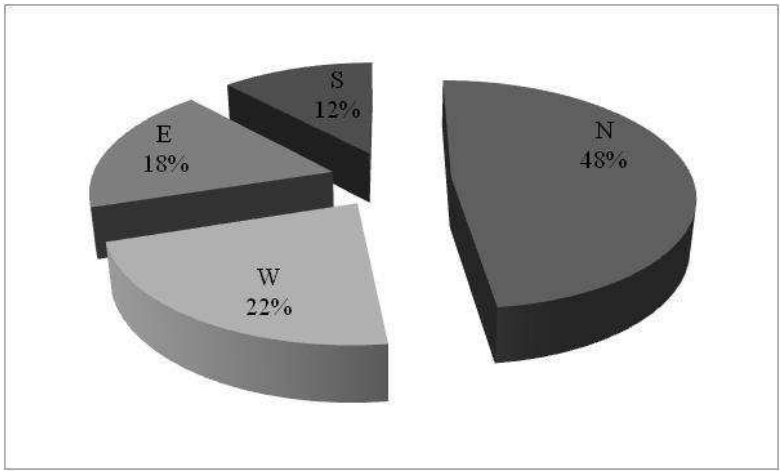

Figure 2. Occurrences of fires in agreement with the exhibition of the slope

This distribution is due to the fact that surfaces with different orientations and inclinations receive different amounts of solar radiation compared to a flat surface, in the same location and time of year (Torres & Machado, 2011). The Sun culminates at zenith (representing greater energy gain) in places whose latitude is equal to the tilt of Earth's axis. Thus, the equinoxes (March 21 and September 23) the Sun culminates at zenith over the equator, with these dates, in all places on Earth , days and nights of equal length. At the Summer Solstice in the South and Winter Solstice in the Northern Hemisphere (December 22), the Sun culminates at zenith for latitude 23° 27' (South), because this is the greatest declination reached the southern hemisphere, this latitude is called the Tropic of Capricorn. On June 21 the Sun culminates at the zenith to 23° 27' (North) latitude that defines the position of the Tropic of Cancer, has thus the Summer Solstice in the Northern Hemisphere and Winter Solstice in the Southern Hemisphere for the higher latitudes 23° 27' the sun does not culminate on zenith on any day of the year.

We observe, therefore, that the sun for much of the year culminates in Zenith north of the city of Juiz de Fora, located at latitude 21° 41' 20" S. This factor tends to raise the temperature in the areas of North orientation directly influencing the physical characteristics of fuel and fire occurrences.

The difference between the West and te East aspect can be explained by the hour of greatest concentration of occurrences (between 15 and 16 hours), during this time the slope the West aspect is getting greater amount of solar energy relative than East aspect, increasing the percentage of occurrences. Another factor is the West aspect receives more energy in the afternoon when the earth's surface and the air are already heated and usually there is no fog. Beside these, the East aspect get humid winds from the Atlantic Ocean, distant, straight, about 150 km from the city.

Hugget (1995) points out that in the southern hemisphere, oriented north slopes receive more insolation than facing the South, which, in turn, receive higher rainfall due to moisture-laden winds from the sea (SW, S and SE). Oliveira *et al*. (1995) found significant differences in the two approaches

with respect to parameters such as temperature, precipitation and humidity. According to these authors, the South aspect has leaf litter on average 41.9% more humid than those toward the North. The authors also claim that the loss of this moisture also occurs much faster on North aspect, because the South one retains moisture 1.6 times more. Consequently soil moisture behaves the same way, only varying according to the type of associated vegetation.

This moisture variation is reflected primarily due to different rates of temperature of these two types of aspects, since the North are significantly warmer due to higher incidence of heat that turned to the South, with 98% occurrence of maximum temperatures on those aspects. The minimum temperature also occurred mostly in the northern aspect (86 %), which should be attributed to higher relative humidity in the South, over the longer period of deposition of dew that acts as a "buffer" effect reducing extreme temperatures (Oliveira *et al*., 1995).

At low relative humidity, the probability of occurrence and spread of fire is greater in view of the direct correlation with the drying of the fuel. The thinnest material, represented by one of time lag of an hour, according the Brown (1982) classification is present in greater quantities and in most environments. In critical weather situations, this material comes to lose up to 66 % humidity in the range of an hour, leading the fuel moisture below the extinction moisture.

According to Nunes (2005) this is due to atmospheric humidity have a direct effect on the flammability of fuels, with a constant moisture exchange between the atmosphere and plant dead. The dry material in a humid atmosphere absorbs water and releases water when the air is dry. The amount of moisture that dead material can absorb or release depends on the relative humidity. During extremely dry periods, moisture may even affect the moisture content of dead or live material.

Furthermore, there are internal variations within geomorphological character that individualize the slopes more or less favorable to the fire occurrence. These are geometric segments which are presented in three main forms: concave, convex and straight. The concave shapes are characterized as areas of convergence of flow and consequently a higher concentration of moisture, while the convex and straight (on slopes) influence the formation of zones of divergence of water and low moisture content and thus more susceptible to the fire occurrence (Coura, Souza & Fernandes, 2009).

This influence is confirmed by the results of the study (Figure 3), showing the largest number of occurrences and the convex rectilinear strands in relation to concave.

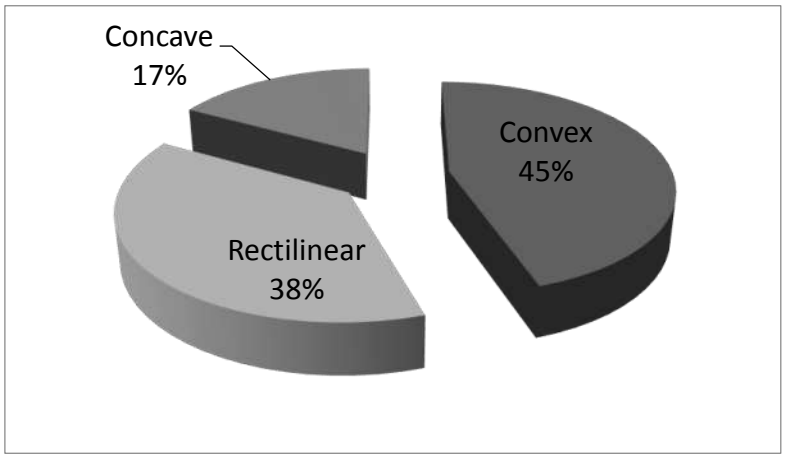

Figure 3. Fire according to the shape of the slope

Regarding the slope, the data point to the following results (Figure 4), confirming that greater when the slope the greater the percentage of occurrences.

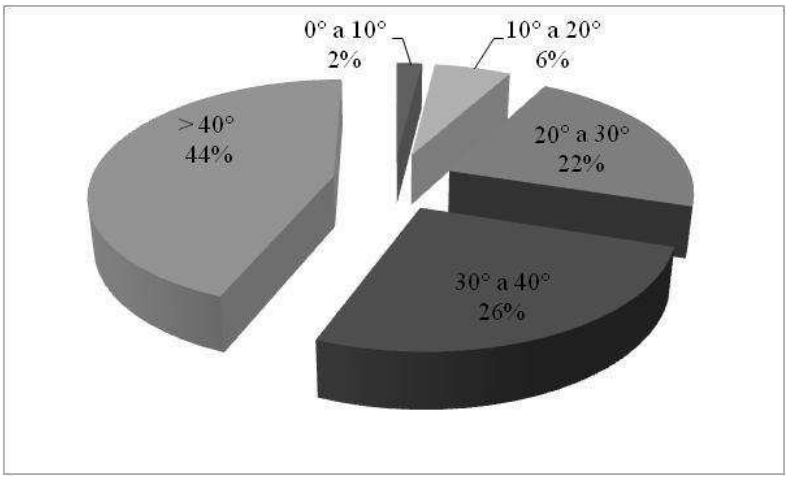

Figure 4. Fires according to the slope

The influence of slope can be explained due to the humidity, according Valeriano (2008), on steeper slopes, it can realize easily that rainwater flows very quickly, seeping in smaller quantities, making it the driest place.

Besides the interference of inclination in water flow, Viegas (2004) explains that the spread of fire in places with some slope is distinct from behavior that occurs in areas without slope, due the effect of additional factors such as convection and radiation. If there are minimum declivity, the rate of spread tends to grow and will be greater the larger the microclimatic changes in the combustion zone. This fact is also confirmed by Ribeiro *et al*. (2008) when they argue that the intensity of the fire in the areas of acclivity is greater due to overheating of fuel above the front of the fire line, the flames closer when compared to flat terrain. On the other hand, the wind tends to help as much on the drying of the fuel material as the spread of fire.

The wind is a major factor in the combustion rate and spread of the fire like described by Torres *et al*. (2011) in addition to affecting the rate of oxygen supply during the burning. The drying of the fuel is accelerated by the removal of the air layer in contact with the surface and induce the tilt of the flames, approaching those of the material not yet burnt and hastening the preheating stage.

The data (Table 1) show the relation between the wind direction and the occurrences of fires. Slopes to windward of the preferred daily winds have higher numbers of occurrences of fires. When the preferred wind direction is north, there is a predominance of fires in windswept strand with the same direction 71 % of the occurrences. When the wind direction is north-west, 87 % of the occurrences are located on slopes facing N and W; when the direction is north-east there is a greater number of occurrences in the areas N and E with 81 % of fires in these respects; with the wind direction West, 77 % of cases occur in the present toward the W; the preferred direction of the wind when it favours eastern occurrences hillsides N and E. This influence can be best observed when the winds are predominant directed in the southern quarter (SW, S , SE), where there is a superiority of occurrences in the southern side, countering the dominance of events that occurs in slopes with further guidance. When the situation is calm (C) without occurrence of winds, the situation normalizes in relation to the order observed in Figure 2 with higher occurrences in the present N, then the slopes neatly Exposure W, E and S.

Table 1. Percentage of occurrences according to the location of the fire and the wind direction

Slope occurrence	Wind direction								
	N	**NW**	**NE**	**W**	**E**	**SW**	**SE**	**S**	**C**
North (N)	71%	44%	54%	23%	40%	22%	28%	33%	65%
West (W)	15%	43%	15%	77%	25%	41%	12%	23%	26%
East (E)	10%	8%	27%	0%	29%	9%	29%	8%	6%
South (S)	4%	5%	4%	0%	6%	28%	31%	36%	3%
% of days with prevailing wind	20%	11%	19%	1%	11%	5%	15%	14%	4%

In summary, when the wind direction is the same as the orientation of the slope, there is the named "wind up the hill" in this situation the wind accelerates the spread of fire, whereas it tends to raise the flames of bottoms for higher still unburned.

Conclusion

The results of this study allow us to conclude that:

- the land aspect has a direct correlation on the fires occurrences;
- the North aspect have a higher percentage of occurrences for receiving greater amount of solar energy during the year;
- the west aspect were in second place with more fire occurrences, which can be explained by the time in which they receive higher solar radiation that coincides with the time of lower humidity;
- the slopes to windward of the preferred daily winds are more susceptible to the occurrence;
- those aspects that favour the spread of water tend to have higher number of occurrences;
- the higher the slope the greater the number of events;
- the strategies to prevent fires must take into account the influences of topography and the prevailing winds through preventative in areas more conducive to the event work. Also the fight actions must take into account such information, reducing the costs and risks of operations.

Abstract

In 1998, the indiscriminate use of fire to manage agricultural and forest areas in favourable weather conditions in the state of Roraima resulted in one of the largest forest fires in the modern era, which was immensely aggravated by the lack of preparation of public institutions that are responsible for fire prevention and protection.

This event, however, left important lessons and prompted the establishment of new forest fire fighting and prevention policies across Brazil. Fifteen years later, Operation Roraima Green 2013 adopted a new fire prevention and fighting model based on concepts, methods and routines of "Integrated and integral forest fire management". Joint coordination was established to constitute the Integrated Multi-Agency Operational Coordination Centre (*Centro Integrado Multi Agências de Coordenação Operacional*) - CIMAN Federal - with a situation room to monitor high fire-risk forest areas, namely protected federal, state and municipal zones, public forests and forest areas of national interest. Greater emphasis was placed on the detection of hotspots by means of remote sensing, warning and quick initial attack on behalf of response bodies, in accordance with priorities established by all the involved entities and institutions.

A Unified Command Unit was constituted to establish priorities for forest fire fighting and prevention activities based on the doctrine of the Incidents Command System - SCI.

Key challenges of integral management were:

1 – Forecasting risk situations;
2 – Fire prevention actions and control of intentional forest burning;
3 – Fire fighting preparation;
4 – Forest fire fighting;
5 – Civil and criminal accountability of offenders;
6- Recovery and reconstitution of affected areas.

The Centre also promoted intense flow of information on implemented actions, which allowed perfect integration between the involved institutions.

Keywords*: Integrated management, Comprehensive management, Prevention, Combat, Accountability*

Introduction

The Climate Report Data, prepared by the Amazon Protection System - Sipam for the period of September, October and November/2012, indicated that during the quarter the coastline of eastern Amazonia was under the influence of a subsidence branch, with short rains in region increasing temperatures. The fallout would be below the climatological patterns, particularly the south-central Amapá, Pará northeast, northwest of Maranhão, Tocantins and Amazonas northern, and **Roraima** south.

These data also indicated a probable **occurrence of *El Niño,*** where its effects enhance normal climate, i.e., change the dry period of the state of Roraima which tends to have a more severe and prolonged summer (drought), with rising temperatures, gusty winds and consequently low relative humidity, favoring the spread of flame in case of wildfires.

At the request of the Environmental Protection Director -Dipro/IBAMA a **Special Report** was drafted by the Operating Technical Center of Manaus / Meteorology Division DivMet-CTO/MN/Sipam for **Roraima** where the study indicated the following prognosis: ***"Precipitation below the climatological patterns, especially at the beginning of the quarter, however the maximum and minimum temperatures may be slightly (about 1-2 ° C) above their climatological values."***

Later the Prevention and Environmental Monitoring Division of Femarh located in Roraima, based on the Climate Report of the Amazon under No. 97, Year 9, prepared by the Amazon-Sipam Protection System with forecasts for December 2012, January and February 2013, noted that the state of Roraima would present precipitation from normal to below the climatological pattern, the temperatures being normal and above the climatological pattern.

Based on climatological information, the Director of Environmental Protection - Dipro / IBAMA decided to conduct an operation targeting preventive actions to protect federal and / or public interest areas in the state of Roraima.

With the assigned mission, the operation was based on the applicable legislation: Article 18 of Decree No. 2.661, of July 8th, 1998, Complementary Law No. of December 8th, 2011, Law No. 12.651, of May 25th, 2012, Law No. 12.727, of October 17th, 2012, MMA Ordinance No. 94 of March 19th , 2012, and we found that with the current legal basis we had to establish a relationship among the federal institutions.

On November 26th the shared planning proposal was submitted following the model of multi-agency Integrated Centers of Operational Coordination - CIMAN's deployed statewide in 2009, 2010 and nationally in 2010.

The proposal was to establish a Joint Coordination, the multi-agency Federal Integrated Operational Coordination Center - **CIMAN RR / Federal,** where a situation room was established. Such structure was conditional on the formation of a unified command that uses the doctrine of the Incident Command System - ICS.

The operating period from December 1st, 2012 to March 31st, 2013 was set, therefore the data used for comparisons of hotspots, combat, visits, burning and supervision observe this period of work.

2. Integrated Multi-Agency Center - CIMAN RR / Federal

The purpose of CIMAN RR / Federal within the 2013 Green Roraima Operation was to enhance the actions of the federal institutions involved, optimize the human and material resources looking for integrated and comprehensive management in preventing and fighting wildfires where the challenge was to predict risk situations, propose and implement preventive actions, prepare institutions for firefighting, hold offenders accountable and finally reconstruct areas affected by the fires.

CIMAN also installed a unique situation room and therein shared information about ongoing operations as well as search for joint solutions among participating entities. The results of actions undertaken were evaluated, seeking to optimize the strategies adopted. In every meeting an Integrated

Action Plan – PAI was prepared, which contains, among other directives, the specific objectives for the operational period, pointing to each institution involved the requested activities, as well as actions already implemented.
Throughout the period 17 meetings of CIMAN RR / Federal were held, 02 Non-Face-To-Face and 15 Face-To-Face meetings; with the presence of 14 federal agencies, plus the participation of a member of the State Committee for Prevention and Control of Wildfires, and the support of the Fire Brigade of the Federal District (CBMDF), constituting the integrated management of wildfires in Roraima (table 1).

The Integrated Center meetings were held every Wednesdays, always at 10am maintaining a routine with the opening followed by a brief introduction of the participants, the agenda exposed forecasts prepared by SIPAM, after which an analysis was made of hotspots of the operational period and the previous day. When we did not have a GIS specialist present at the meeting we made the analysis directly on the official monitoring of federal areas, an INPE website especially developed for the Green Roraima Operation, and at the end we updated and signed the PAI.
In the second half of January we had additional support with the arrival of technicians from the Brazilian Environmental Protection Agency (IBAMA) and the Fire Brigade of the Federal District - CBMDF in the operation to assist in the logistics and implementation of the Incident Command System- ICS. Thus the logistics establishing physical structure plus the ICS, which assigns concepts of command and control, with the GIS support, established a Situation Room idealized since December 2012 as follows in the chart below (Figure 1).

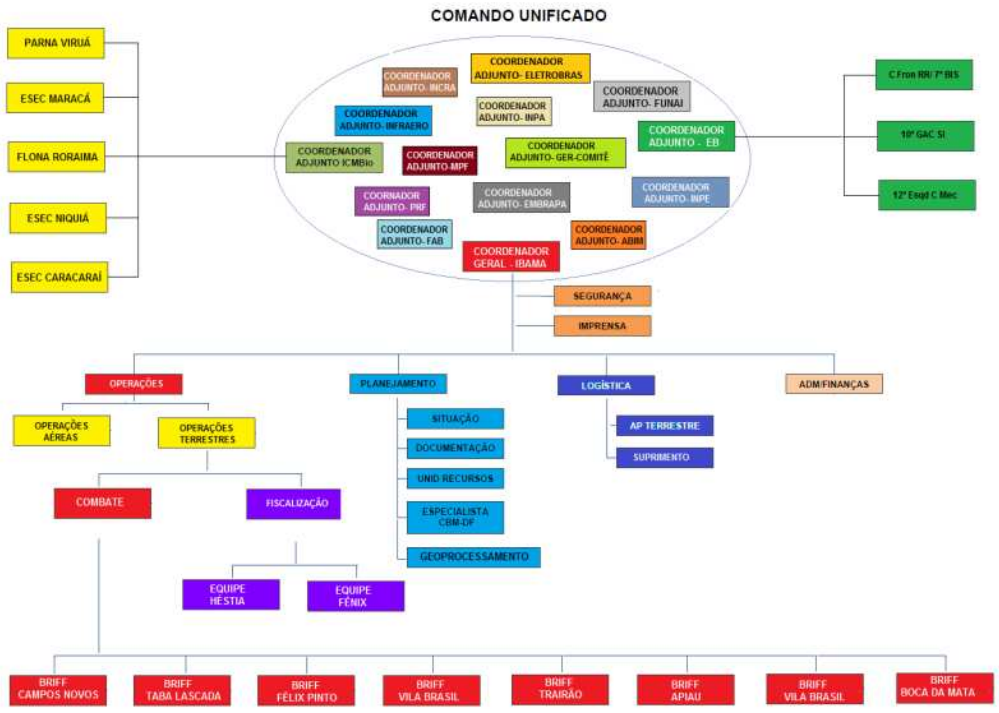

Figure 1. Chart of CIMAN RR / 2013 Federal. Green Roraima Operation. Source: CIMAN RR / Federal.

Remember that the participation of the institutions in this plan was voluntary and did not involve any transfer of funds, where each institution had contributions of capital already budgeted for the implementation of its final activities.

A logo was also created referring to the operation, inspired in similar events, keeping the brand already registered in other Brazilian states (Figure 2).

Figure 2. Logo of CIMAN RR / Federal. Source: CIMAN RR / Federal.

In the situation room the risk areas susceptible to deforestation when associated with burning and wildfires, the federal protected areas, forests and other public areas of security, economic and social interest were monitored, such as federal highways, GURI transmission lines and airfields. Emphasis was given on detection of hotspots, warning to quick initial attack by the response agencies, according to the priorities established by the agencies, institutions and organizations involved. For illustrative

purposes, find below pictures of the situation room assembled in the Supervisory Board of IBAMA in Roraima. The pictures were captured from the four corners of the room, with an emphasis on the meeting table (Figure 3).

Figure 3. Situation Room CIMAN RR / Federal - SUPES / IBAMA / RR. 2013 Green Roraima Operation. Source: CIMAN RR / Federal.

CIMAN RR also had a mission to find mechanisms to predict risk situations and provide information to participating agencies and maintain the situation room provided with information.
CIMAN RR initiated the monitoring of hotspots in the conventional manner, i.e., used a GIS Specialist who intersected the hotspots overlapped in the features of protected areas, indigenous lands, right of way, easement strips, military areas, rural settlements, border areas and aerodromes (Table 2).

Table 2. Areas monitored by CIMAN RR / Federal on the INPE website. 2013 Green Roraima Operation. Source: CIMAN RR / Federal.

Monitored Features	Responsible Agency	Monitored Areas
Overview	IBAMA	Throughout the State of Roraima
Federal protected areas	ICMBio	1,615,971 ha
State protected areas	Femarh	Not available
Indigenous lands	FUNAI	10,331,521.34149 ha
Federal highways	DPRF	1404 km
Aerodromes (Boa Vista, Caracaraí and Pacaraima)	Brazilian Airport Authority (INFRAERO)	Radius of 6 km from the center point of the aerodrome
GURI Transmission line	Eletronorte	190 km
Federal Settlements	INCRA	1,371,856 ha
Military areas	Army	279 421 hectares
Border area	Vice Consul of Brazil in Venezuela	954 km border

The daily monitoring has been replaced by the Special Report for Roraima developed by INPE. The report for the monitoring of outbreaks of fires in Green Roraima Operation presents all outbreaks detected by all satellites (blank) used in the monitoring of fires by **INPE,** in a radius of up to 400 kilometers (per 100 km) around the airport Boa Vista - Roraima. The figure also showed the Points of Attention representing significant persistent fires over the last 24 hours (yellow dots); 48 hours (orange dots) and 72 hours (red dots). Moreover, the red areas are the indigenous territories, the green areas are the state protected areas and the dark green areas are the federal protected areas (figure 4).

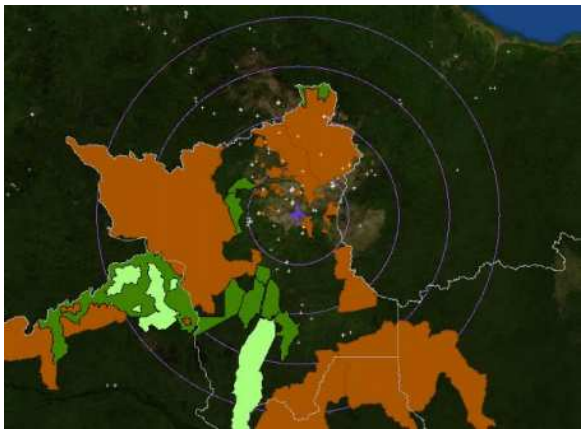

Figure 4. Active fire outbreaks detected by the monitoring satellites - Overview. Source: INPE.
http://peassaba.cptec.inpe.br/queimadas/boletim_roraima/

The monitoring exposes a list of fires presented according to an index that combines the duration and extent of events detected by the nine satellites currently used by the INPE monitoring system.
All the features of interest were also monitored individually and automatically, and when some hotspot is registered in these areas the information was passed along by email to the Situation Room and the agency responsible for the area.
In the figure below, from the top left to the bottom right corner, pictures of the monitoring of federal protected areas administered by ICMBio, Indigenous Lands managed by FUNAI, the easement of Guri line maintained by ELETRONORTE settlements promoted by INCRA , federal highways policed by DPRF, border areas where the Brazilian Consulate in Helena and Venezuela was reported (Figure 5).

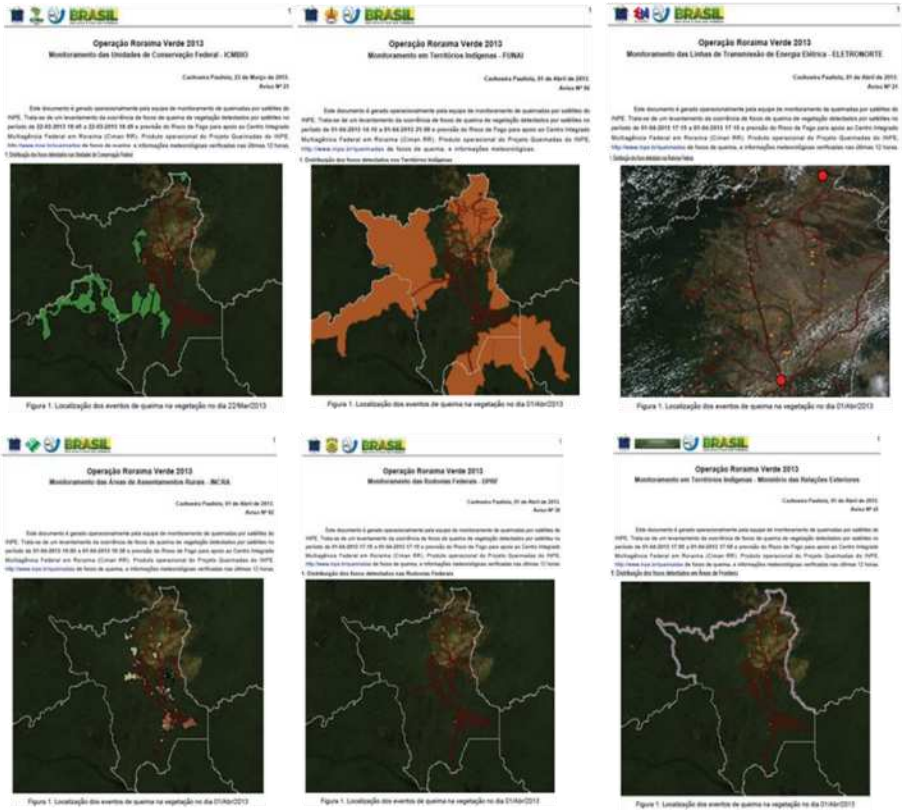

Figure 5. Features monitored by satellites. Source: INPE

The documents were generated operationally by the team of fire monitoring by satellites of INPE. The survey of outbreaks of wildfire outbreaks detected by satellites in the period and the prediction of fire risk for support to CIMAN RR.

Climatology, Forecasting risk situations

Climatological Report is a product based on data from INPE (National Institute for Space Research), INMET (National Institute of Meteorology) and SIPAM (Amazon Protection System), which presents the systematization of meteorological information related to spatial and temporal coverage of Roraima in the quarter January-February-March 2013 and it has strong application in the planning and operation of public services, among others. The information contained herein represents the assessment, treatment and secure dissemination of data, usefully contributing to the expansion of knowledge and the direction of public policy.

The average behavior of the oceans during the month of January is shown in Figure 6. The Pacific Basin was marked by the predominance of colder water (negative anomalies) of sea surface temperature (SST), especially in the equatorial zone comprising the *Niño* region. On the west coast of South America, there was expansion of surface waters with negative anomalies (colder than average) extending from the *Niño* 1 +2 region towards the region of *Niño* 3.

In the Tropical Atlantic Ocean there was a decrease in the area with warm anomalies in the northern tropical basin, while isolated areas of south tropical basin had a water colder than average. In the South Atlantic region there is a predominance of Negative SST anomalies, which created favorable conditions for the cold front in the southeastern of Brazil, resulting in precipitation.

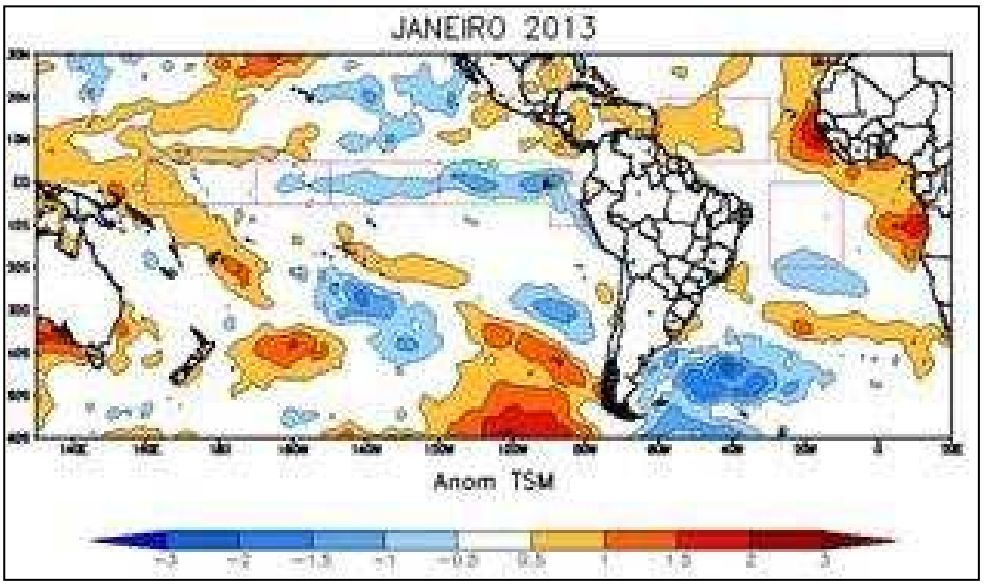

Figure 6. SST anomalies (° C) in January 2013.Rectangles in the Pacific represent areas of Niño 1 +2 (red), Niño 3 (green), 3.4 (dashed red) and Niño 4 (blue). Source: Data from CPC/NCEP processed by SIPAM.

During the month of January 2013, the Convergence Zone of the South Atlantic (SACZ) operated in the region resulting in very irregular spatial distribution of precipitation in the rest of the country, but in Roraima this system does not contribute to accumulated rain, particularly in the northeast sector of the State. ZCAS is a weather system characterized by a region of moisture convergence oriented from northwest to southeast, forming a deep band of cloudiness able to generate abundant precipitation. So in January, low precipitation was recorded across the state of Roraima as in figure 7.

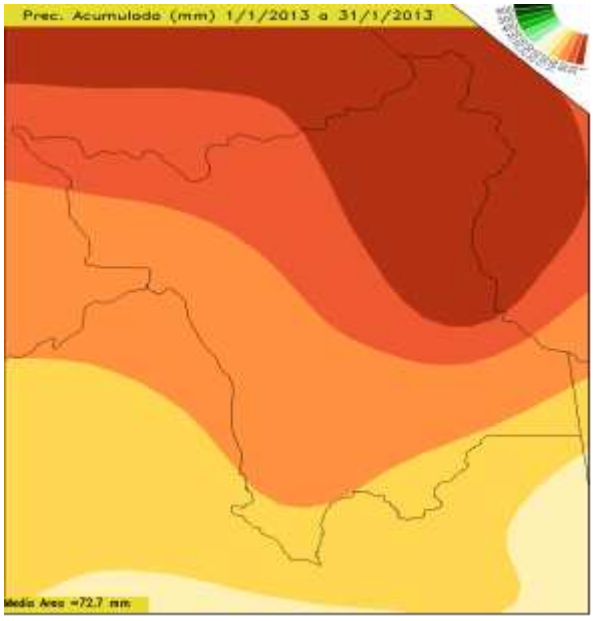

Figure 7. Precipitation recorded in January 2013 in the State of Roraima. Source: INPE.

Such low accumulated precipitation in January, or absence thereof, in some cases, contributed significantly to the increase in fire outbreaks in Roraima, as per the histogram below (Table 3).

Table 3. Histogram of fire outbreaks in the state of Roraima. Listing only of the states municipalities with occurrence of outbreaks in January 2013. Source: INPE.

(14) São Luiz / RR	*(3)*
(15) Mucajaí / RR	*(1)*

In February 2013, the average behavior of the ocean is shown in Figure 08. The Pacific Basin was marked by the predominance of colder water (negative anomalies) of sea surface temperature (SST), especially in equatorial regions comprising *Niño*. On the west coast of South America, there was

expansion of surface waters with positive anomalies (warmer than average) in the entire length of the Chilean coast.

In the Tropical Atlantic Ocean there was a decrease in the area with warm anomalies in the northern tropical basin. While in the southern tropical basin there was predominantly standard of neutrality, except on the African coast where surface waters were warmer than average. In the South Atlantic region negative SST anomalies remained predominantly. The performance of the Alta da Bolívia together with the cooling in the Pacific Ocean intensified convection in western Amazonia and the ITCZ activity (Figure 8).

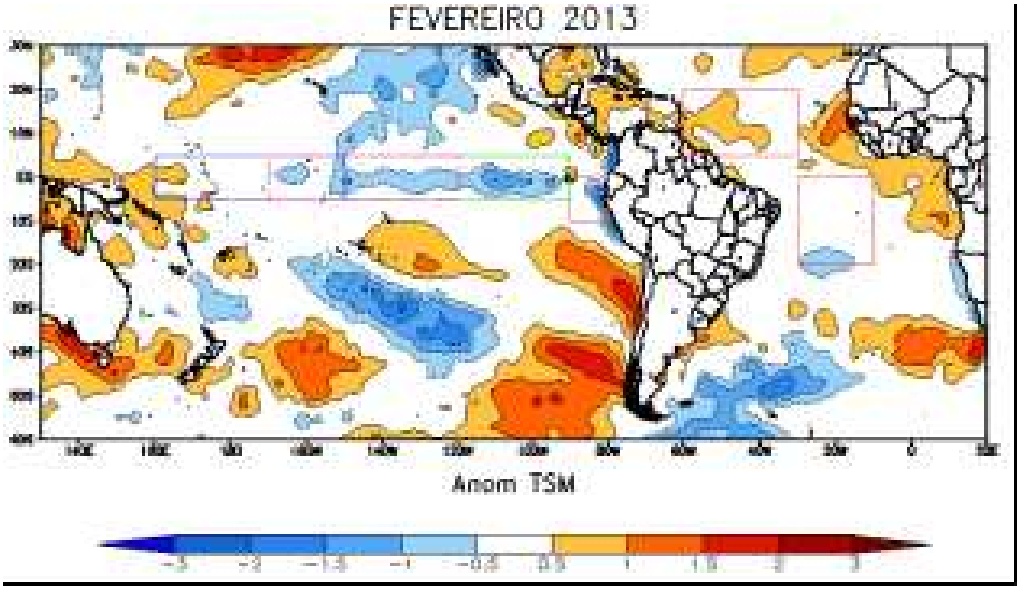

Figure 8. SST anomalies (° C) in February 2013. Rectangles in the Pacific Ocean represent areas of Niño 1 +2 (red), Niño 3 (green), 3.4 (dashed red) and Niño 4 (blue). Source: Data from CPC / NCEP processed by SIPAM.

Figure 09 shows the Accumulated Precipitation during the month of February 2013. The performance of the Intertropical Convergence Zone (ITCZ) in the region caused great irregularity in the spatial distribution of precipitation. The ITCZ is a weather system formed by clusters of clouds of great vertical development with the potential to cause large volumes of rain. The most northerly position of the ITCZ and warming in the tropical north Atlantic basin, which contributed to an increase in the transport of moisture from the ocean toward the continent, were primarily responsible for the emergence of positive anomalies over the state of Roraima.

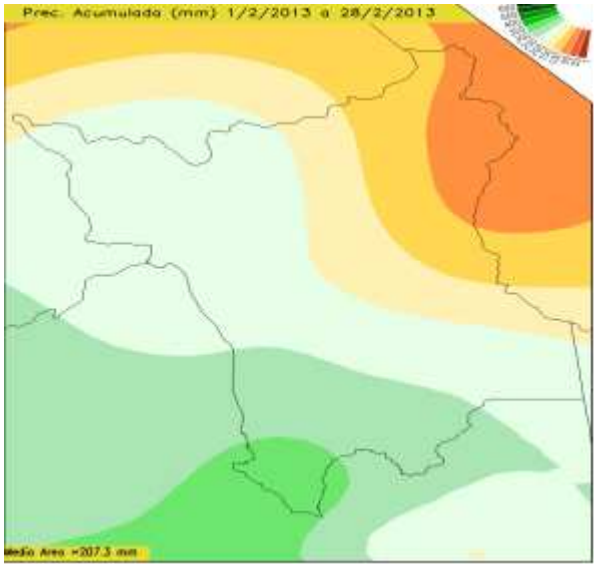

Figure 9. Accumulated Precipitation in February 2013 in State of Roraima. Source: INPE.

Such increased precipitation in the previous month led to a reduction of hotspots in the State of Roraima, as per the histogram below (Table 4).

Table 4. Histogram of fire outbreaks in the state of Roraima. Listing only of states municipalities with occurrence of outbreaks in February 2013. Source: INPE.

	(3) Boa Vista / RR *(2)*
	(4) Caracaraí / RR *(1)*
	(5) Normandia / RR *(1)*

In March 2013, Figure 10 shows the weekly oceanic pattern observed until the 24th day. The monitored areas in the Equatorial Pacific show large spatial and temporal variability of SST anomalies, predominantly colder water than average in the first two weeks of March. In the period from 17 to 24 March there was a significant increase in positive SST anomalies in the equatorial Pacific region, with warmer water than average.

In the Atlantic Basin Tropical there was no significant change over the past three weeks, keeping two extensive areas with positive SST anomalies in the northern portion. In the Subtropical South Atlantic, near Brazil's east coast, there was a slight reduction in the negative SST anomalies, with an almost neutral standard.

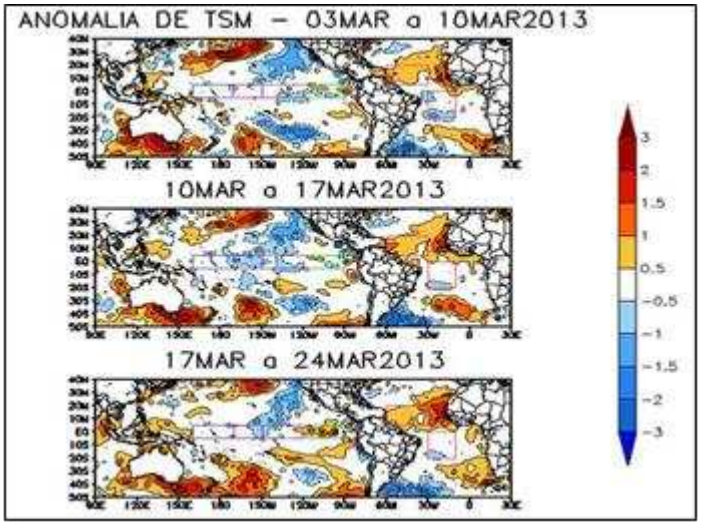

Figure 10. Weekly SST Anomaly (° C) for month of March 2013 over the range between 40 ° N and 50 ° S. Source: Data from NWS / CPC processed by SIPAM.

The performance of the Intertropical Convergence Zone (ITCZ) to the north of its climatological position contributed to the below average precipitation in Roraima during the month of March 2013. The anomalous position of the ITCZ is occurring in response to warming of surface waters in the tropical North Atlantic.

Another reason that explained the lack of rain in much of the state was the anomalous westward displacement of the flow at high levels between the past months of January and February. Over the past few months, signs of intraseasonal variability have interfered in oceanic and atmospheric patterns in tropical areas around the globe.

As a result, these same patterns sometimes contribute to the occurrence of precipitation, sometimes to the inhibition of the rains. As a result Figure 11 shows that the accumulated precipitation was below normal in March 2013.

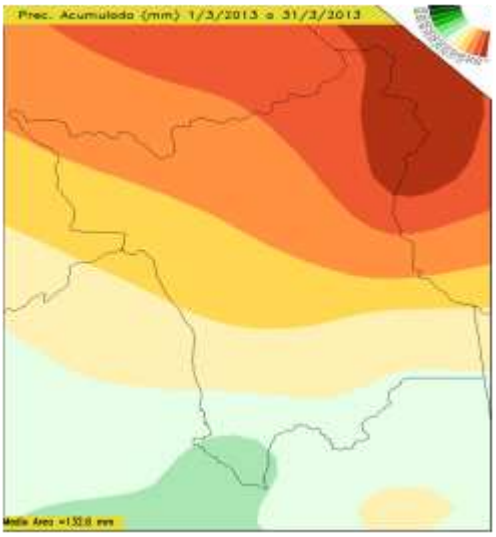

Figure 11. Accumulated Precipitation in March 2013 in the State of Roraima. Source: INPE.

Making a general summary, the data from INMET show that in the quarter January-February-March there was low precipitation as per Figure 12.

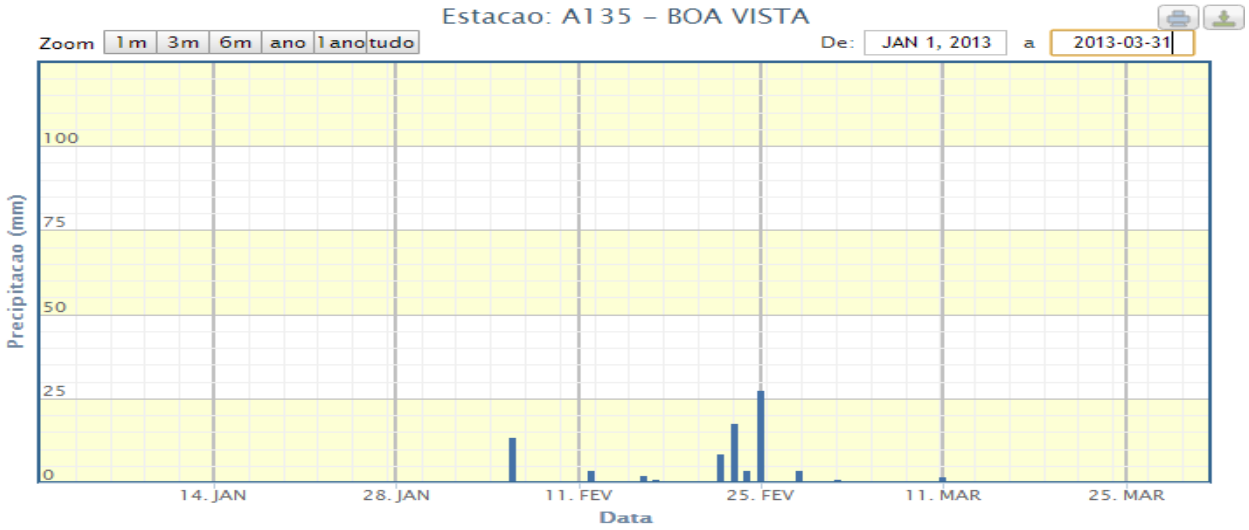

Figure 12. Monthly accumulated precipitation of Boa Vista-RR in the months of January, February and March. Source:INMET. **http://www.inmet.gov.br/portal/index.php?r=home/page&page=rede_estacoes_auto_graf**

That is, in January no precipitation was recorded in Boa Vista. Back in February there were 10 days with rains, registering a cumulative 81.4 mm in the capital. In March the record was 14.5 mm in 5 days of rain. These values indicate a low precipitation for the whole northeast sector of Roraima, where the major cities at risk of fire and wildfires are located. As per the histogram below (Table 05) 267 outbreaks were recorded in this critical quarter of low precipitation, thus showing that this joint operation of CIMAM RR achieved the expected success.

Statistics of hotspots

4.1. Quantitative Analysis

Hotspot is the heat record captured in the ground surface by a satellite sensor, the sensor captures and records any temperature above 47 ° C and interprets it as "hotspot" The data are generated and made available by the National Institute for Space Research - INPE, on http://www.dpi.inpe.br/proarco/bdqueimadas .

When comparing with other years (2007/2008 and 2012/2013), the detection of hotspots of the years 2012/2013 is below the expected average for the period (Table 6 and Figure 13).

Table 6. Comparison of the number of hotspots for the period described.

Ano	Número acumulado de focos entre 01/12/2013 a 31/03/2013 de cada ano utilizando o satélite referência	Percentual dos focos de 2012/2013 em relação aos anos anteriores
2007/2008	813	-13,55
2008/2009	379	47,07
2009/2010	1528	-113,41
2010/2011	501	30,03
2011/2012	695	2,93
2012/2013	**716**

Fonte dos dados: INPE.

Figure 13. Graph comparing the number of hotspots for the period described.

According to historical concentration of hotspots (reference sensor) grouped by month for the period 2007-2013, the most critical period of the occurrence of fire in Roraima is between November and March, with the peak detection in months from January to March (Figures 14 and 15).

This year the hotspots showed the same trend, but there was considerably greater number of hotspots detected in January (analysis through the reference satellite in the period from 12/01/2012 to 03/31/2013), and this number has decreased considerably in the following month (Figure 16).
The distribution of hotspots (reference satellite) was also analyzed for the same period, between the municipalities of Roraima where hotspots occurred and the result is shown in Figure 17.
We emphasize that the most critical region in this period (12/01/2013 to 03/31/2013) was the Northwest region, an area with predominant savannah vegetation, for this analysis all hotspot monitoring sensors were used in the period described for the case of monitoring of hotspots (Figure 18).

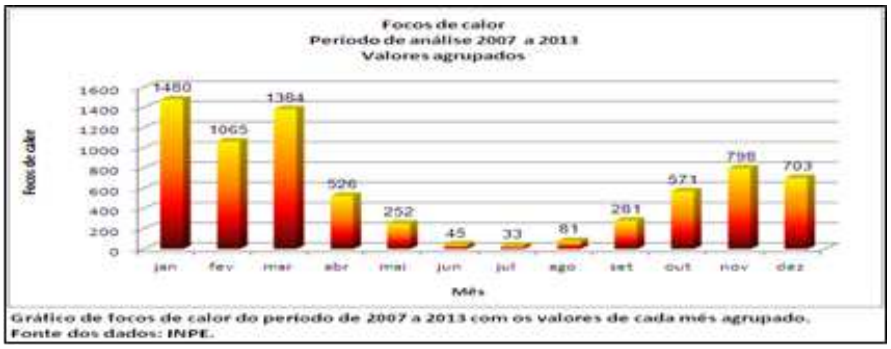

Figure 14. Graph comparing the number of hotspots for the period described.

4.2. Spatial Analysis

To better understand the dynamics of fires during the operational period of 2012/2013 (2013 Green Roraima Operation), an analysis of the evolution of hotspots was made from 12/01/2012 to 03/31/2013 within federal areas: military areas, border area, federal highways, settlement projects, indigenous lands, federal protected areas and other areas (Figure 19). The maps for hotspots were generated using parameters for kernel[1] map (Figures 15, 18, 20, 21, 22, 23, 24 and 25) the result enables better visualization of the region where the hotspots occur during the year.

[1] Statistical method for estimating concentration density of events and highlighting critical points

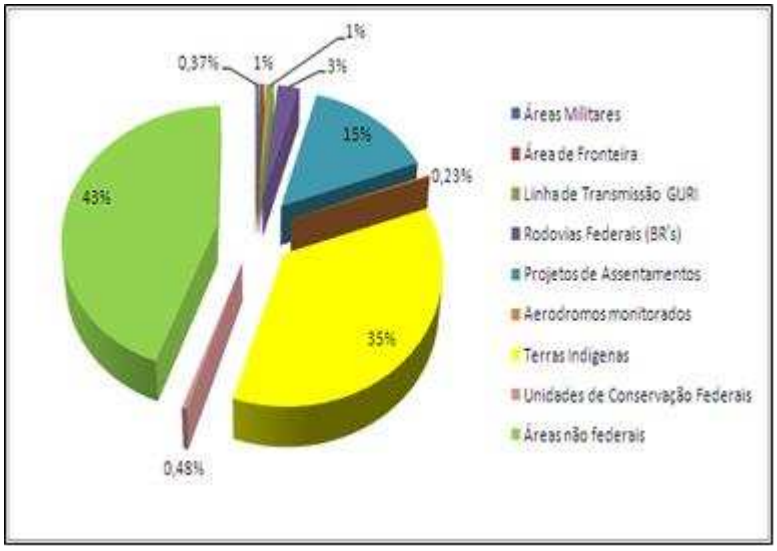

Figure 19. Distribution of hotspots (all sensors, for the case of monitoring) for the period from 12/01/2012 to 03/31/2013 in the areas monitored by CIMAN RR / Federal. 2013 Green Roraima Operation. Source: CIMAN RR / Federal.

Military areas:

Concerning military Areas of the State of Roraima only plots used by the Brazilian Army were considered for monitoring, specifically the 1st Jungle Brigade with a forest area of 279,421.00 ha.

Among the military areas monitored by CIMAN RR / Federal, the plot Serra do Tucano, located in the municipality of Bonfim - RR, was the one with the highest concentration of hotspots (Figure 20). The monitored Military Areas represent 0.37% of the hotspots for the operational period.

Military areas were used for military exercises, being totally bounded with signs indicating the property and warning the use, in some places there are physical barriers that prevented the passage of people in risk areas. This care to warn the military use of the space, in addition to enclosure thereof, prevented the passage of pedestrians in the military unit.

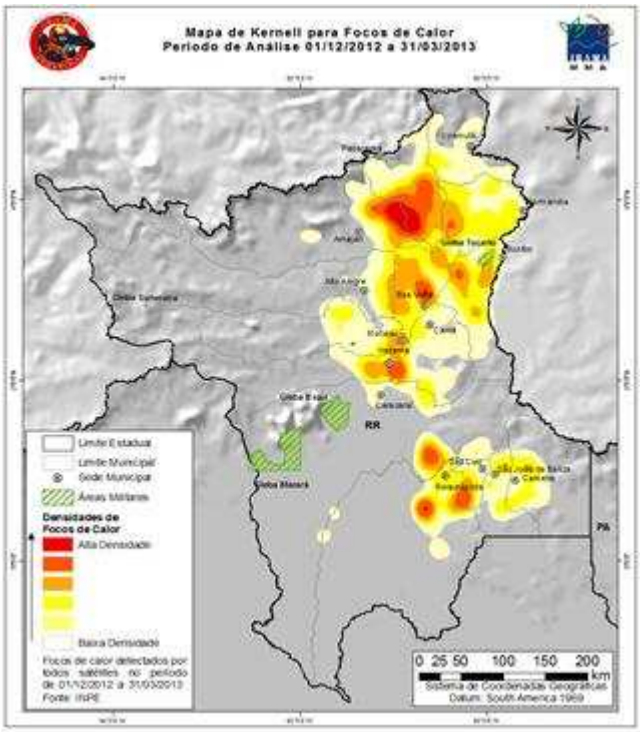

Figure 20. Concentration of hotspots x Military Areas. Source: CIMAN RR / Federal

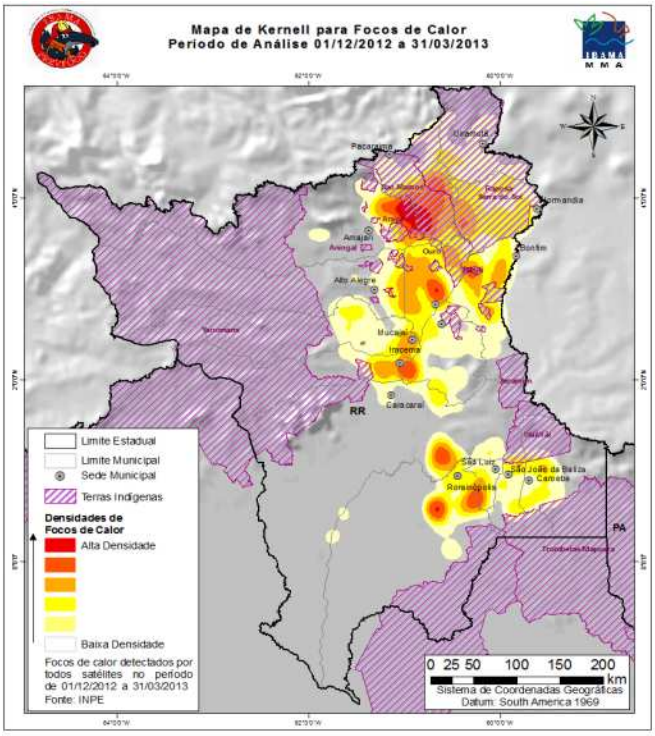

Figure 21. Concentration of hotspots x Indigenous Lands. Source: CIMAN RR / Federal.

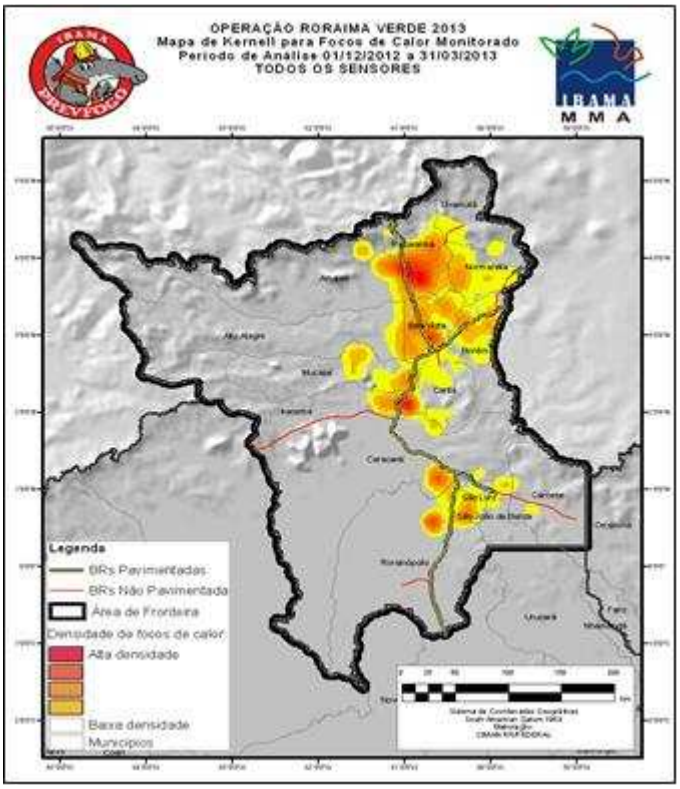

Figure 22. Concentration of hotspots x Border Area. Source: CIMAN RR / Federal.

Indigenous lands:

CIMAN RR / Federal monitored Indigenous Lands in the period from 12/01/2012 to 03/31/2013, i.e., throughout the 2013 Green Roraima Operation, and the Indigenous Lands had the highest number of outbreaks (35% of total outbreaks recorded for the period), compared with the areas monitored by the Multi-Agency Integrated Centers. Indigenous lands with more numbers of hotspots were Raposa Serra do Sol and São Marcos, which together represent approximately 55% of the hotspots detected on indigenous lands (Figure 24).

A part of the natives has also given good contribution to the increase of fires in Roraima, because they usually set fires to process food, get rid of undesirable insects or just put fire in the forest without any purpose.

Border Area:

The boundaries that border with the State of Roraima were monitored by CIMAN RR/ Federal, Venezuela (954 km from the border) and Guyana (964 km from the border), and the hotspots for the period from 12/01/2013 to 03/31/2013, 2013 Green Roraima Operation, concentrated on the border with Guyana and the municipalities of Bonfim and Normandia and of the state of Roraima (Figure 21). The Border Area monitored represents 1% of the hotspots for the operational period.

Through the Sub Consulate of Brazil a contact was made with the institutions of neighboring countries to exchange information related to the prevention and fighting of wildfires in the border area.

In the event of an accident there would be no physical intervention unless we were contacted through diplomatic channels. But the exchange of information related to fire behavior in potential accidents was planned..

INCRA Settlement Projects:

In Settlement Projects, 15% of hotspots monitored for the period were detected, as shown in Figure 23.
The highest incidence of wildfires is undoubtedly due to lack of care when causing burning, whether for pasture renewal, elimination of rest of cultivation or for pest control. These typically agricultural activities without due care to contain the advancing flames have generated the largest wildfires in Roraima.

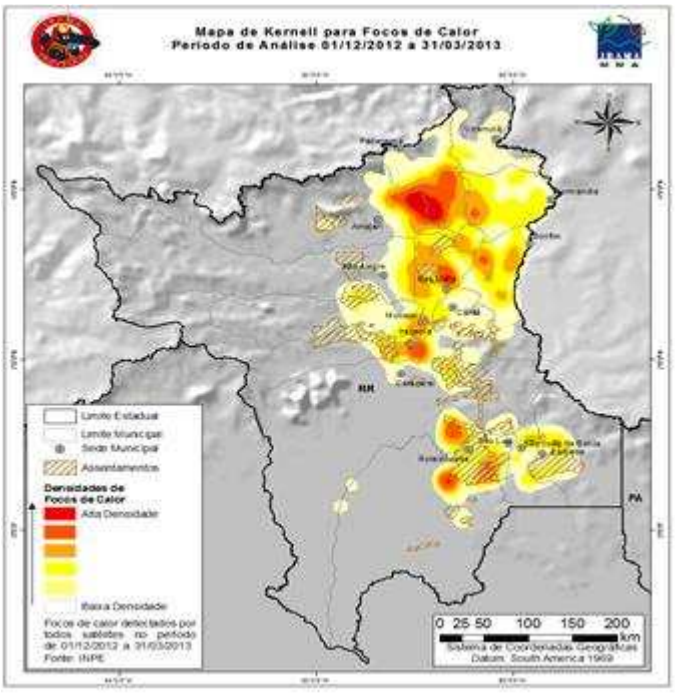

Figure 23. Concentration of hotspots x INCRA Settlement Projects. Source: CIMAN RR / Federal.

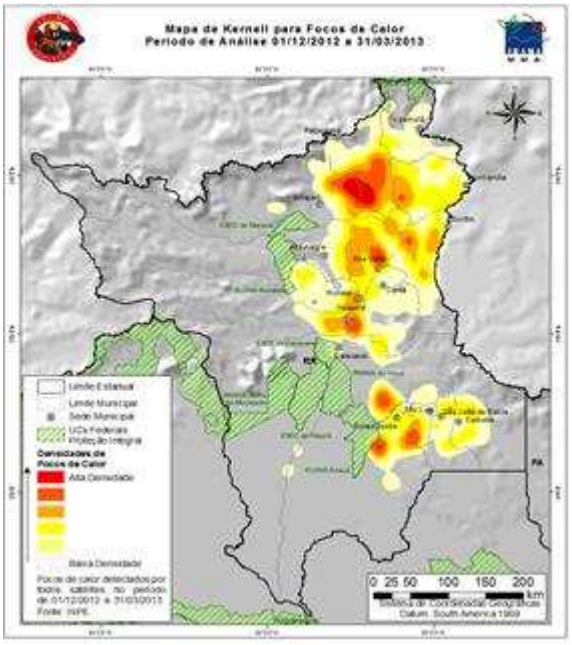

Figure 24. Concentration of hotspots x Federal Protected areas Source: CIMAN RR / Federal. Source: CIMAN RR / Federal.

Protected areas:

The analysis was made for Federal Protected areas of full protection and sustainable use. 0.48% of hotspots were detected during the analysis period. From this number, only one spot is on protected areas for sustainable use: FLONA of Roraima. The rest is on Full Protected areas: ESEC Caracaraí and PARNA and Monte Roraima (Figure 25).
Protected areas of Roraima, though protected by equipped brigades, are of difficult access, which prevents the presence of the main causal agent of fire, man.

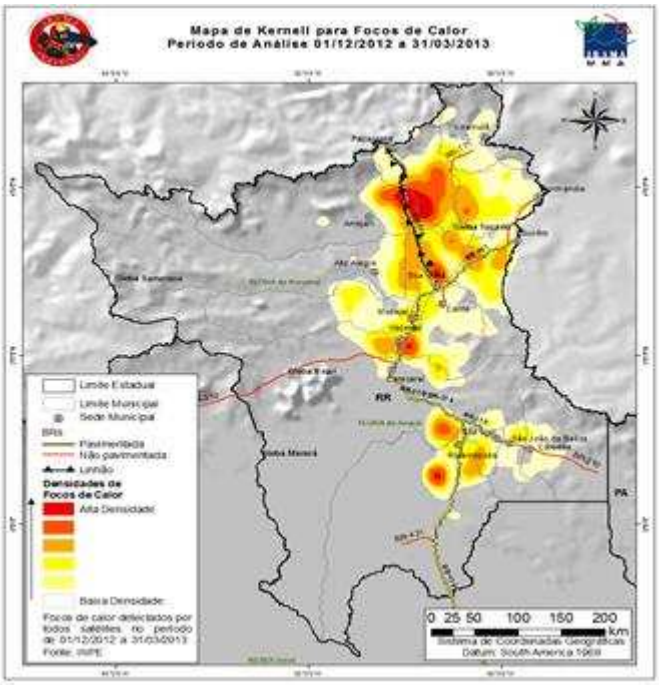

Figure 25. Concentration of hotspots x Federal Highways, GURI line and monitored Airstrip. Source: CIMAN RR / Federal.

Federal Highways, GURI Transmission Line and Monitored Airstrip:

1404 km of Federal Highways were also monitored (3% of hotspots for the period), 190 km of Transmission Line (1% of hotspots for the period) and a radius of 6 km from the center point of aerodromes in the municipalities of Boa Vista, Caracaraí and Pacaraima (0.23% of total hotspots for the period), as shown in Figure 22.

Wildfires in federal, state and municipal roads and highways occur due to lack of maintenance of the right of way, combined with the traffic of vehicles with low compression engines. These engines tend to accumulate carbon particles in the cylinders and the exhaust system when used for long periods and overheat causes softening and loosening of the accumulation of deposited carbon, whose deposited particles can be expelled by the exhaust, usually when the vehicle shifts gears.

The high-voltage lines in forests and lack of maintenance of the easements in transmission networks can cause serious problems, because the contact of wires with vegetation can cause sparks that will cause the fire. And also with the occurrence of fire in these lines wires can heat up, causing network outages resulting in disconnection of power supply.

The accumulation of particles in suspension near the aerodromes, particularly in the headwaters of the strips, can hinder or impede landing and takeoff procedures. As in previous years, it can even close the aerodromes for takeoffs and landings.

Preventive Actions

With preventive actions implemented when the brigades were not acting in firefighting, the main activity was visiting indigenous communities, settlements or farms aiming to educate the local population about the consequences of the problems arising from fires and burning in the region and disseminate controlled burning techniques seeking to establish a safety belt between the edges of the settlements and the rest of the forest, as per Table 07 and Figures 26 and 27.

Preventively a helicopter became available for operation aiding in preventing and fighting wildfires, as well as in enforcement actions. We conducted a flight next to conservation areas and settlement projects, at the time instructions and guidelines were given to the Brigades on procedures for boarding and unboarding. There were two monitoring flights, one in the mosaic of military areas and another to the northeast of the state, such location covering Indigenous Lands and Military Areas (Table 09 and Figure 29).

TOTAL FLIGHT HOURS	69.5

As actions of interaction with Civil Society, 25 dampers were donated to the Club of jeeps the State of Roraima for purposes of fighting small wildfires, Fire Brigade training for handling GPS-Global Positioning System and motor-pumps, lectures on labor unions and rural workers, indigenous communities and monitoring of environmental education project of Eletronorte.
The Brazilian Army, the Brazilian Air Force and employees of the company FIT Manejo Florestal Ltda., were trained on techniques for preventing and fighting wildfires in a course taught by experts of Prevfogo, 72 (seventy-two) students completed the course.
A mission of the National Institute for Space Research-INPE was conducted for monitoring and validation of hotspots detected during 2013 Green Roraima Operation. This validation consisted of analyzing the hotspots detected by the passage of satellites used by INPE, in relation to omission and commission, taking into account hotspots with the indications of burning on images of medium spatial resolution sensors. The missions were conducted by land and air (aircraft assigned by FUNAI) to collect data on photographs, geographic coordinates and local information.
Aiming at the preparation of a Letter of Intent on rebuilding of affected areas, three meetings were held at IBAMA / SUPES RR-03 in the scope of the Green Roraima Operation, where the following entities were present: IBAMA, the Brazilian Agricultural Research Corporation- Embrapa, the National Indian Foundation - FUNAI, Eletronorte and Department of Agriculture and Food Supply and Production of Roraima and the company FIT Manejo Florestal Ltda., which assume the commitments listed below:.
A Climate Meeting was held with the participation of the Head of the Meteorology Division of the Amazon Protection System-Sipam, who discussed in his presentation the mission of Sipam, diagnosis, analysis and prognosis for the weather in Roraima.
At the meeting, where ABIN, UFRR, IBAMA, ICMBio, FUNAI, FEMARH, EB, CBMDF, CBMRR, Civil Defense and SIPAM were present, the importance of creating a representation of SIPAM in the State of Roraima was highlighted, as well as the need to identify weather stations available, assess conditions and provide access by establishing a minimum network of shared information.
Find below a summary of preventive actions during the Green Roraima Operation (table 10).

As part of the preparation for the fight five (05) Brigades of IBAMA were hired, with 143 (one hundred and forty-three) Brigades installed inside or near Settlement Projects and Indigenous Lands. ICMBio also hired its Brigades to prevent and fight wildfires with a total of 77 (seventy seven) Brigades distributed in the units that offer greater risks, added to 52 (fifty two) soldiers of the Armed Forces, who were trained and equipped by IBAMA, CIMAN RR / Federal had 272 (two hundred seventy-two) Brigades directly for preventing and fighting wildfires in Roraima during the 2013 Green Roraima Operation (table 11).

Federal brigades for the Prevention and Fighting of Wildfires of IBAMA-BRIFs / IBAMA

Since 2001, the National Center for Prevention and Control of Wildfires - Prevfogo seeks to establish control over wildfires through the hiring of prevention and fighting brigades. Primarily restricted to the federal protected areas, such brigades have achieved important goals for the conservation of local

biodiversity by creating prevention routines, providing first response to frequent occurrences and composing field teams in large-scale fighting.
In 2009, hiring UC's brigades became the responsibility of the Chico Mendes Institute for Biodiversity Conservation - ICMBio. In 2008, Prevfogo began developing the "Wildfire Brigades of Prevfogo in Critical Municipalities" program, which aims to promote the prevention and fighting of fire incidents in locations especially threatened by wildfires.
The selection of municipalities for the implementation of the brigades observed the technical and objective criteria for detection of hotspots in remnants of native areas and coverage of protected areas (indigenous lands, and federal and state conservation), forest remnants and settlement projects.
In 2013 Prevfogo hired 143 (one hundred and forty-three) Brigades in five municipalities of Roraima: Cantá, Mucajaí, Iracema, Pacaraima and Amajari, which were located in forward bases, prioritizing the contact areas of savannah with temperate rainforest (Figure 30). The period of hiring Brigades in 2013 in the state is December to April, except Cantá whose hiring was during December extending until April.
When Prevfogo Brigades were not acting in firefighting, the main activity was visiting indigenous communities, settlements or farms aiming to educate the local population about the consequences of the problems arising from fires and burning in the region and promote controlled burning techniques. Altogether 2201 (two thousand two hundred and one) preventive visits (see Figure 27) were done. When possible, the brigade supported the authorized controlled burning.

7. Brigades for the Prevention and fighting of Wildfires of ICMBIO

The Chico Mendes Institute for Biodiversity Conservation has, among its duties, the responsibility for the protection of Federal Protected areas. Among the activities for the protection, Firefighting and prevention is one of the most important.
The existing fire brigades in federal protected areas has as their main goal to work under the command of the head of the unit and the manager of fire in all actions to prevent and fight wildfires within the protected areas and their surroundings provided in the Management Plans (Figure 30).
In 2012 ICMBio hired 77 (seventy-seven) Brigades to act in five protected areas in the state of Roraima. Their distribution was as follows: Parna do Viruá with 28 (twenty eight) Brigades; ESEC Caracaraí with 14 (fourteen) Brigades; ESEC Niquiá with 07 (seven) Brigades; ESEC Maracá with 14 (fourteen) Brigades and Flona Roraima with 14 (fourteen) Brigades. The hiring period of the brigades in the state starts in November and goes until April.
When the risk of fire within the UC's is zero, the brigades of ICMBio usually work on prevention of incidents along the nearby communities, conducting lectures, educational visits and supporting authorized controlled burning. In fact, firefighting in Federal Protected areas is the last resort of the unit, after completion of all the efforts in prevention and public awareness, causing Brigades of ICMBio, after all, to act as social actors in their communities.

8. Brigades for the Prevention and Fighting of Wildfires of the Army

During the month of November 2012, meetings between IBAMA servants and a representative of the 1st Jungle Infantry Brigade were held, where it was agreed that the Army would indicate a representative to participate in the situation room that would be installed and that IBAMA would promote prevention and fighting courses for one hundred (100) Soldiers.
At the beginning of December 2012, the Commander of the 1st Jungle Infantry Brigade signed Service Order No. 27, regulating the activities to be performed to support CIMAN in case of fighting wildfires in Roraima and determining the initial composition of fifty (50) Soldiers for the "Fire Brigade" of the Army in Roraima, after training with the staff of IBAMA - Prevfogo (Figure 30).

Thus, in the period from January 21st to 25th, 2013, the Course for the Prevention and Fighting of Wildfires was conducted, promoted by CIMAN, through IBAMA and the 1st Jungle Infantry Brigade. 46 (forty six) Soldiers successfully completed the course: 26 (twenty six) from C Fron RR / 7th BIS; 10 (ten) from the 12th Esqd C Mec and 10 (ten) from the 10th GAC S1.
Finally, the Brigade is interested in training more fifty (50) Brigades, with the goal of assigning them to the Special Border Platoons (with road access) in the future.

9. Fire Record – ROI

The records of occurrences of wildfires and the statistical analysis thereof are essential tools for defining strategies for prevention and firefighting, indispensable for countries that seek to manage the issue of fire in an efficient and organized manner.
The ROI's are filled by field teams and entered into the National Fire Information System - SisFogo. It is a system of IBAMA in which it is possible to enter and search ROI's with information on the agency itself, ICMBio and Fire Stations. It integrates information and allows the use of data safely and autonomously by users and is available on the following website: http://siscom.ibama.gov.br/sisfogo/.
Also according to the ROI's of the 2013 Green Roraima Operation, Canta is the municipality that has the highest number of records, followed by Pacaraima and Amajari. It is worth-mentioning that these data do not fully reflect the reality of the occurrences of wildfires, since there are a lot of gaps in the records, as well as records without dates and coordinates.
425 (four hundred twenty-five) firefighting actions were recorded by CIMAN RR / Federal during the 2013 Green Roraima Operation, distributed by the deployed Brigades (Table 12 and Figure 31).

10. Accountability for Environmental Crimes

In order to be successful, wildfire fighting actions were accompanied by actions of enforcement activities. The inspection teams conducted educational and repressive actions in the critical regions of fires, illegal deforestation, illegal logging and other illegalities. The intensive supervision contributed to the inhibition of infringing actions and reduction of environmental crimes, in particular those related to wildfires, fires and deforestation.

Figure 32. Graph of the work done by NUCOF. Source: CIMAN RR / Federal.

The years 2012/2013 prioritized the fight against deforestation, especially in the Amazon. Most of the inspection teams of IBAMA were focused on these activities, but by no means the supervisory activities of misuse of fire was impaired. 14 notices of violation were issued for illegal burning during 2013 Green Roraima Operation; such number is insignificant when compared to 2010, when 347 notices of violation (Table 13, Figures 32 and 33) were issued.

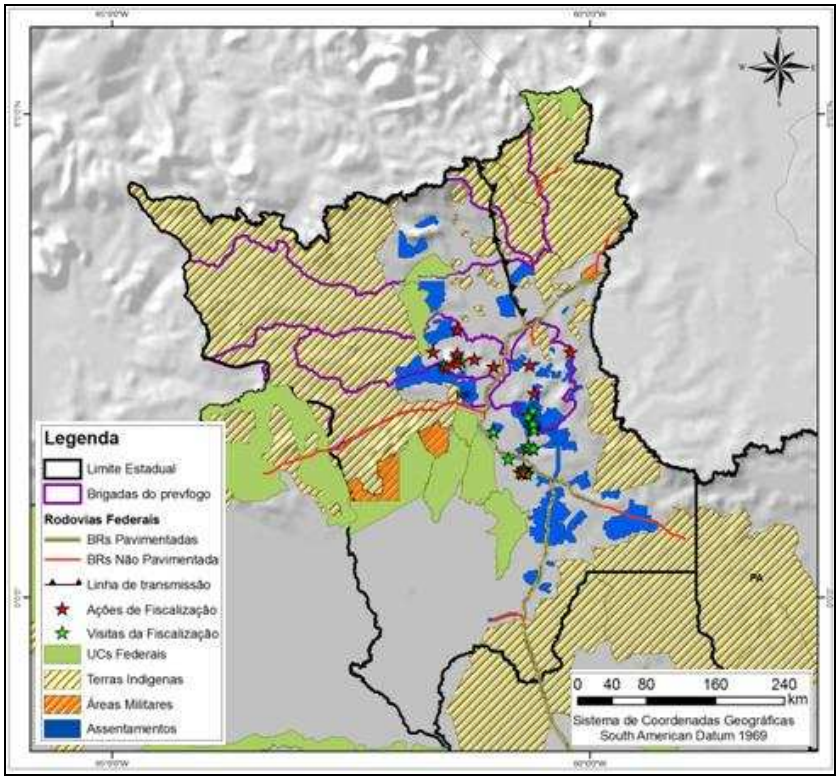

Figure 33. Work done by NUCOF. Source: CIMAN RR / Federal

11. Difficulties

Notably the lack of a specific and compatible structure of the agencies can be considered as the main obstacle to satisfactory response of CIMAN/RR Federal. The deficiencies are: insufficient system of communication, means of transport and capacity below what is needed.

11.1. Equipment

Regarding communication, the lack of adequate means results in difficulty of calling some Brigades located in the most isolated municipalities, loss of agility in firefighting activities and huge delay in informing the situation to the central coordination, which is critical for efficient management of available resources.

The personal and vehicle tracking devices, currently nonexistent, are an important and complementary part of a communication system, and increase situational awareness of national coordination and security of the Brigade members.

The transport was also deficient during the whole operation, making it difficult to mobilize teams for firefighting and prevention. Vehicles available for operation are rented, the maintenance and supply being the responsibility of the lessee. Even so, the maintenance issue was demonstrably very poor and there is a huge delay in service authorization and release of substitute vehicles. The supply is made only in Boa Vista, which complicates the operationalization of the brigades.

Brigades of Prevfogo were strongly damaged by the delay of delivery of PPE or the absence of some items.

11.2. Deficit of skilled personnel

While servants from other states have been made available to integrate the operation, some areas were not covered during the operation.

The lack of know-how on the Incident Command System-ICS, by some members of Ciman / RR caused the tool to be underused, jeopardizing the establishment of standardization activities.
Another activity that was jeopardized was geoprocessing, where there were difficulties in providing technicians to work with the tool.

12. **Final Remarks**

The Green Roraima operation is a milestone in the implementation of the national policy for preventing and fighting wildfires with integrated and comprehensive management giving a new direction to actions of firefighting, prevention and control.
Again, the need for expansion and consolidation of the Integrated Centers - CIMAN was clear in all regions of Brazil where recurrent wildfires occur.

Large airtanker use in the United States: what do we know?

Matthew P Thompson, Crystal Stonesifer, and David E Calkin

Rocky Mountain Research Station, US Forest Service, Missoula, MT, USA,
mpthompson02@fs.fed.us, csstonesifer@fs.fed.us, decalkin@fs.fed.us

Abstract
In this paper we will review recently uncovered trends in large airtanker (LAT) use in the U.S., explore implications, and discuss opportunities for improving efficiencies. First, we will review results of two studies attempting to characterize LAT use between initial attack (IA) and extended attack and/or large fire support (EA) missions. Collectively these studies identified significant LAT use for EA despite a history of prioritizing LATs for IA, and further identified potentially counterintuitive results where fires receiving LAT support during IA were more likely than not to escape IA efforts. These results suggest potential operational efficiencies in LAT use, and that improving success in IA efforts may be in part premised on reducing the time between ignition and LAT arrival on the fire. Here we examine trade-offs between LAT usage for IA and LAT unavailability for IA operations due to EA use. To do so we use a mathematical optimization model to identify efficient LAT air base location and deployment strategies. The model is designed to minimize the total deployment time of meeting LAT IA demand, with demand quantified as a function of a fire weather index. Results indicate, as expected, that model performance degrades as LATs are increasingly unavailable. Results further indicate substantial sensitivity of LAT air base location strategy to LAT availability, with potentially significant implications for air base staffing and capacity decisions, as well as fleet composition decisions. To conclude we will describe ongoing and future work analysing opportunities for efficiency gains in LAT management, focusing on the role of forecasting and optimization frameworks, as well as ongoing data collection and analysis regarding retardant drop conditions and outcomes.

Keywords*: initial attack, resource use, large fire management, efficiency*

The views expressed here are the authors', and do not necessarily represent the views of the USDA

Introduction

Large airtankers (LATs) are part of a broader suite of aviation assets including scoopers, helicopters, and single-engine airtankers, each with different operational capacities and limitations that can perform a wide variety of mission critical activities. LATs are prized for their large storage capacity and their ability to quickly travel to fire starts to facilitate containment during initial attack operations. Nominally, initial attack has been the primary role for LATs in federal fire suppression in the United States. Subsequently, optimization models supporting LAT fleet composition and location-allocation decisions are premised on the primary use of LATs being for initial attack (Fire Program Solutions 2005; Keating *et al*. 2012). These analyses have great policy relevance, as the U.S. Forest Service is facing decisions about how best to address an aging fleet of contracted aircraft. Questions to consider include whether to contract or purchase aircraft, how many aircraft to contract/purchase, of which type, in what mix, with what equipment, and for what role.
But is initial attack really the primary role for federally contracted LATs in the United States? And do the data exist to support comprehensive analysis of the costs and benefits of alternative fleet composition strategies? In 2013 the U.S. Government Accountability Office (GAO) released the findings of an investigation into federal agency actions regarding their fleet modernization and analysis efforts, which identified a need for improved data collection systems (GAO 2013). Similarly, our past and ongoing research has identified inadequacies and deficiencies in data collection, ranging from a limited ability to track and characterize LAT use at the national level, to an even more limited ability

to characterize the objectives and outcomes of individual drops at the incident level. Fine-scale evaluation of LAT drop effectiveness is the fundamental piece of information for supporting decisions related to choosing efficient combinations of aviation and ground-based firefighting resources and establishing appropriate flight mission objectives at the incident-level, for prepositioning and dispatch decisions across multiple incidents, and ultimately for arriving at efficient aviation resource mixes across fire seasons at the national level. Fortunately, recent work in the U.S. and elsewhere around the globe is providing new data and tools to better characterize the costs and benefits of aerial suppression efforts.

Three recent studies are particularly relevant to analyses of aerial firefighting effectiveness and efficiency. First, Plucinski and Pastor (2013) outlined a set of criteria and methodologies for evaluating the effectiveness of aerial suppression drops, and applied their methods during field fire experiments performed in eastern South Australia. The authors identified information needs for environmental and delivery conditions to support evaluation of drop effectiveness, including characteristics related to the type of aircraft, the drop location, fire behaviour, and ground suppression activities. Questions related to evaluation of drop success include whether a drop objective was clearly defined, whether drop placement and coverage were sufficient, and whether spatiotemporal effects on fire behaviour met drop objectives. In the U.S. the ongoing Aerial Firefighting Use and Effectiveness study will ideally be able to provide much of this information, but in the interim critical knowledge gaps remain.

Second, Thompson *et al*. (2013) examined the availability and sufficiency of U.S. federal agency aviation data to support cost-effectiveness analysis, finding that significant data quality issues and limited interoperability across data management systems precluded an in-depth analysis of the sort recommended by Plucinski and Pastor (2013). Instead, the authors as a first step summarized LAT flights according to mission type (initial attack (IA) versus extended attack and/or large fire support (EA)) across the years 2007-2010, using information on both the flight's job code description, and fire size class at the time of the drop. Depending upon assumptions for how to group job codes, results indicated that somewhere between 6.6% and 48.1% of flights were used for IA operations. Fire size results similarly showed limited usage for IA (10.8%), and further indicated extensive use on very large fires. Nearly 35% of drops occurred on fires larger than 4,047 ha (10,000 ac), and nearly 23% of flights occurred on fires larger than 8,094 ha (20,000 ac).

Third, in a more in-depth study, Calkin *et al*. (2014) linked spatially-explicit drop location data with fire occurrence and firefighting resource ordering records to better identify the period in the fire history when drops occurred as well as the resulting outcomes of fires that received drops during IA. The authors analysed LAT drops across 2010-2011, and results confirmed earlier work indicating extensive use of LATs on EA. In 2010, a relatively quiet fire season, 34.4% of all drops were used in EA; this increased to 50.9% in 2011. The number of drops per incident exhibited high variability, largely a reflection of heavy usage for significant events during EA operations, including multiple incidents with more than 75 drops. Results further indicated that drops during IA tended to be associated with incidents that escaped IA and transitioned into EA. In 2010, 67.5% of IA LAT use incidents eventually escaped, and this increased to 84.8% in 2011.

Results of these two latter studies highlight possible inadequacies in contemporary LAT usage, as well as significant complexities in quantifying cost-effectiveness given limited understanding of the marginal contribution of LAT usage to reduced damage across of the spectrum of LAT drop objectives during EA operations. That the majority of overall drops occurred during EA operations suggests that LATs are "sticky" and that fire managers tend to retain LATs for use outside of what has historically been considered their most suitable role. EA LAT use could still be cost-effective under a range of circumstance, of course, but potentially comes at the cost of diverting resources from IA demands. Additionally, that a large majority of drops occurring during IA are associated with escaped wildfires suggests that fire managers are appropriately calling for LAT support on incidents with high escape potential, but also suggests inefficiencies in the positioning, dispatch, availability, and delivery of

LATs for IA operations. The degree to which LAT use on EA can directly degrade IA operational efficiencies has yet to be rigorously quantified, however.
In this paper, we rely on a formalized optimization framework to better understand trade-offs in LAT usage patterns, with the aim to generate information useful for future cost-effectiveness analyses. Specifically we build upon a resource allocation model tested on a select set of units managed by the California Department of Forestry and Fire Protection (Chow and Regan 2011). We develop a static allocation model where LATs are assigned to the same air base for the entire season, and focus on isolating the influence of systemic LAT unavailability for IA due to use for EA operations. In the following sections we introduce the reformulated optimization model along with a sensitivity analysis, present results, discuss implications, and offer recommendations for future research.

Model Formulation

Our model expands upon a previously developed model by Chow and Regan (2011), and has similarities to facility location problems. The problem is defined as the allocation of LATs to air bases over the course of a fire season to minimize the cost (using travel time as a proxy) of deploying LATs to wildfires. The problem formulation is designed to recognize important features of LAT location and deployment, such as the potential demand for multiple LATs to respond to a wildfire, and the ability to co-locate multiple LATs at a given air base. Demand for LATs is dependent upon location-specific seasonal averages for the National Fire Danger Rating System's Burning Index. Structurally, the problem considers a network of nodes (air bases) and arcs with fixed travel times between air bases. Model outputs include assignments of LAT air base locations as well as LAT deployment rules to cover LAT demand from other air bases. We expand upon this formulation by accounting for the possibility of LATs being unavailable for IA due to EA use, and explore how total deployment time changes with various LAT availability rates.

$$\text{Min} \quad \sum_i \sum_j d_{ij} Z_{ij} \tag{1}$$

$$\text{s.t.} \quad Z_{ij} - \gamma_j X_j \leq 0, \ \forall\, i,j \tag{2}$$

$$\sum_j Z_{ij} \geq k_i \quad \forall\, i \tag{3}$$

$$\sum_j X_j = P \tag{4}$$

$$X_j \geq 0 \ \ \forall\, j, \ UD_i \geq 0 \ \forall\, i, \ Z_{ij} \geq 0, \ \ \forall\, i,j, Z_i, X_j \text{ integers} \tag{5}$$

Where

Z_{ij} integer number of LATs at node *j* covering node *i*
d_{ij} matrix of travel times from *i* to *j*
X_j integer number of LATs based at node *j*
k_i minimum demand threshold for number of LATs covering node *i*
γ_j LAT availability rate at node *j*
P number of LATs

Equation 1 minimizes the travel times of the closest tanker bases delivering LATs to demand nodes. Equation 2 limits the number of LATs that can be assigned to node *i* by the availability-weighted number of LATs at node *j*. Equation 3 forces assignment of the *k* closest available LATs to node *i*. Lastly, Equation 4 limits assignment of LATs to the total number of LATs in the fleet, and Equation 5 ensures non-negativity.
To examine the sensitivity of model performance to LAT availability, we first uniformly vary LAT unavailability rates in 0.05 increments from 0.05 to 1.00. We then consider variable LAT availability rates across air bases. As a simple rule we define air bases as low or high demand nodes (and therefore high or low availability nodes, respectively) based upon whether their demand levels are below or above the median demand across all air bases. We then vary the availability rates according

to three paired sets of (0.70, 0.90), (0.60, 0.80), and (0.50, 0.70), which correspond to average availability rates of 0.80, 0.70, and 0.60, respectively.
Additionally we explore introducing penalties for otherwise infeasible solutions with unmet demand. To account for unmet demand in the model the objective function is updated to include penalty costs (Equation 6) and the constraint to meet LAT demand is updated to include a dummy variable for unmet demand (Equation 7). We explore three weights (1, 10, and 25) for the penalty that in effect act as a scaling parameter to convert unmet LAT demand into the equivalent deployment time. In practice, the ρ parameter could be based on the cumulative travel times of alternative firefighting resources necessary to achieve an equivalent level of firefighting production capacity.

$$\sum_i \sum_j d_{ij} Z_{ij} + \sum_i \rho_i UD_i \quad (6)$$

$$\sum_j Z_{ij} + UD_i \geq k_i \quad \forall i \quad (7)$$

Where
UD_i unmet demand at node *i*
ρ_j unmet demand penalty at node *j*

For parameterization of the model we use the same set of demands and travel times for the test network applied by Chow and Regan (2011). This test case includes 20 LATs and 12 California Department of Forestry and Fire Protection air bases. Table 1 presents summary information on the demand levels and availability classifications we used.

Table 1. Summary information on air bases in test network

Air Base #	Air Attack Base Name	# of LATS	Demand Level	Availability Classification
1	Hollister	2	4.16	High
2	Chico	1	10.4	Low
3	Fresno	1	9.8	Low
4	Rohnerville	1	5.58	Low
5	Sonoma	2	4.8	High
6	Ukiah	2	6.2	Low
7	Ramona	2	9.9	Low
8	Hemet	2	5.12	High
9	Redding	2	5.69	Low
10	Paso Robles	2	5.47	High
11	Columbia	2	5.18	High
12	Porterville	1	4.06	High

Results

Figure 1 displays how total deployment time varies with LAT availability, using the first model presented in Equations 1-5. As expected, total deployment time decreases as LAT availability increases, reaching an overall minimum of 31.46 at full availability. Results are not presented below an availability rate of 0.55 because solutions are infeasible. At the rate of 0.55 total deployment time (63.64) is more than double that of full availability.
Figure 2 instead focuses on LAT air base assignments, summarizing how these assignments can vary with LAT availability. The figure compares the number of LAT assignments per air base under the baseline (full availability) scenario to the mean number of assignments across availability rates ranging from 0.55 – 0.95. Results indicate substantial variation in LAT air base assignments, suggesting a high

degree of sensitivity to LAT availability. Particular prominent differences are observed for air bases 2 and 3 (fewer assignments under baseline scenario) as well as air base 8 (more assignments under baseline scenario). Optimal LAT air base locations also differ significantly from current (as of 2011) actual LAT assignments (see Table 1).

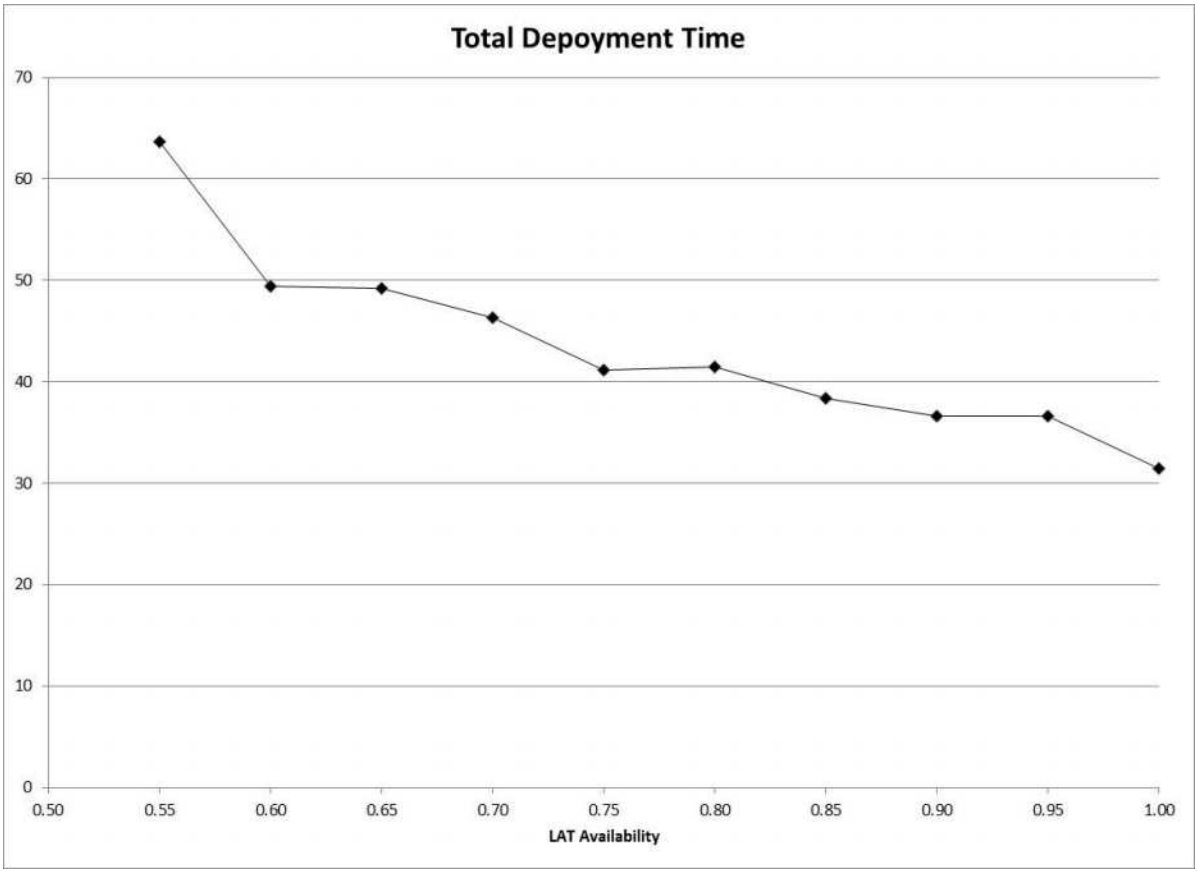

Figure 1. Total deployment time as a function of LAT availability

Table 2 compares total deployment times and LAT air base assignments across six LAT availability scenarios – those for uniform availability rates of 0.80, 0.70, and 0.60, as well as the low/high paired sets. At least over these availability rate combinations, the model performs better with variable availability rates, and in general shows substantial sensitivity to LAT availability. This is because the model preferentially selects air bases with low demand levels and therefore higher availability rates (see Table 1). For instance compare the number of LAT assignments to air bases 2 and 3 under uniform and variable availability rates.

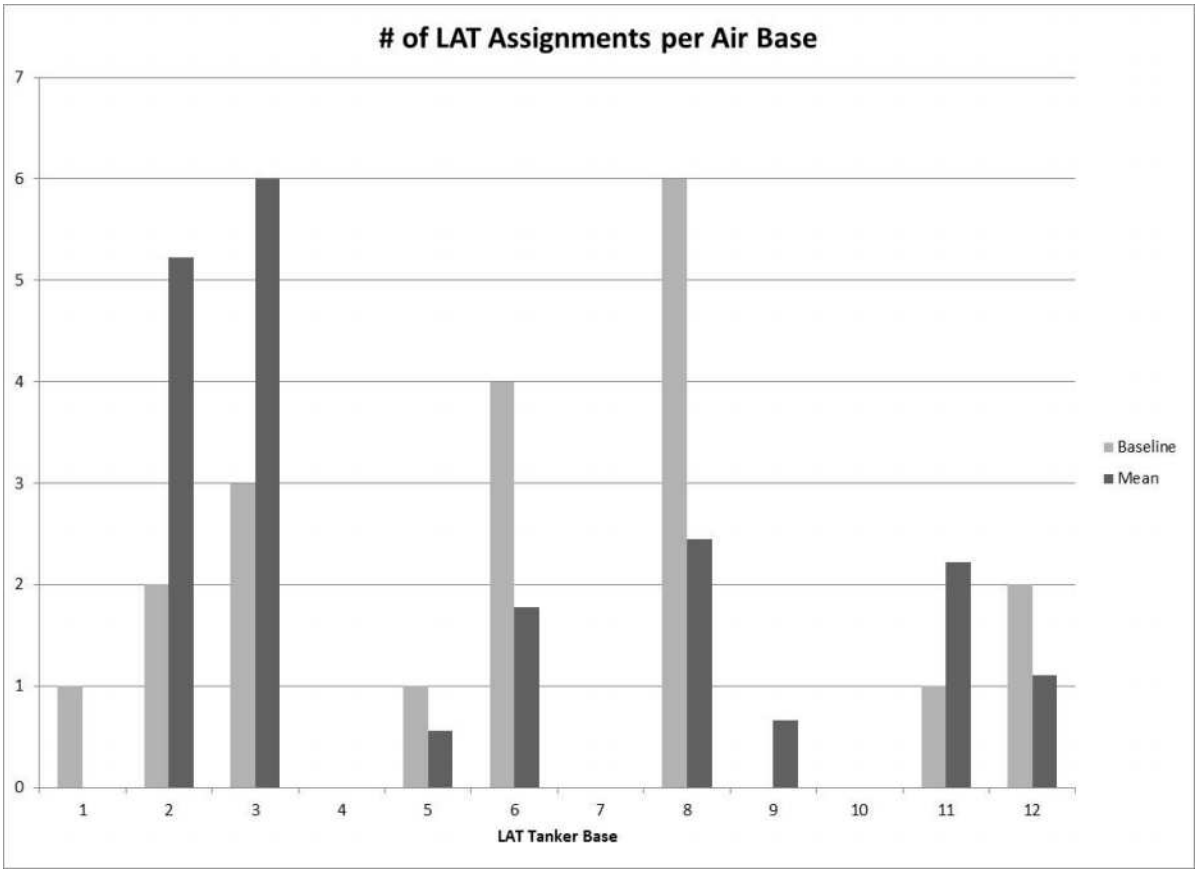

Figure 2. Number of LAT assignments per air base across different LAT availability scenarios

Table 2. Total deployment times and LAT air base assignments under different LAT availability rate scenarios

Air Base #	Uniform LAT Availability Rate Across Air Bases			Variable LAT Availability Rate Across Air Bases		
	0.80	0.70	0.60	0.70, 0.90	0.60, 0.80	0.50, 0.70
	Total Deployment Times					
	41.5	46.27	49.45	39.59	42.68	47.5
	Number of LAT Assignments per Air Base					
1	0	0	0	0	0	0
2	5	10	5	0	0	0
3	5	10	5	0	0	0
4	0	0	0	0	0	0
5	0	0	5	8	5	10
6	3	0	0	0	0	0
7	0	0	0	0	0	0
8	4	0	0	6	5	0
9	0	0	0	0	0	0
10	0	0	0	0	0	0
11	0	0	0	0	5	0
12	3	0	5	6	5	10

Figures 3-5 incorporate unmet demand based on the updated model incorporating Equations 6 and 7. Figure 3 displays total penalty-adjusted deployment times as a function of LAT availability, using a log-scale to better differentiate results at the higher availability rates. At rates below 0.55, where the original model becomes infeasible, objective functions with higher penalty rates begin to climb more steeply. Over the range 0.55 to full availability, results for the penalty weight of 25 are identical to results presented in Figure 1. Where the penalty for unmet demand is only 1, the solutions never fully me*et al*l demand because it is cheaper to incur the penalty than to travel to other air bases. Figure 4 further illustrates this relationship between unmet demand and deployment time where the penalty is 1, showing that unmet demand never drops to zero. Neither does deployment time exhibit a negative slope after availability of 0.55 (see Figure 1), again because the gains in availability are less important relative to the low penalty of not meeting demand. By contrast, Figure 5 shows the same relationships but where the penalty is 10. Travel time rises and unmet demand drops steeply until roughly the point where the problem becomes feasible. From that point forward deployment time continues to drop as availability increases, consistent with Figure 1.

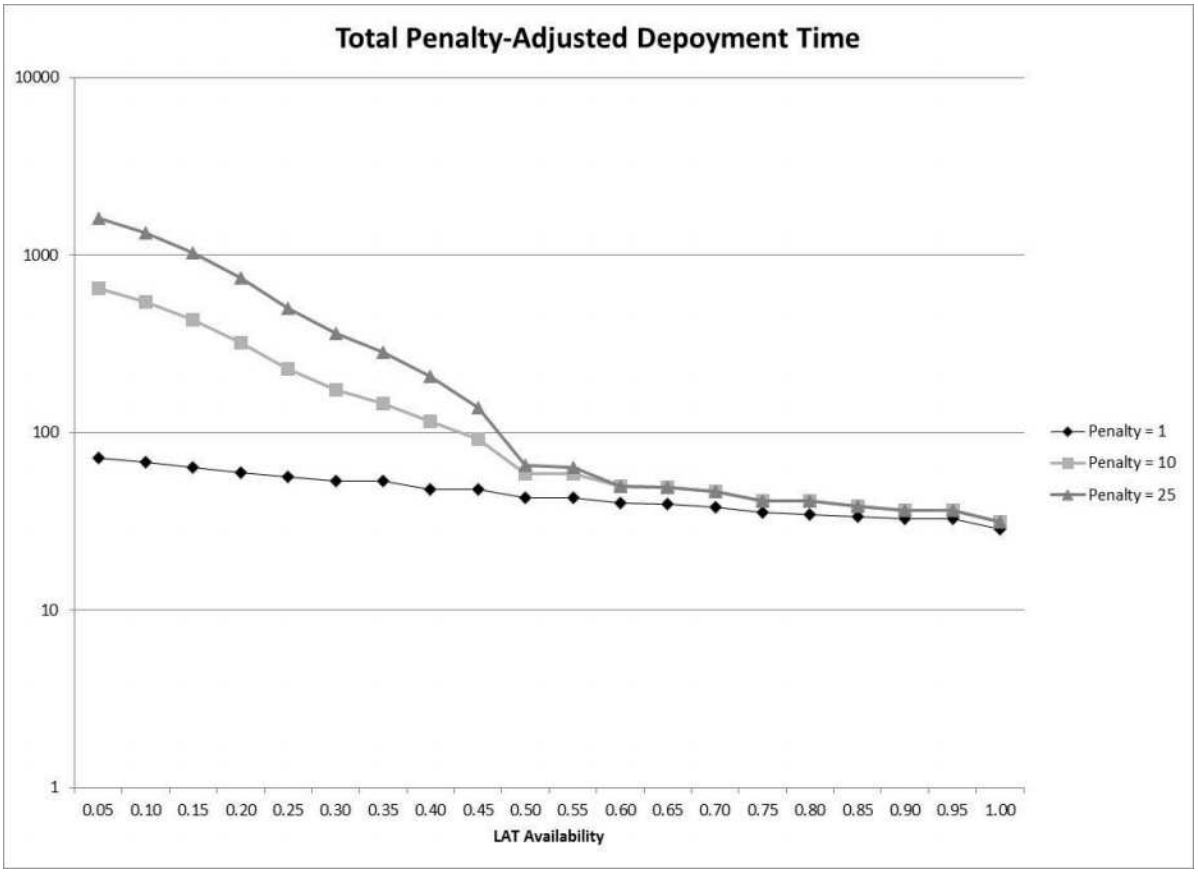

Figure 3. Total penalty-adjusted deployment time as a function of LAT availability

Discussion

We reviewed recent research indicating significantly different LAT usage patterns than has been typically assumed within LAT location and deployment optimization efforts. Specifically these models have assumed near total use for IA, whereas recent evidence suggests EA use can comprise a significant share of overall use. Additionally, recent research indicating low IA success rates on fires that receive LAT support during IA suggest possible inefficiencies in LAT usage. In response we

augmented a mathematical optimization model to explore trade-offs between IA and EA use, and examined model sensitivity to LAT unavailability for IA efforts.

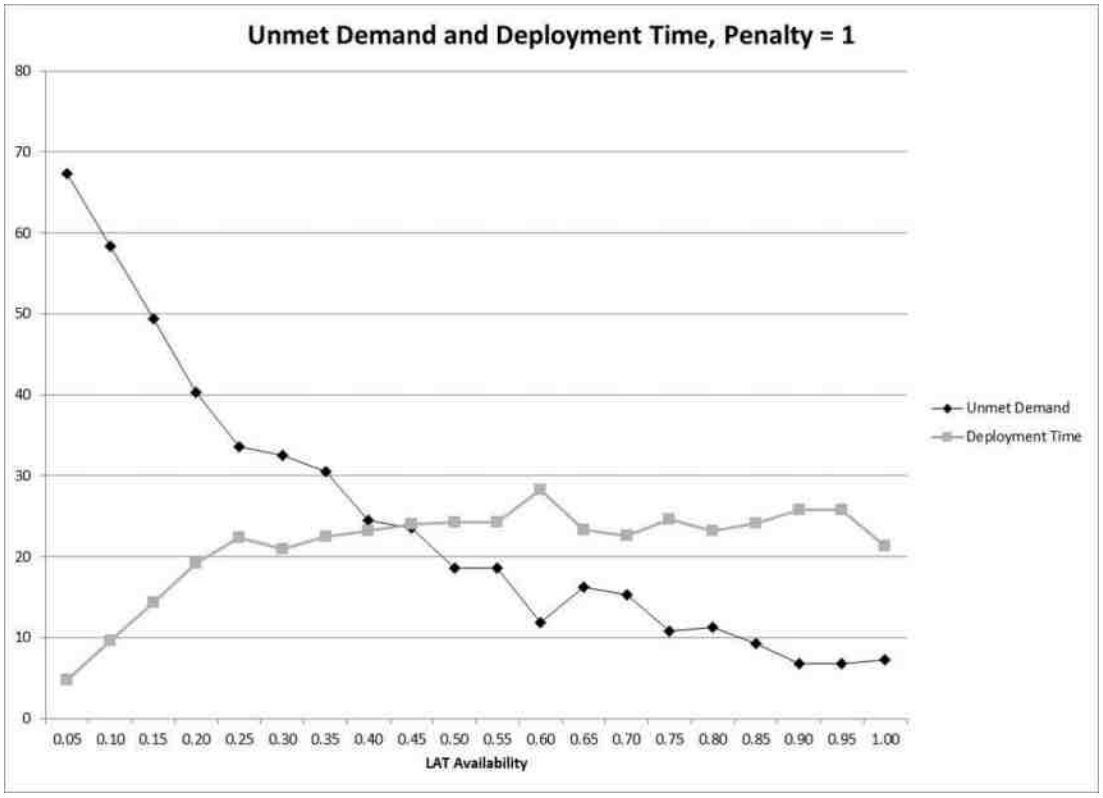

Figure 4. Unmet demand and deployment time as a function of LAT availability, penalty = 1

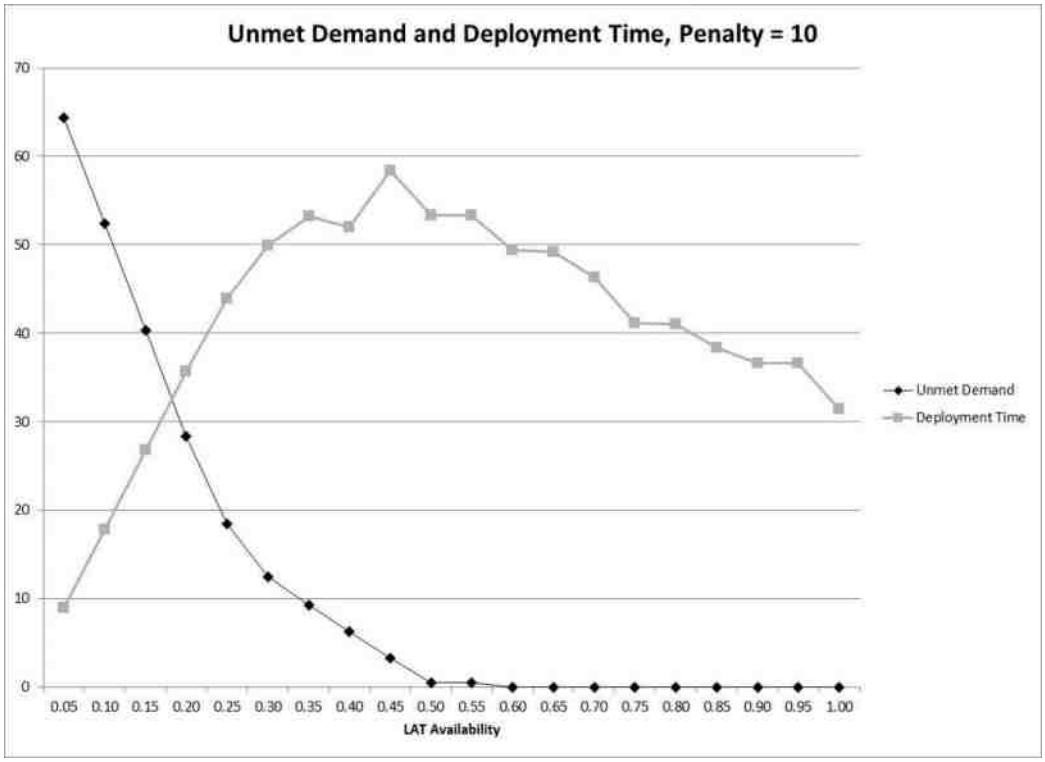

Figure 5. Unmet demand and deployment time as a function of LAT availability, penalty = 10

Our results indicated that model performance degrades as LATs become less available, and that results are highly sensitive to LAT unavailability. This sensitivity is particularly evident when examining optimal LAT air base locations (the same is true for optimal LAT deployment rules, not provided here for economy of presentation). These results could carry significant implications for efficient updating of LAT location and deployment strategies, especially when considering additional real-world factors like staffing needs and air base capacities. Our results also lead to questions of how changes in fleet size could mitigate or exacerbate potential IA/EA trade-offs. A more complete model would ideally seek to better compare with a common metric the costs and benefits of LAT use for IA and EA rather than focus on degraded IA performance, although data gaps still present significant challenges to building such a model.

One immediate extension to our model is to consider a dynamic model that can relocate LATs on a daily basis in response to observed and/or predicted fire activity (Chow and Regan 2011). This extension requires a more complicated framework and increased computational demands, a verifiable ability to forecast future aerial firefighting needs, and an approach to translate relocation costs to the value of improved deployment time considering factors such as avoided damages. Further, incorporating LAT unavailability into the model on a daily basis would require a more complicated model to characterize LAT unavailability due to EA support. However, this approach can better capture the nature of a truly dynamic suppression organization that makes responsive location and relocation decisions. This modelling approach may also better illustrate opportunities for efficiency gains relative to current practice.

Additional future modelling efforts could consider variation in demand in addition to supply, could explore probabilistic efforts to better capture possible pulses of high IA activity, and adopt combined simulation-optimization efforts. Additional research to calibrate and parameterize these models is necessary as well. These efforts could seek to quantify the predictive skill of fire weather forecasts as well as the degree to which these forecasts influence suppression resource prepositioning. Critically, research efforts will need to better characterize the benefits and costs of LAT usage to move beyond the simplistic model based on travel time alone. Thus, beyond modelling efforts, continued empirical analysis of LAT usage, fire outcomes, and particularly drop effectiveness are warranted.

Abstract
An appropriate system of fire detection and proper preparation of the forested areas for emergency and fire extinguishing activities have a significant impact on the magnitude of losses caused by forest fires. The basis of the forest fire protection planning is the forest categorisation in the context of fire risk, which is performed on the basis of the percentage of area covered by the most vulnerable habitats: dry coniferous, fresh coniferous, fresh mixed coniferous, wet coniferous, wet mixed coniferous and riparian forest. Maps of forest habitat are available for the State Forests however for private forests this information does not exist, so the proper categorisation of fire risk in these forests is very difficult and costly. The object of the study is to develop a method for the estimation of the area cover of the above-mentioned forest habitats using open source data Corine Land Cover (CLC) database and SRTM - Digital Terrain Model in order to fill the information gaps for the private forests. Employing GIS environment the analysis of the correlation between CLC land cover classes and specific forest habitat was performed. Then, the terrain characteristics such as curvature and slope were correlated with habitat humidity. Also, the shape analysis of units was carried out. On the basis of these three parameters was estimated the areas covered by fire vulnerable habitats for forest inspectorates in central and north-west Poland where the state forests constitute 98% of the area so the ground verification data was accessible for almost the entire terrain. The overall agreement between obtained and reference maps is 89%, and the error of the estimation of the specific fire vulnerable habitats is lower than 20%. The proposed method is relatively fast and low-cost and may be used for fire risk categorisation of the forested areas where the ground verification information is not available.

Keywords*: fire detection, Corine Land Cover (CLC), forest habitat*

Introduction

The appropriate organisation of the fire detection system and preparation of forest areas to conduct prevention-extinguishing activities has a significant influence on the size of losses caused by forest fire. The basis for planning activities in the extent of forest fire protection is the forest fire risk category (KZPL). It is determined according to the requirements specified in the Ordinance of the Minister of the Environment of the 22nd of March 2006 concerning detailed principles of forest fire protection of forests (Journal of Laws No. 58 entry 405 with subsequent amendments). It concerns forests of a similar level of susceptibility to fire, established on the basis of frequency of fire occurrence, stand and climatic conditions and anthropogenic factors. This category is established on the basis of the sum of points resulting from calculations for four, following parameters:

a) average annual number of forest fires in the period of the last 10 years per thousand hectares of afforested area,
b) sums of percentage participation of stands growing in habitats: dry forest, fresh forest, moist forest, moist mixed forest and riparian forest,
c) average relative air humidity at height of 0.5 m and percentage of days with air humidity less than 15% at the hour of 9.00,
d) average number of inhabitants per hectare of forest area.

The range of forest habitat types (STL) considered in the establishment of KZPL results from analysis of flammability of forests presented in the study "Categorisation of fire risk of Polish forests" (Szczygieł *et al*. 2009, in which to categorise flammability is used the flammability indicator, being the quotient of the share of the number of fires of given stands to the areas of these stands. As flammable habitats, the share of which is influences KZPL, those are recognised, for which this indicator is greater than the units. They are: dry coniferous forest (Bs)-4.39, moist coniferous (Bw)-1.81, fresh coniferous forest (Bśw)-1.66, fresh mixed broadleaved forest (BMśw)-1.30, moist mixed coniferous forest (BMw)-1.18 and riparian forest (Lł)-1.03.
Insofar as for forests managed by State Forests National Forest Holding the decisions of KZPL do not give rise to greater difficulties and are updated each time while drawing up forest management plans, to that extent for remaining forests, principally private, its decisions cause significant difficulties. This is connected primarily with the lack of detailed information, concerning the proportion of surface area covered by particular forest habitat types. In individual provinces these forests consist of from 2.9 to 54.2 per cent of the afforested area. Equally the density of occurrence of fires in particular years in the period 2003-2012, as also the average area of one fire are clearly greater for forests in other forms of ownership, in comparison to forests managed by State Forests (Figure 1).

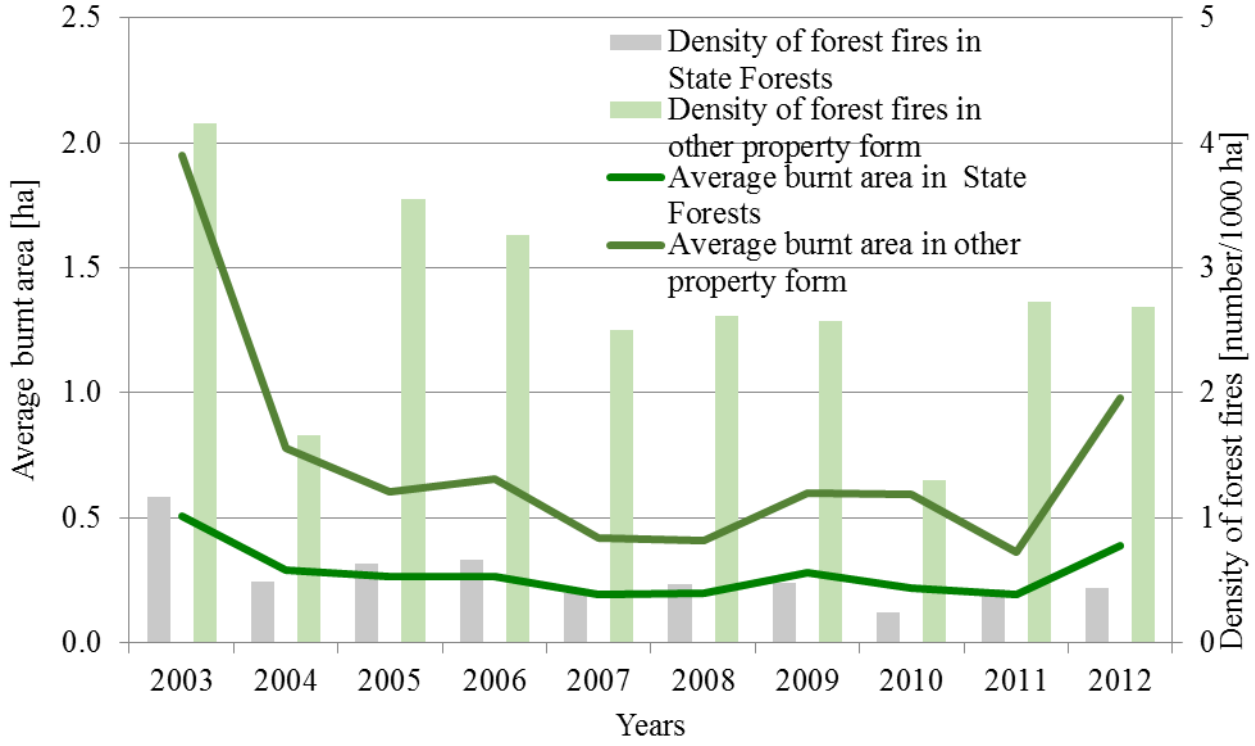

Figure 1. The occurrence of forest fires in the years 2003-2012

Density of occurrence of fires in State Forests is fivefold less in comparison to forests in other forms of ownership, fluctuating in particular years between 3.4 and 6.4. Equally the average area of a single forest fire in forests in other forms of ownership is significantly greater (from 1.9 to 3.8) than in State Forests. In this situation it is essential to seek a method determining the proportion of surface area taken by habitats Bs, Bw, Bśw, BMśw, BMw, Lł, enabling appropriate determination of KZPL for these forests, and in consequence appropriate preparation of forest areas for the conduct of prevention-extinguishing activities. This problem is diligently solved by drawing up a modelling method for proportion of selected forest habitat types on the basis of the Corine Land Cover land-use map and numerical terrain models.

Comparative works to the CORINE maps and models exist in the databases of national forest maps and for defining its suitability in forest cartography on regional scales (Waser, Schwarz, 2006). Because of the great generalisation of information, direct interpolation of data is not possible, especially in mountainous areas typified by great heterogeneity. In such a situation it is essential to use various auxiliary materials in order to increase the spatial resolution of CORINE. Such assumptions were accepted by Pekkarinen *et al*. (2009) in the cartography of afforested areas. It is simultaneously supported by Landsat ETM+ satellite photographs. In the work presented below the increase of CORINE spatial resolution is obtained by use of numerical terrain model.

Area of research

For the purpose of drawing up the habitat designation method two research areas were chosen. The first research area served as a research area, the second as a testing area. For the research area was chosen the territory of the following Forest Districts: Dobieszyn, Kozienice, Marcule, Radom and Zwoleń of a combined area of approximately 500 000 ha, among which almost 63 000 ha is covered by forest, managed by these forest districts. The combined area of forests on the territory of these forest districts according to CORINE amounts to 101 816 ha. The basic characteristic of the stands of these forest districts in comparison to conditions for the area of all Poland is shown in figures 2-4. These forest districts are typified by proportions of high flammability class habitats: dry coniferous forest, fresh coniferous forest, moist coniferous forest, fresh mixed broadleaved forest, moist mixed broadleaved forest and riparian forest that are close to the national average. Equally the distribution of forests in specified age group is similar to the national average. In relation to Polish forests as a whole, in these forest districts there is an approximately 20% greater proportion of pine stands.

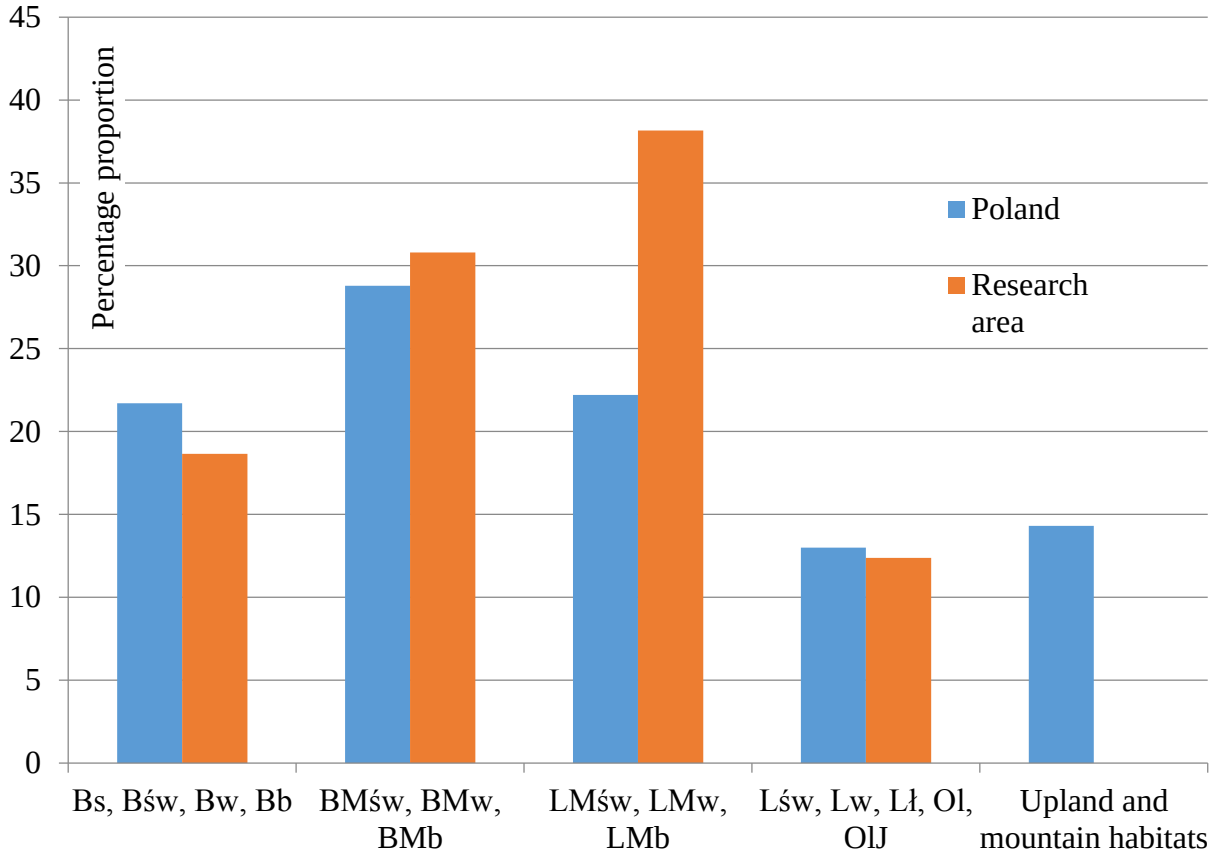

Figure 2. Percentage proportion of stands according to forest habitat types

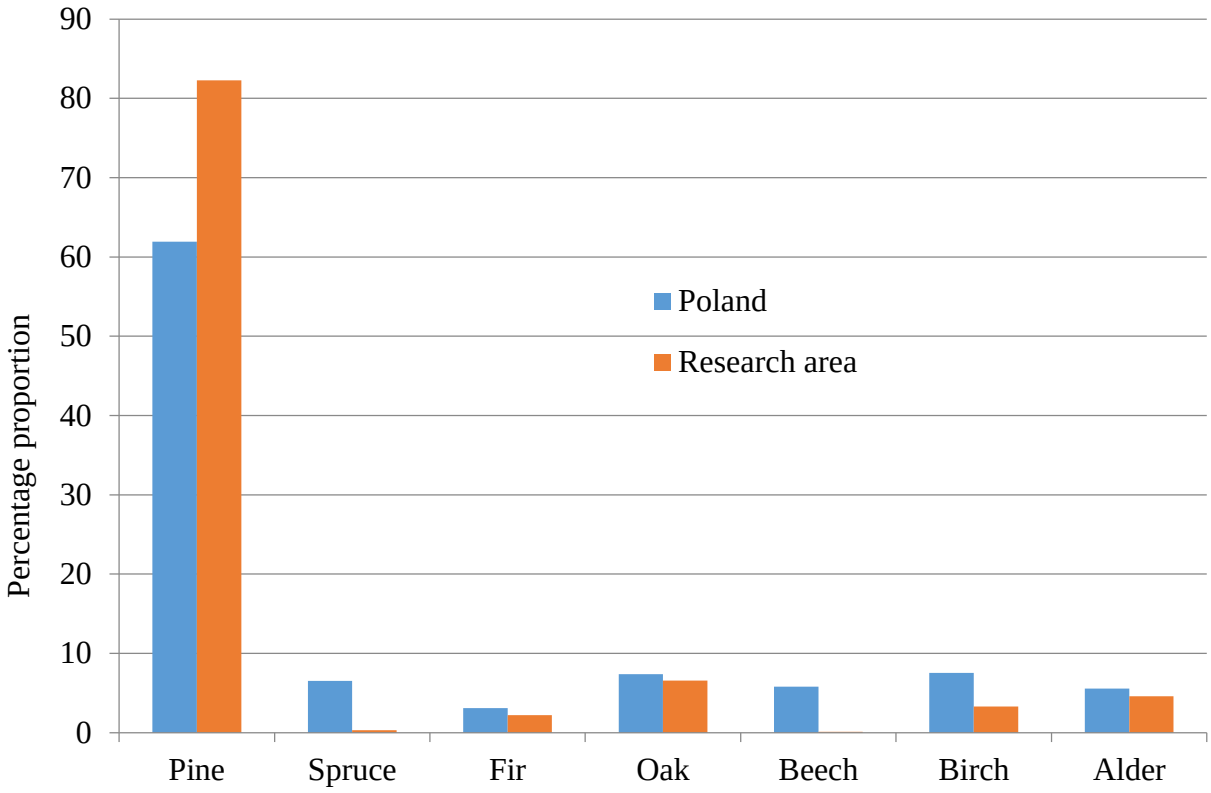

Figure 3. Percentage proportion of stands according to prevailing species

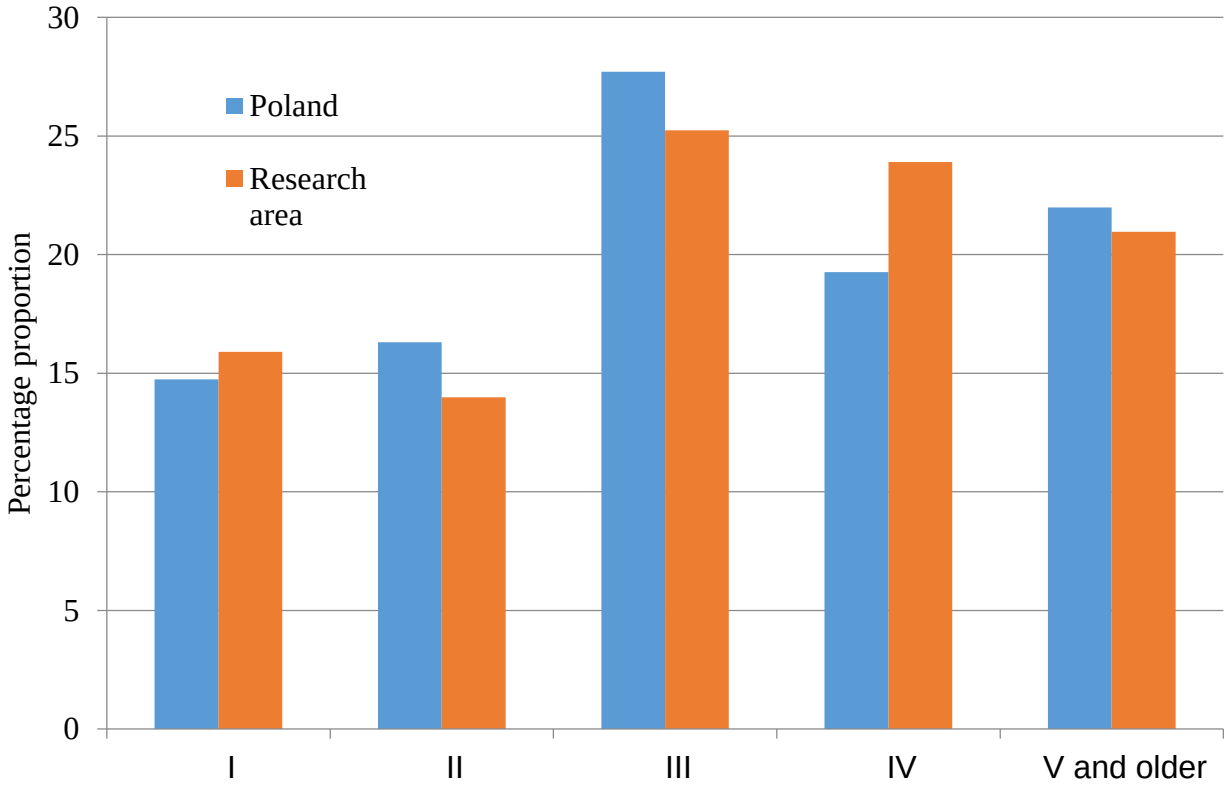

Figure 4. Percentage proportion of stands according to stands age

In the verification of the drawn up method it was applied to the area of forest districts within the whole or part of the province of Western Pomerania (57 forest districts). This area was chosen with regard to the virtually 98% share of state forests in the ownership structure of forests in the given province.

Source data

In the study, data generally available with the aid of Internet services was used. The basis for the performance of the work was the terrain use data CORINE Land Cover – CLC2000 and also data of the numerical terrain model SRTM (Shuttle Radar Topography Mission). For reference material the Forest Numerical Map supplied from the State Forests database was used.

3.1. CORINE Land Cover 2000 Database

The CLC2000 database is constructed in three hierarchical levels. The first level (European) differentiates 5 basic groups of terrain cover, agricultural, forest and semi natural ecosystems, boggy terrains and water. The second level (regional) separates 15 classes and the third (national) distinguishes 44 classes, of which 31 occur within Poland. In the study only three classes are used from the third group - forests and semi natural ecosystems: 3.1.1 deciduous (broadleaved) forests, 3.1.2 coniferous forests, 3.1.3 mixed forests. Their definitions are placed below.

Deciduous forest - code 3.1.1. - This class includes botanical communities consisting primarily of trees, with regard to the undergrowth layer, where deciduous species are dominant. The crowns of the trees should cover over 30% of the surface and deciduous trees should represent over 75% of the stand. The height of trees of this class should exceed 5 m in normal climatic conditions.
Coniferous forest - code 3.1.2. - Flora classified as coniferous forest should consist primarily of trees, with regard to the undergrowth layer, where coniferous species are dominant. Similarly to the deciduous forests the height of the trees in this class should exceed 5 m. Coniferous trees should represent over 75% of the stand.
Mixed forest - code 3.1.3. - General class definition is similar to the preceding cases i.e. flora should consist primarily of trees, with regard to the undergrowth layer and height of trees in this class should exceed 5 m. Nonetheless however percentage participation of deciduous or coniferous may not be dominant.

CORINE Land Cover map sheets covering the study terrain were taken from the website of the European Environment Agency (European Environment Agency) http://www.eea.europa.eu/themes/landuse/interactive/clc-download in .shp. format. Subsequently the reproduction of the maps obtained was changed to UTM zone 34, reference system WSG84.

3.2. Numerical Terrain Model

Numerical Terrain Model (NMT) SRTM was obtained for Polish terrain from the website http://srtm.csi.cgiar.org/SELECTION/inputCoord.asp in format GeoTiff. This model has spatial definition of 80 m. For the needs of the work the terrain definition of the model was increased to 30 m. The sheets taken were joined in one layer and the reproduction was changed to UTM zone 34, reference system WGS84. Then two types of errors occurring in the model were located: height value anomaly, above 2600 m above sea level and lacking pixels and designated as no data. Corrected anomalous pixel values and supplementation of lacking pixels through interpolation with nearest surroundings.

3.3. Numerical forest map

Reference data are obtained from Numerical Forest Map, which contained basic data concerning all designated forest areas lying within the boundaries of the research polygon. These areas are designated

during the drawing up of forest management plans for piece of land constituting a part of uniform forest section with regard to biotope and biotic forest community. For each of these data is available relating to:

- forest habitat type,
- layered vertical zones structure,
- area,
- layer structure,
- species composition,
- age of stand
- height of stand
- density.

Methodology and results of studies

4.1. Analysis of occurrence of CLC terrain cover class and types of forest habitats.

In order to verify the comparability of data of particular habitat types they were pre-classified according to CORINE nomenclature, those in which percentage share of coniferous trees in the stand exceeded 80% were classified as class 3.1.2, those in which percentage share of deciduous trees in the stand exceeded 80% were classified as class 3.1.1 and the remainder as mixed 3.1.3. Percentage proportional quantities of particular CLC classes in succeeding habitat types being the object of interest are shown in table 1. From the table it is seen that with a very high probability it may be stated, that CLC classes of coniferous and mixed forests shall correspond to forest classes on forest map. Riparian forest habitat type completely fulfils the criterion of CLC deciduous forest. Remaining types in an exceptional majority correspond to CLC criterion for deciduous or mixed forest degree.

Table 1. Percentage share of quantity allocation of specific classes of Corine Land Cover in analysed habitat types.

Habitat type	CLC 3.1.1	CLC 3.1.2	CLC 3.1.3
Dry coniferous forest	2%	89%	9%
Moist coniferous forest	4%	74%	22%
Fresh coniferous forest	4%	67%	29%
Fresh mixed coniferous forest	4%	52%	44%
Moist mixed broadleaved forest	10%	36%	54%
Riparian forest	98%	0%	2%
Other forests	65%	15%	20%

4.2. Study of profile indicators on the basis of numerical terrain model to achieve a more detailed localisation of habitats

Each habitat is associated with a specific genetic soil type, which in turn is associated with the sediment deposit type, from which it is created. Depending on the origin and mechanical composition of deposit subjected to various types of geomorphologic processes and differing intensities, it is reflected in the shape of the terrain. The predominant part of Poland is covered with Quarternary formations of glacial, water, river, lake and aeolian origin. Various types of loose sands, clay sands, clays, dusts or silts dominate. Bearing in mind equally: origin, manner of settlement, resistance to processes occurring on the surface, as also age of deposit it may with considerable generalisation be stated, that terrains constructed of older substrates are flatter, and those in areas with a sandy substrate have a less varied terrain topography. Together with increase of the values of silts in surface formations, reaching the level of heavy clay, the morphological sculpting is ever more varied. Areas formed from silts are typified by a large quantity of deep cut ravines. Areas formed from silts are normally flat. This is the result of sedimentation processes, which lead to the creation of geological formations.

On the basis of the numerical terrain model the degree of terrain topography variation may be defined through definition of two parameters: terrain inclination and its curvature (Zeverbergen, Thorne, 1987, Moore *et al*. 1991). Variable terrain inclination is generally known and does not require further comment, if however it concerns curvature of terrain this defines three basic situations: flat terrains, concave terrains and convex terrains.
In table 2 are shown an average dimensions of standard deviation values, and also span of extent of terrain curvature and inclination of slopes for particular types of forests, with the exception of dry coniferous forest, the rare appearance of which in the studied terrain prevented taking the appropriate samples. From the table it is shown that terrain curvature enables separation of fresh and moist habitats. Fresh habitats are typified by an average terrain curvature exceeding 0, corresponding to areas with "curvature" dominance, moist habitats though are typified by values less than 0.006, corresponding to "concave". Mixed forest habitats are characterised by greater deviation of standard terrain inclination.

Table 2. Values of terrain shaping indicators for forest habitats

	Incline of slopes			**Curvature**		
STL forest types	Variation extent	Average	Standard deviation	Variation extent	Average	Standard deviation
Fresh coniferous	5.5874	1.2071	**0.8887**	0.6719	**0.0071**	0.0644
Fresh mixed forest	7.2093	1.1821	**0.9588**	0.6563	**0.0070**	0.0600

4.3. Study of terrain shape indicators to achieve very detailed habitat localisation.

Shaping indicators may provide information on circularity, extension and degree of complication of polygons. In the case of definition of types of forest habitats, shape parameters have great significance in the emergence of riparian forests among all deciduous forests. The PARA shape indicator being the relationship of the polygon circumference to its surface area describes the degree of elongation of polygons or their shape complication. Poligony, for which the PARA indicator is less than 0.007, does not correspond to riparian forest shape criteria. Polygons described in PARA with greater value than given threshold value may be riparian forests, but additional criteria are necessary in order to separate them from other forests with an elongated shape.

4.4. Developing method of habitats designation on the basis of CLC and previously enumerated indicators.

With regard to excessive numbers of polygons for showing on CLC maps (minimal area 25 ha) additional terrain division was made. Utilising the numerical terrain model, areas were designated every 30 m of height, and then CLC polygons were "fragmented" with the use of the designated areas. Thus was segmentation achieved of terrain surface polygons, which enabled the obtaining of more precise statistics for smaller polygons. For particular habitats of high flammability groups a procedure was drawn up leading to the imaging of the given habitat on map. Dry coniferous forest constitutes an exception, because of the very small statistical size of the classification. Basic layers used to designate these habitats are: CORINE Land Cover (CLC) map and also those received from numerical terrain model of declines and curvatures. In some instances other variables were also used, which were described together with the necessitating case.

Moist coniferous forest was designated on the basis of the following routine:

1. polygons coded as coniferous forest were selected from the CLC map (3.1.2),
2. average terrain curvature and standard deviation from terrain inclination values were calculated for the selected polygons,
3. polygons of curvature less than 0.006 and standard deviation of terrain inclination less than 0.9 were reclassified as moist coniferous forest. Fresh coniferous forest was designated on the basis of the following routine:
4. polygons coded as coniferous forest were selected from the CLC map (3.1.2),
5. average values of terrain curvature and standard deviation of terrain inclination were calculated for the selected polygons,
6. polygons of curvature greater than 0.006 and standard deviation of terrain inclination less than 0.9 were reclassified as fresh coniferous forest. Fresh mixed coniferous forest was designated on the basis of the following routine:
7. polygons coded as coniferous forests were selected from the CLC map (3.1.2),
8. average values of terrain curvature and standard deviation of terrain inclination were calculated for the selected polygons,
9. polygons of curvature greater than 0.006 and less than 0.02 and standard deviation of terrain inclination greater than 0.9 were reclassified as fresh coniferous forest,
10. polygons coded as mixed coniferous forest were selected from the CLC map (3.1.3),
11. polygons of curvature less than 0.007. Moist mixed forest was designated on the basis of the following routine:
12. polygons coded as coniferous forest (3.1.2), were selected from the CLC map
13. average values of terrain curvature and standard deviation of terrain inclination were calculated for the selected polygons,
14. polygons of curvature less than 0.006 and standard deviation of terrain inclination greater than 0.9 were reclassified as fresh coniferous forest. Riparian forest was designated on the basis is the following routine:
15. polygons coded as deciduous forest (3.1.1) were selected from the CLC map
16. PARA indicator values were calculated for selected polygons,
17. selected polygons of PARA indicator greater than 0.007,
18. water flows system was generated from the numerical terrain model,
19. only those deciduous forests were classified as riparian forests, which fulfilled the condition of elongated shape and at least partially covered with water flows and having a surface area less than 500 ha.

4.5. **Method validation**

Habitat maps received with the aid of described procedures were compared with the Digital Forest Map. Analysis was conducted of the percentage surface share taken by particular habitats (figure 5). A large conformity of results is visible, though an increased share of riparian forest habitats should be noted. Perhaps is a result of fact that they are mainly outside the area of State Forests.

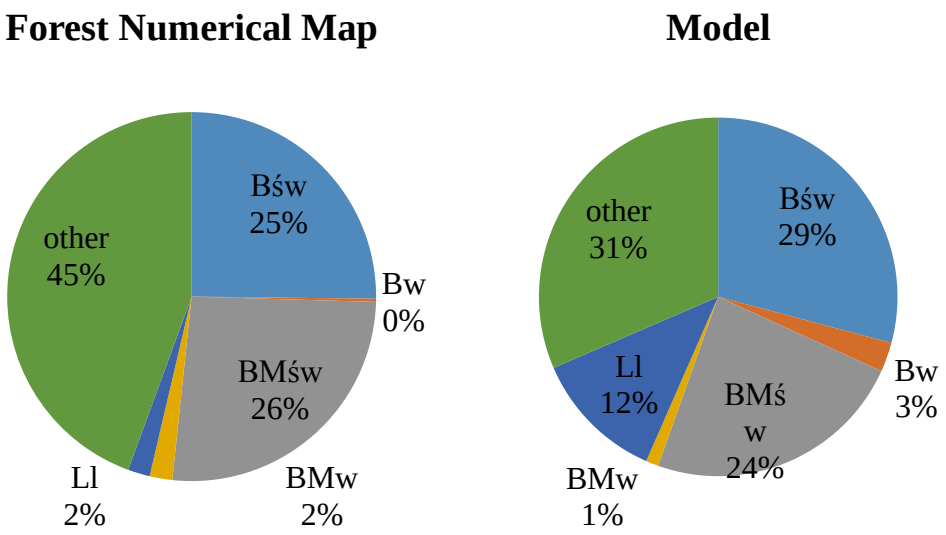

Figure 5. Percentage share of habitats according to numerical forest map and model

Application of method for the Western Pomerania province

On the terrain of forest districts being at least partially within the Western Pomerania province there are 1 130 918 ha of forest according to Corine CLC and 1 006 647 according to forest reports. As a whole the difference of forest areas between the two sources of information amounts to 124 270 ha, which constitutes 12% of the total area.
Habitat modelling results are shown in figure 6. The greatest percentage participation of habitats with a high flammability indicator is found in forest districts located in the southern and eastern parts of the province. The least percentage of these habitats may be noted in the central part of the province.

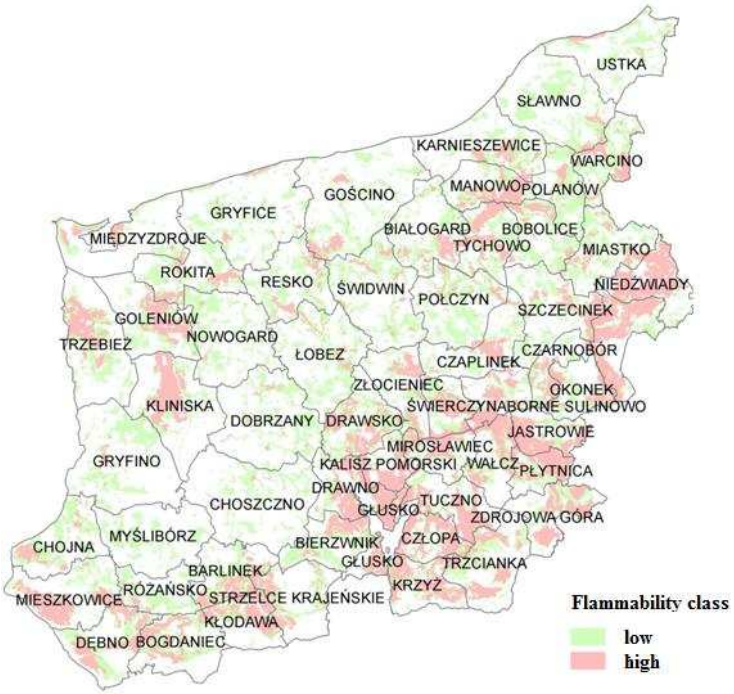

Figure 6. Habitat map according to flammability class indicator in forest districts of Western Pomerania province

At the provincial level 89% conformity was received, relating to surface area of groups of habitats of high flammability. In 39 out of 57 cases the error of designation of percentage of habitats of high flammability class did not exceed 20%. In 4 cases, where this error was greater than 20% it might equally be noted that the total forest surface difference according to Numerical Forest Maps and Corine Land Cover is greater than 21%. One may therefore accept that the difference in percentage participation of flammable habitats may arise from differences of types of habitats of forests contained in the digital forest map and those charted in the CORINE database. From this it results that 76% of forest districts estimated percentage participation of flammable habitats with an error not exceeding 20%. In 44 cases follows the estimation that may equally result from a greater forest area charted in comparison with the CORINE database. Considerable non-estimation, exceeding 30%, was noted only in two forest districts: Barlinek and Kłodawa. Perhaps this results from generalisation of the CORINE database, where small single patches of forest other of mixed and coniferous forest interlaced with each became jointly classified as mixed.

Summary

The method presented above enables the definition of percentage participation of habitats of a high flammability in forests on the basis of generally available low resolution data.
The difference of proportion of flammable habitats in the study area is established according to Forest Numerical Map and the study model is connected with the significant difference in forest area of forests being managed by forest districts being part of this area and areas of forests charted on the basis of Corine data.
Differences in the precision of methods for the study area (Forestry Districts: Dobieszyn, Kozienice, Marcule, Radom and Zwoleń) and the control check area (forestry districts being at least partially in the Western Pomerania province) may suggest that it requires local calibration of thresholds accepted in the method. This may be associated with a different geological substrate and type of terrain shape in both areas, which have an influence on values of indications.

Abstract
Fire management systems materialize the integration of fire science models and decision support planning modules. Their operational usage often requires the concurrent execution of a large number of fire growth simulations by multiple users. Intensive computations such as the creation of burn probability maps demand not only high expertise but also high computing power and data storage capacity.
The purpose of this paper is to present some of the initial results of the AEGIS platform, which is a Web-GIS wildfire prevention and management information system currently under development. More specifically, the paper focuses on the utilization of the Minimum Travel Time (MTT) algorithm as a powerful fire behavior prediction system. MTT in AEGIS will be applied in a transparent way through its graphical user interface. Several end users will be able to conduct on-demand fire behavior simulations. To achieve this, end users must provide a minimum amount of inputs, such as fire duration, ignition point and weather information. Weather inputs can be either inserted directly or derived from selected remote automatic weather stations or forecasted weather data maps based on the SKIRON system (Eta/NCEP model).
Seasonal burn probability maps will be also prepared and provided to the end users. Socioeconomic data, weather predictions, topographic and vegetation data will be combined with artificial neural networks to produce an ignition probability map. Based on the ignition probability map, thousands of potential ignition points located in areas of anticipated high risk will be generated. These ignitions will be further used as inputs on MTT simulations, running FConstMTT as a command line-based executable. FConstMTT calculations will be conducted on a parallel mode in Microsoft Azure infrastructure using a different subset of ignition points in each simulation.
The current deployment of the AEGIS platform consists of a number of machines resided on premises and a scalable Cloud Computing environment based on the Microsoft Azure infrastructure. This parallel computing environment ensures high processing power availability and high data storage capacity. During a fire emergency, the scalability of the Cloud can also provide extra processing power and storage, if needed. It is anticipated that by integrating MTT into the AEGIS platform, the firefighting and civil protection agencies will gain great assistance to organize better and more reliable plans for fire confrontation.

Keywords*: Minimum Travel Time (MTT); Ignition Risk; Wildfire Behavior; Burn Probabilities; FConstMTT; Cloud Computing; Web-GIS*

Introduction

Large wildfires break out on an annual basis causing problems for societies and firefighting agencies across several fire prone areas of the world. Information technology provides the means for the utilization of sophisticated solutions on pre-fire management and planning, post-fire effects mitigation and potential wildfire behavior evaluation.

Towards the development of effective fire management operational systems, the integration and utilization of fire behavior and risk models and decision support planning modules plays an important role. Today's firefighting needs demand systems that are able to conduct on a timely manner and without devastating delays multiple concurrent fire behavior predictions for several different users of fire suppression and civil protection agencies involved. However, this kind of operation requires trained and skilled operators with expertise in fire propagation simulation and behavior modeling. In advance, substantial computing resources are required to conduct these intense spatiotemporal calculations; nevertheless, local civil protection agencies often do not own these resources due to limited financial means (Kalabokidis *et al*. 2014).

To deal with the aforementioned issues, the Web-GIS wildfire prevention and management information system AEGIS is currently under development. AEGIS will be a cost effective, easy to use forest fire management system that will utilize the Minimum Travel Time (MTT) algorithm (Finney 2002) as a powerful and sophisticated cell-based tool for fire behavior predictions, fuel treatments and fire risk estimation. The MTT algorithm is applied in strategic and tactical fire management planning throughout the United States (Andrews 2009) integrated into the Wildland Fire Decision Support System (WFDSS) (Pence and Zimmerman 2011). It actually typifies wildfires in the Mediterranean region, which are relatively short in duration with respect to those in the western USA. AEGIS is applied on seven study areas of Greece with different environmental and socioeconomic characteristics.

The scope of this paper is to present some of the initial results of MTT incorporation into the AEGIS platform. MTT in AEGIS is applied in a transparent way through a Web-GIS platform for a single fire simulation. Several end users are able to conduct concurrently on-demand fire behavior simulations by providing a minimum amount of inputs, such as fire duration, ignition point and weather data. Beside the predefined weather data by the user, the simulation can be also based either on real weather data retrieved from Remote Automatic Weather Station (RAWS) of the study area or can be based on predicted weather conditions retrieved from a weather prediction model that supports the platform.

Seasonal burn probability and flame length maps are automatically generated periodically (when the weather pattern is suspected to change), by simulating thousands of possible wildfire ignitions across each study area. Simulations are conducted by applying parallel computer processing techniques of High Performance Computing (HPC) that resides on premises and/or Cloud Computing of Microsoft Azure. ArcGIS Server is utilized for storing the outputs in geo-databases and creating the visualization services that enables end-users to see the results in the Web-GIS platform over high resolution satellite Bing Maps[1].

The Minimum Travel Time algorithm

The MTT algorithm can either compute the potential fire behavior characteristics (spread rate, fireline intensity, time of arrival, flow paths, etc.) for a single fire or burn probabilities/ flame length for the entire landscape from thousands of simulated fires based on landscape data, weather and fuel moisture information. The fire perimeters created by MTT are similar to wave-front expansion (Richards 1990; Finney 2002), but they are mathematically and computationally more efficient. Holding all environmental conditions constant, the MTT algorithm searches for the fastest path of fire spread along straight-line transects connected by nodes (cell corners) (Finney 2006) and it exposes the effects of topography and arrangement of fuels on fire growth (Ager and Finney 2009).

The MTT algorithm replicates fire growth by the Huygens' Principle, where the fire edge growth (and behavior) is a vector or wave front (Richards 1990; Finney 2002). While holding environmental

[1] http://www.bing.com/maps

conditions constant, fire growth calculation exposes the effects of topography and arrangement of fuels on fire growth (Ager and Finney 2009). Extensive testing over the years has demonstrated that the Huygens' Principle, originally incorporated into FARSITE (Finney 1998) and later approximated in the more efficient MTT algorithm, can accurately predict fire spread and replicate large fire boundaries on heterogeneous landscapes (Ager *et al*. 2010; Arca *et al*. 2007; Carmel *et al*. 2009).
In addition to fire spread that is predicted when a new fire spot is provided, MTT has the advantage of producing the burn probability of the entire study area by simulating thousands of potential fires that could burn throughout the area. It permits Monte Carlo simulations of many fires (>100,000), to evaluate burn probability and fire intensity for very large (>2 million ha) landscapes (Ager and Finney 2009). Burn probability is an estimate of the likelihood of a pixel burning given a single random ignition under burn conditions in the simulation. The likelihood measures are required for quantitative risk assessments. Burn probability modeling represents a major advancement in wildfire behavior modeling compared to previous methods, such as those where fire likelihood was quantified with relatively few (<10) predetermined ignition locations. As a result, the product of this process is the burn probability map that reveals which areas are more susceptible to encounter a fire event and which are less.

Methodology

The system architecture is structured by combining different on-premises and Cloud resources. On demand single fire simulations are conducted inside an on-premise Datacenter, while seasonal burn probability outputs are initially calculated in four Virtual Machines (VMs) in the Cloud infrastructure of Microsoft Azure (8x cores machines, 14 GB RAM, 1.6 GHz) and then finalized in an on-premise HPC cluster environment (24x cores machines, 8 GB RAM, 2.9 GHz) that contains 4 VMs. All fire behavior outputs are handled and visualized by using an ArcGIS Server deployment, installed on premises.
For the creation of the burn probability maps, cloud resources are utilized on specific time frames, when the weather pattern is suspected to change. During such a time frame, the VMs in the Cloud are allocated and command line-based executables of MTT (called FConstMTT) are running simultaneously on each VM. On the other hand, on demand fire simulations are better suited to run on premises than in the Cloud. This is because of the significant amount of time overhead (approximately 15 min) required to allocate new VMs in Microsoft Azure. On demand fire behavior simulations need to be conducted instantly and thus, time overheads should be minimized to achieve a timely and effective response when a wildfire breaks out.
After the execution in the Cloud's and/or on-premises VMs, output results are handled by the ArcGIS Server on premises which enables the visualization of the results from the graphical interface of AEGIS (Figure 1).

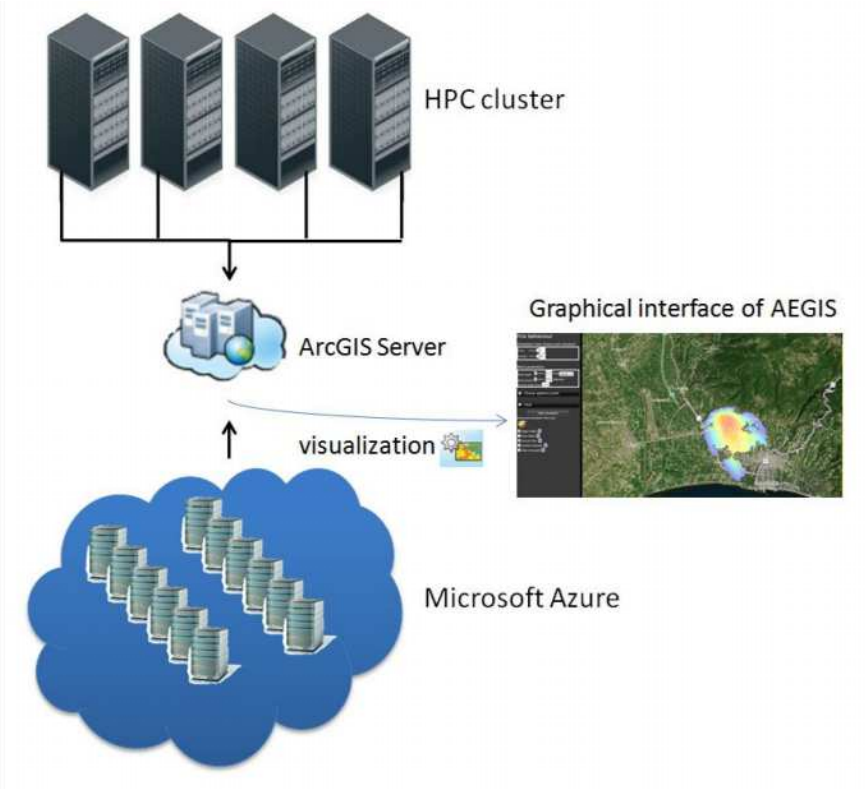

Figure 1. Combining Cloud resources and HPC for simulating fire behavior and burn probability in AEGIS

Running on demand fire simulations

When a new fire simulation is triggered, a command line execution of MTT is starting. If multiple users begin their fire simulations simultaneously, each simulation will be assigned to one of the available VMs and execution takes place in parallel. Before the execution starts, a configuration file is generated on the fly that stores all the necessary input parameters of the simulation (duration, wind speed and direction). Similar to FARSITE simulations, conditional fuel moisture is calculated by providing the corresponding weather and wind files. These files are automatically created if a conditioning period is defined, calculated from RAWS data of the past five days. If the user does not define a preferable RAWS, then the system automatically finds the closest to the fire ignition. Users have also the ability to use forecasted wind data from the closest gridded prediction point provided by the weather forecast prediction model called SKIRON, based on Eta/NCEP model (Kallos *et al*. 1997). Upon the completion of execution, several output files are generated either in ascii format (arrival time, fireline intensity, ignition point and rate of spread) or vector files with information for regular and major flow paths. After the creation of the output files, several ArcGIS Server geoprocessing services are running to transform ascii files to vector and to store them in corresponding ArcSDE geo-database feature classes. Data from different users are separated by providing the user name and execution date and time. Finally, ArcGIS Server mapping services retrieve the appropriate information from the geo-database feature classes, by performing filtering that request's the corresponding simulation outputs and then, visualize them over the AEGIS platform.
In Figure 2, the architecture behind the on demand MTT execution is explained. End users trigger a new simulation (step 1) and then, the first available machine retrieves the input parameters and starts a new process of MTT execution (step 2). Outputs are stored in a shared repository (step 3) from where a geo-processing service retrieves them (step 4), performs the necessary data transformations, adds descriptive information, stores them in a geo-database (step 5) and, finally, notifies the users that the

execution is finished. Visualization of the results is achieved by mapping services directly over the AEGIS graphical interface (step 6).

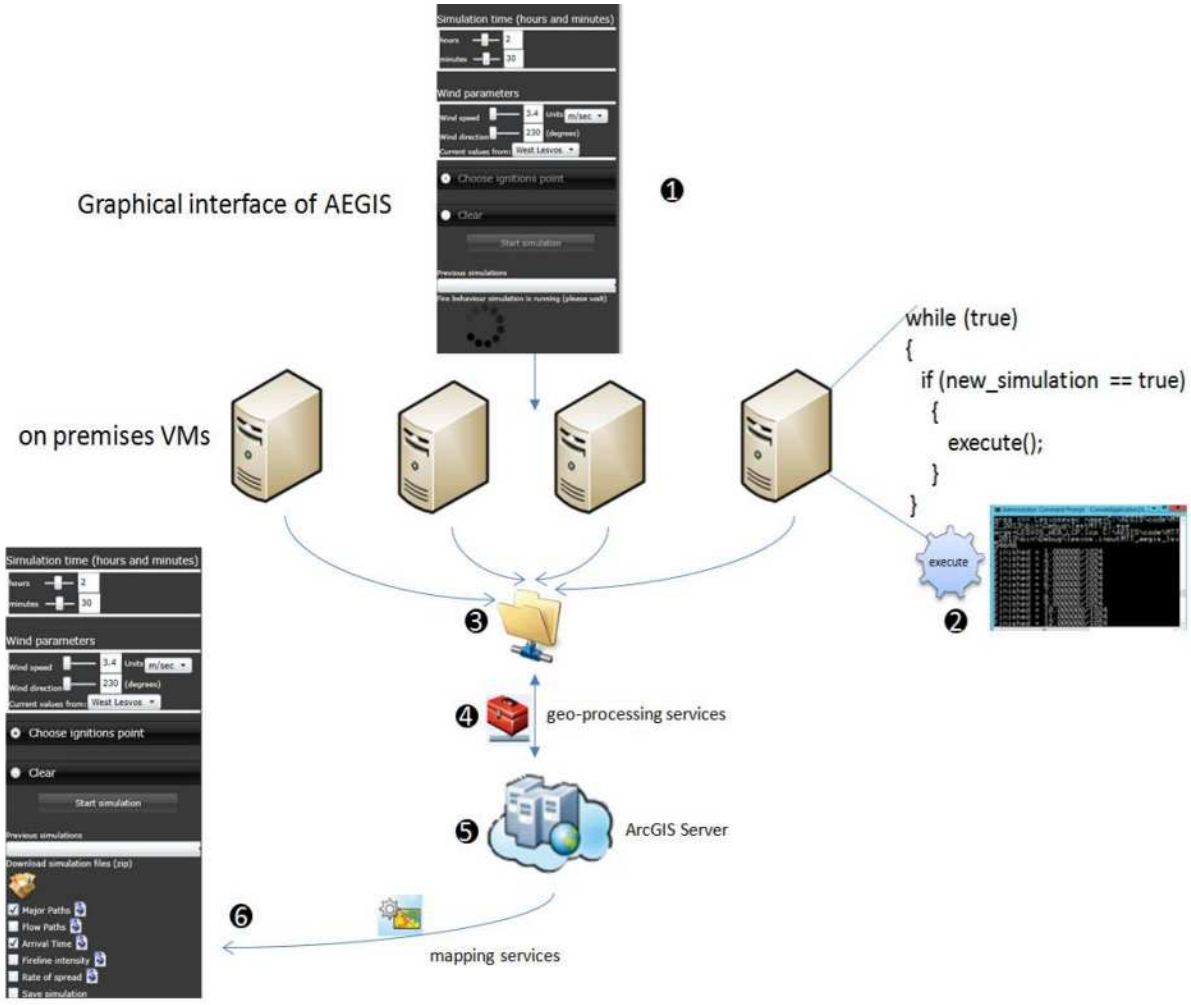

Figure 2. Information flow for on demand MTT simulations

Running MTT for fire burn probabilities

Conducting an on-premise FConstMTT simulation for a single study area takes approximately 24 hrs to be completed (3,000 km^2, 30 m cell size, 100,000 fires). This extraordinary execution time reveals the need for a parallel processing approach, to make the results available on a timely manner for each of the seven study areas. The phases for conducting a parallel processing FConstMTT simulation on Microsoft Azure cloud infrastructure are the following:

1. **Initialization.** A deployment is uploaded in the Microsoft Azure cloud infrastructure. The deployment encapsulates the FConstMTT command line-based executable.
2. **Execution.** Parallel execution of the FConstMTT executable is conducted, by dividing the overall number of ignition points (i.e. 100,000) equally among the available VMs. This partitioning of the ignitions significantly reduces the execution time.
3. **Merging.** The output results are combined into a new ascii text file to calculate the burn probabilities and the flame length categories (i.e. 20 categories) for the entire number of ignitions.

4. **Extraction.** The burn probability and every flame length category are extracted from the merged output.
5. **Visualization.** The extracted outputs are loaded in a geo-database to be visualized through the AEGIS platform. Furthermore, outputs are available for download from the end-users to perform meta-analysis on them (e.g. with ArcFuels).

At the initialization phase, a .NET deployment is uploaded in the Microsoft Azure cloud. The deployment encapsulates the FConstMTT binary executable. Once the deployment has been uploaded, execution of the executable is starting concurrently in four VMs in the Cloud. Each of the VMs starts a new process that initializes the executable. With a total number of 100,000 ignition points, each of the VMs is running FConstMTT with 25,000 of them. Every FConstMTT calculation produces a flame length probability file that contains for each calculation point the corresponding burn probability and flame length probabilities for each of 20 flame length classes. Currently, the ignition points are generated randomly across each study area. However, it is planned to locate the ignition points based on an ignition probability map in areas of anticipated high risk. Socioeconomic data, weather predictions, topographic and vegetation data will be combined with artificial neural networks (Vasilakos *et al.* 2007; 2009) to produce a daily fire ignition probability map.
After the parallel execution of the executables, the intermediate results are combined together and merged. For this merging, the calculated burn probability is transformed to total numbers of burnings on each pixel, a methodology described in Kalabokidis *et al*. (2014). If t1, t2, t3 and t4 are the total numbers a pixel is burned from each FConstMTT calculation, the mean burn probability (BP) for each pixel is calculated as:

$$BP = \frac{(t1 + t2 + \cdots + tN)}{(f1 + f2 + \cdots fN)} = \frac{\Sigma_{i=1}^{N} t_i}{\Sigma_{i=1}^{N} fi} \qquad (1)$$

where:

- N is the number of the available machines in the Cloud (in the current deployment N = 4)
- fi is the fraction of the total fire ignition points (in the current deployment f = 25,000)
- t_i is the partial number of burnings, calculated at the i^{th} VM.

In a similar way, the mean flame length probability (FLP) for each flame length category is calculated as:

$$FLP = \frac{\Sigma_{i=1}^{N} ti}{BP} \qquad (2)$$

Given the FLP, the conditional flame length (CFL) is calculated as:

$$CFL = 0.25 \times FIL1 + 0.75 \times FIL2 + 1.25 \times FIL3 + \cdots + 9.75 * FIL20 \qquad (3)$$

After the calculation of the (1), (2) and (3) for each pixel of the study area, the values are stored in a file with the following structure:

XPOS,	YPOS,	BP	FLP1,	FLP 2,	…	FLP 20,	CFL
X_{ij},	Y_{ij},	BP_{ij},	FLP 1_{ij},	FLP 2_{ij},	…	FLP 20_{ij},	CFL_{ij}

From this merged file, 22 separated ascii output files are generated (one output file for the burn probability, 20 output files for the flame length probabilities and one CFL output file). This extraction takes place in parallel on the HPC cluster environment. Each machine reads the merged file, extracts and transforms one of the categories in a corresponding file. Every file contains three columns: the latitude and longitude of the ignition point and the value of the corresponding category. After the extraction, the GDAL/OGR utility is used to convert each file to raster format. Geo-processing services

retrieve the raster files and store them in a corresponding geo-database to visualize them over the AEGIS graphical interface through corresponding mapping services. In Figure 3, the information flow for the creation of a seasonal burn probability map in AEGIS is presented. At a specific time, the deployment is uploaded from one of the on-premises machines to the Cloud (step 1). Execution starts concurrently at available VMs (step 2). Partial output results are created and a merged file is generated that stores all values for all output categories (step 3). From the merged file, all output categories are extracted in separated output files (step 4), converted to raster files (step 5) and stored in a geo-database (step 6) for visualization purposes (step 7).

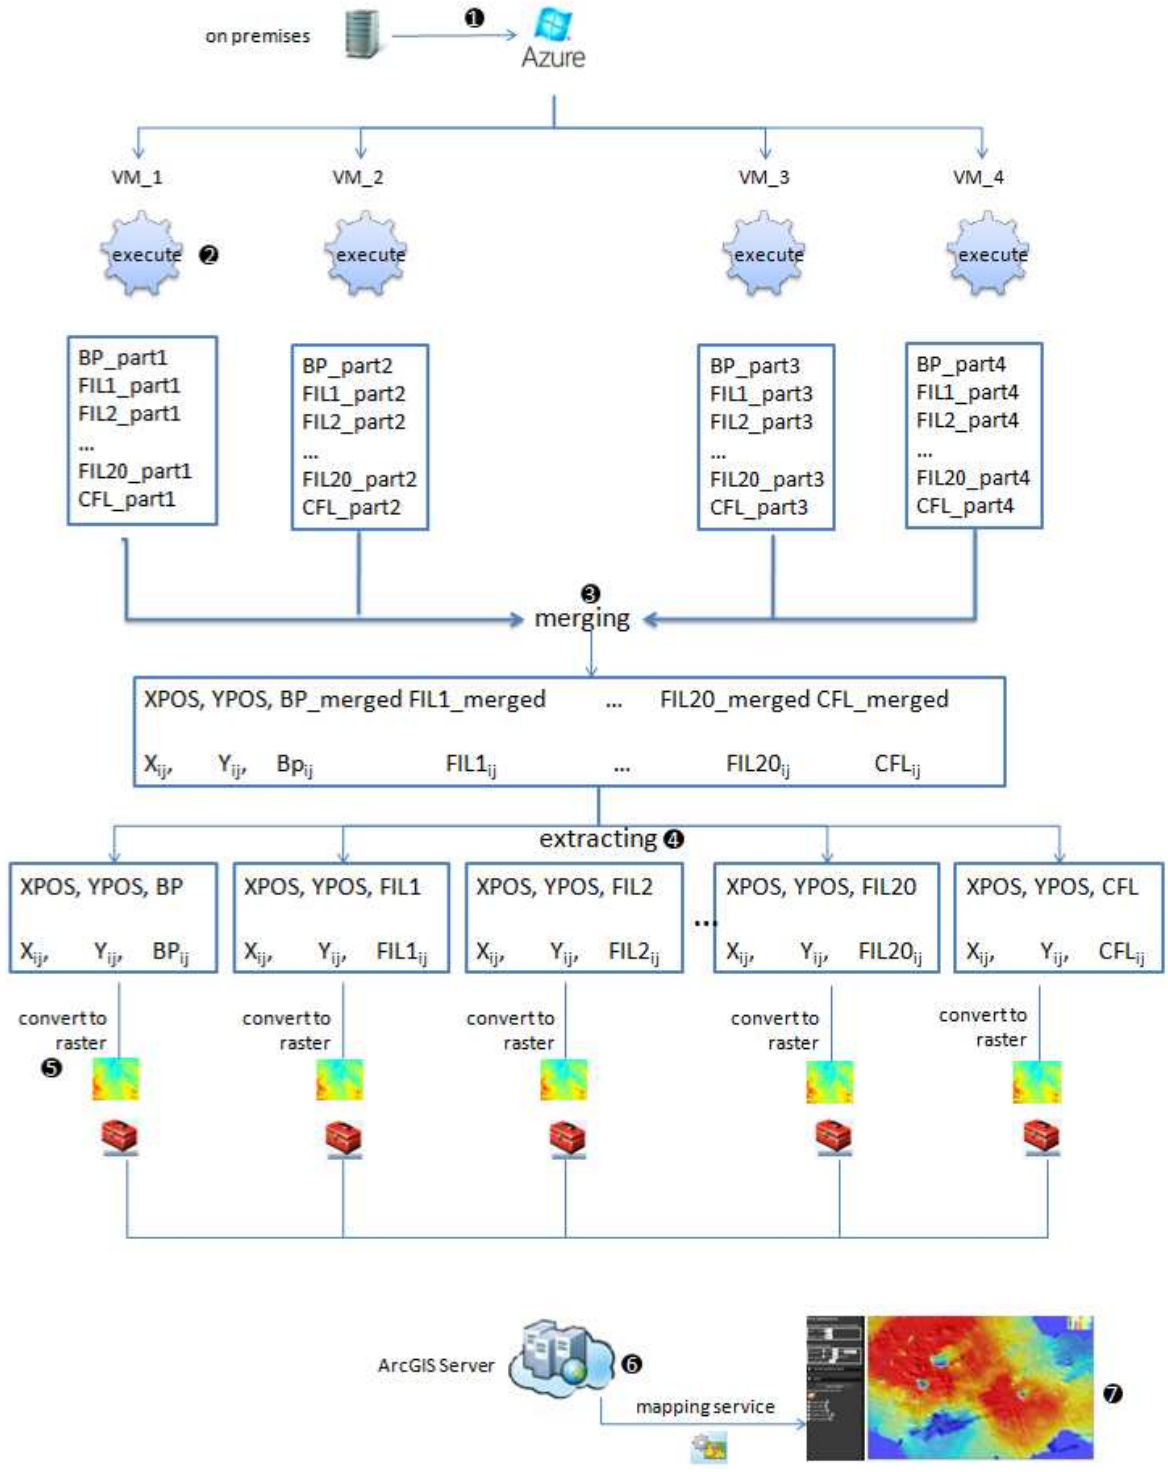

Figure 3. Information flow for the conduction of burn probabilities maps

Visualization of MTT results in AEGIS

Authorized users of AEGIS are able to conduct new MTT simulations or view older stored simulations. If the user decides to conduct a new simulation, the ignition point and the duration time (hrs and min) of the simulation must be specified. The duration time cannot exceed six hrs, since MTT provides better simulations for short term time periods. Real-time wind parameters (speed and direction) are retrieved from RAWS of the study area or can be user-specified to conduct "what if" scenarios simulations. After providing the required inputs, users can trigger the "Start Simulation" button. The platform steadily provides information about the status of the simulation for as long as the execution is in progress. At the end of the simulation, all outputs can be directly visualized over the AEGIS platform by enabling a checkbox next to each mapped attribute. Individual output files can also be downloaded as kml layers or alternatively, can be downloaded in their raw format as a zip file (flow paths, major flow paths, fireline intensity, rate of spread, time of arrival and ignition point). In Figure 4, a visualization of MTT fire simulation from the AEGIS GUI is portrayed (arrival time and major flow paths). Simulation time was set to three hrs, while wind data were retrieved from a nearby RAWS. The check box "store the simulation" is used to store the simulation in the simulations archive.

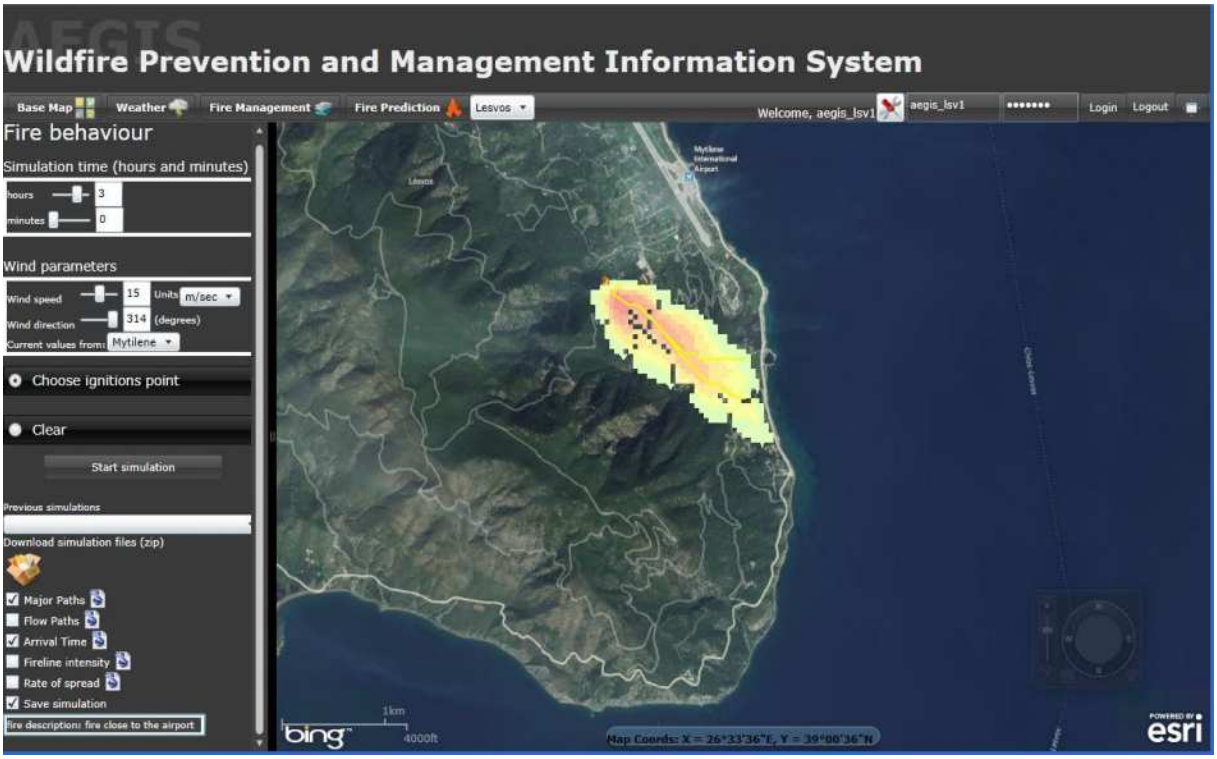

Figure 4. Visualization of on demand MTT results in AEGIS

Seasonal FConstMTT outputs can be visualized by selecting the desired attribute (mean burn probability, conditional flame length and each flame length class probabilities) from a drop down menu (Figure 5).

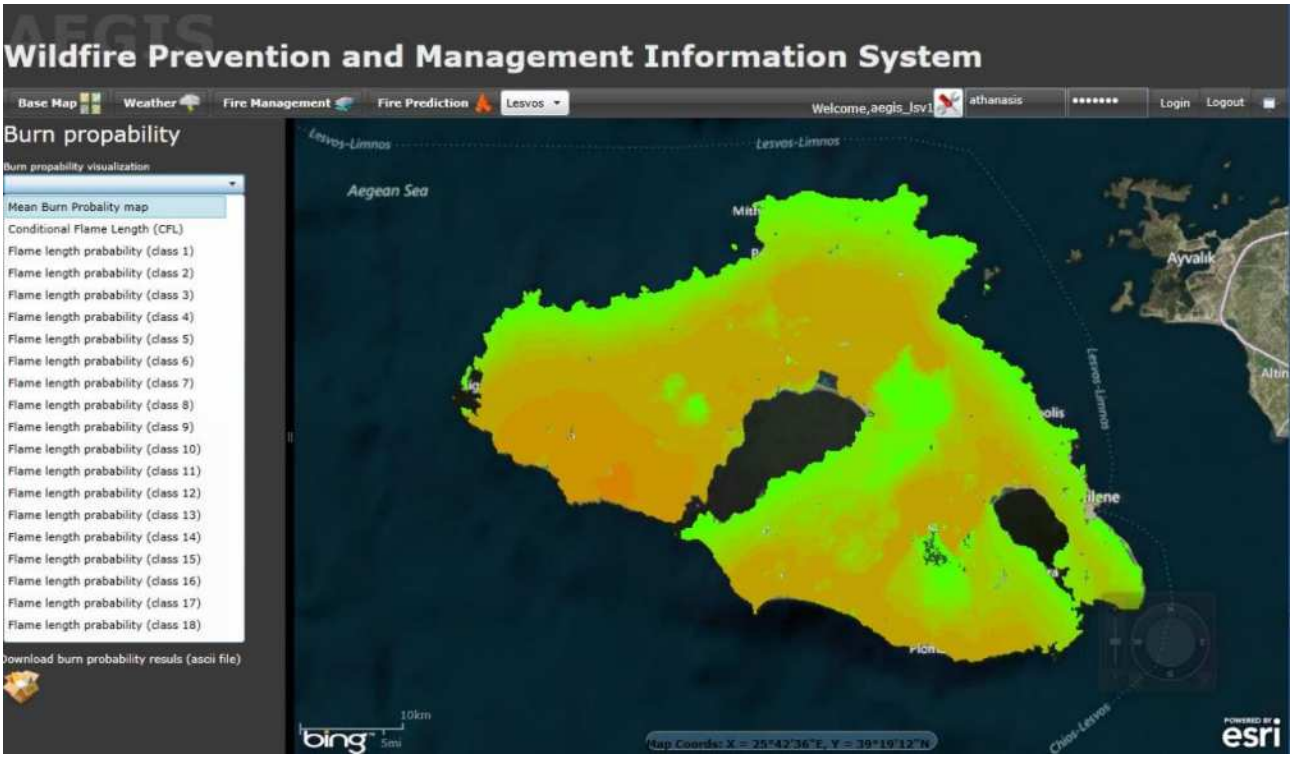

Figure 5. Visualization of burn probabilities in AEGIS

Conclusions

This paper describes the utilization of the fire behavior prediction algorithm of Minimum Travel Time (MTT) algorithm in the AEGIS platform. Calculations are conducted in a parallel computing environment, combining Cloud and HPC resources. More specifically, on demand fire simulations are conducted on premises, while seasonal burn probability maps are first conducted in the Cloud infrastructure of Microsoft Azure and then finalized in the HPC cluster environment. This combination of cloud and HPC resources provides the means to produce useful fire prediction maps without devastating delays.

On an operational basis, the system's functionalities may assist local authorities of wildfire management to extract useful information towards the design of an effective operational wildfire prevention and management plan. Fire behavior predictions are visualized through the web-based front end of AEGIS, eliminating the need to install special desktop software. Users have the ability, without the requirement of knowing the handling of complicated fire management systems, to integrate fire science models and decision support planning modules and to utilize the capabilities of the system.

The visualization of burn probability maps can reveal which areas are more susceptible to encounter a wildfire event. Furthermore, multiple on demand simulations can be conducted simultaneously by changing the weather parameters and simulate different "what if" scenarios. During a fire emergency, the fire behavior can be easily simulated by integrating real time weather measurements. The computation architecture follows the software design principles of parallel processing of high performance computing and cloud computing. All software modules are developed in the .NET language. Execution requires also third-party software of the MTT binary executables. By integrating MTT into the AEGIS platform for all seven study areas of AEGIS, firefighting and civil protection agencies may gain a great assistance to organize better and more reliable plans for fire confrontation.

8. Acknowledgments

The research project “AEGIS: Wildfire Prevention and Management Information System” {Code Number 1862}, is implemented within the framework of the Action ARISTEIA of the Operational Program "Education and Lifelong Learning" (Action’s Beneficiary: General Secretariat for Research and Technology), and is co-financed by the European Social Fund (ESF) and the Greek State. Final results and outcomes of the project are expected by September 2015.

Modelling of fire managers' decision making method

Agoston Restas

National University of Public Service, Budapest, Hungary, Restas.Agoston@uni-nke.hu

Abstract
During fighting against forest fires the situation can change quickly, thus, managers must also be ready to change the strategy and tactic. Firefighting managers have a typical profession, during which – depending on the time – making both analytical and naturalistic decision. Trainings usually focus on traditional – analytical based – decision making, which takes time, however, in many cases there is not enough time to do that. Therefore managers make many times recognition-primed decisions as a symbol of naturalistic decision-making. The first part of this article gives a thorough review of the topic. The second shows a simple and a complex model, created by the author. Method: the author used different tools and methods to achieve his goals; one of them was the study of the relevant literature, the other one was his own experience as a firefighting manager. Other results come from two surveys that are referred to; one of them was an essay analysis, the second one was a word association test, specially created for this research. Results and discussion: the author created a simple and a complex model for firefighting managers making decisions, taking into account time pressure, the limited capability of processing information and also a mechanism complementing the recognition-primed decision.

Keywords*: decision making, fire managers, recognition primed decision, model for making decisions in emergencies*

Introduction

The background of recognition of a special decision-making mechanism in the focus of this paper was given that, in some cases, no sufficient time is available, necessary for classic decision-making. Therefore, strategists sought to design and plan the details of military operations in advance, just as today, however, their proper implementation, the application of different decision support instruments in live situations, designed for optimal decisions, failed many times in spite of these. Decisions made in reality, e.g. fighting against forest fire are often not harmonized, could not be harmonized, considering the circumstances, with the pre-formulated strategies, mostly because there was not enough time needed to achieve them.
In the paper, author illustrates the limits of the possibilities of analytical decision-making, presents the general operating mechanism of recognition-primed decision-making, elaborates on its special model relevant to firefighting managers, as well as explores and systemizes the factors that facilitate (catalyze) the processes.

Characteristic circumstances of emergency interventions

An important element of the activities of emergency responders is that they cannot or only to a very limited extent can modify the terms of the task, improve them as desired. Despite the differences of environment, indications of the *complexity* of the situation, the possibility of the *radical change* in the given situation, *uncertainty* and *ambiguity* of the information available can be recognized and well identified. During fighting against forest fire the weather condition can change radically – for this, a typical example is the change of wind direction –, the accessible resources, because of the intensive plum convection can be new hot spots also behind the existing fire fronts, firefighters can be injured seriously or can fallen in trap requiring help immediately.

The peculiarities of each specialized branch can be illustrated through the examples of several authors: Klein dealt with the analysis of the decision circumstances of the military also using the examples of firefighters (Klein, 1989), Killion took examples from the navy (Killion, 2000), Bruce shows his own medical case (Bruce, 2011), Johansen simplifies difficult circumstances (Johansen, 2007).
Most of above factors are present; occasionally all of them may be present at a certain level of emergency decisions: including the strategic, operational and tactical levels, but certainly with a different focus or at different times. On strategic and operational level, in general, not only more time is available, but also human and technical resources are at hand more broadly, and decision support instruments as well to reduce uncertainties occurring.
The extinction of fire in a smaller grass land requires the implementation of a completely different, simpler scope of tasks than to control forest fire in an extra dry weather period and high articulated area. The different scopes of tasks exist in different environments and structures, so the solution of similar basic problem also exists in other dimensions. Based on author's own experience, the more extensive case we are dealing with in time, space and from the aspect of involvement in the incident, the more the above factors cumulatively prevail, but because of the protracted implementation, it is, however, easier to solve them.
The most limiting factor from the above is *time*, proven also in author's own studies. This provides a framework impossible to burst and a forced drift, a *pressurized channel* for the decision-maker, entangled in which one can no longer break free.

3. General model of recognition-primed decisions

The above proves that, in certain situations, the multi-criteria, analyzing, evaluating decision-making simply cannot be used or in a limited manner. However, it can be seen that managers, directors or commanders are many times in situations that they simply *cannot elude from their decisions*; they should make them in a short time. The functional background of decisions made in a short time, their mechanism different from the conventional was first studied in depth by Klein, who gave the name *recognition-primed decision* to this special decision procedure (Klein, 1989).
Author refers, at the general model of recognition-primed decisions, mostly to Klein's work (Klein, 1989; Klein, 1999), which is analyzed by Cohen with others from the direction of critical thinking (Cohen *et al*., 1996). Killion supplements and combines with his multi-aspect decision-making model, (Killion, 2000). Based on Klein's work, the essence of recognition-primed decisions is that the decision-maker, through his previous experience, has several different solution schemes in his mind, which he is capable of recalling in a new situation from memory. The decision-maker immediately applies the first pattern that matches the typical features of the given problem of, that is to say, makes decisions fast as a result of previous experience.
Supplementing the general model with the assessment of action versions, we receive the model of *analysis of possibilities* (Killion, 2000). In this case, if the action version is not satisfactory, a new action version will be modified or assessed. If the decision-maker has a significantly longer time to assess his concepts, naturally within the framework offered by a recognition-primed decision, there is the possibility to assess on the level of critical analysis (Cohen *et al*. 1996), or according to options characterizing analogical thinking (Killion, 2000).
Recognition-primed decisions do not exclude the possibility to amalgamate conventional, analyzing decision-making (Killion, 2000; Radnóti & Faragó, 2005). At complex tasks, where a given situation is examined from several aspects – and choose from the options with analogical thinking – recognition-primed decision-making can be automatically applied by experienced decision-makers while solving some partial tasks to reduce the time of the decision process.
The above issues harmonize with the observation that decision-makers simplify complex problems, i.e. create partial problems, until the elements broken down become manageable and resolvable (Simon, 1960; Paprika-Zoltay, 2002). By enlarging its interpretation range, of course, we can reach

the point where the decision-maker may say the problem does not exist until he sees its solution (Duggan, 2002), or the problem does not exist at all if it does not have a solution (Ribárszki, 1999). Many times we can see that forest fire managers come face to face with fire and without any time of thinking they are able to give instructions immediately. We say, routine works but it means they use schemes rather than making ad-hoc decision.
It springs forth from the above that the relative position of multi-aspect decision-making and recognition-primed decision-making is not constant. Recognition-primed decision can be the partial process and decision unit of analogical thinking. In this case, the main decision-making mechanism is analogical thinking; recognition-primed decision is the additional element.

Decision-making mechanism of a firefighting manager

Limited time frame allows the elaboration and management of limited amount of information. We know from Miller's researches that the *short-term memory* of the vast majority of people can only process simultaneously 7±2 units of information (Miller, 1956). This information, of course, can be quite different, e.g. a characteristics of fire, the capacity of the response unit, a number, or even the absence of information searched. Our memory handles the combinations, "operations" between the information units as information units (Ribárszki, 1999), from which clearly springs forth that the capacity of the short-term memory of a firefighting manager is exhausted very quickly.
Author has proven by essay analysis how complex the tasks of emergency responders are (Restas, 2013); this shows that in several cases, simultaneously, there is or would be a need to process many more units of information than the capacity of our short-term memory would allow. *The maintenance of our decision-making capability, i.e. our short-term memory, based on the above, clearly requires that we should omit analyzing and evaluating decision-making processes protracted and use the recognition-primed decision-making procedure, based on previous experience.*
Author wishes to create a model element to demonstrate the decision-making mechanism of firefighting managers, which takes into account the limits of the simultaneous processing of information, that is, it also illustrates *Miller's decision-making capacity*. Since the information units may be qualitatively independent of each other, author choses the simplest *graphical representation of the unit-based discrete difference* to separate them from each other. A model element must be such, which can graphically demonstrate the schemes based on earlier experience, the characteristics of different fires, and the interlocking of the former as the application of the scheme, which represents the technically correct solution of the task, i.e. effective decision. The model refers, at the general model of recognition-primed decisions, mostly to Klein's work (Klein, 1989; Klein, 1999).

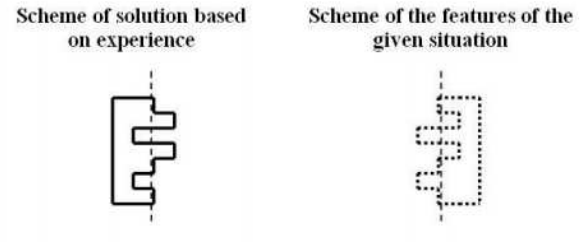

Figure 1. Graphic representation of the empiric scheme of recognition-primed decisions matching a given situation

The schemes in figure 1 represent 7 graphical discrete values each, which are marked by positive or negative protrusions and their "center line"; these values indicate the amount of simultaneous decision-making capacity. Thus, the "negatives" of the schemes can be matched as a given situation and the solution necessary therefor. As an integration of above processes, decision mechanism functions as

follows: an experienced firefighter has performed the elimination of a large number of and forest fires. Despite the fact that as far as the parameters each forest fire is different from another, some characterizing features can be well conceived (figure 2).

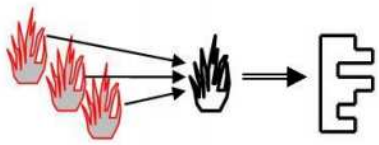

Figure 2. Evolvement of the scheme on forest fire

The characterizing features of identical types of fires are crystallized by experience, and are fixed in our *long-term memory*. Similarly, to the characteristics of a forest fire, the characteristics of successful extinguishing, the facilitating decisions are also fixed (figure 3); just as the mistakes desired to be avoided and the unsuccessful procedures and failures. Experience gained through many years, based on the features of forest fires, formulate the system of schemes, behind which we can find actions (decisions) efficiently applicable to eliminate them.

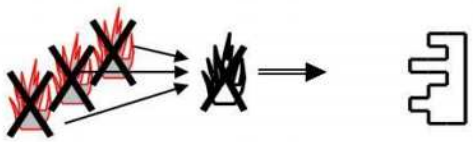

Figure 3. Evolvement of the scheme on the lessons learnt from extinguishing a forest fire

If another incident has almost the same circumstances as one already many times successfully eliminated by a firefighting manager previously (model of positive confirmation), he will attempt to use the same ones in the procedures. Therefore, another fire, quasi bearing the typified properties of previous similar fires, a decision-maker involuntarily immediately recalls the typified decisions in his conscience. The properties of a fire and of previous successful extinguishing operations, based on the above, are closely interlinked; they are each other's "reflections" (figure 4). Author proved with the results of association studies that the above, i.e. the characteristics of a fire and the thoughts directed towards its extinguishing, the schemes of response, in the case of firefighters, are very closely connected in a complex way (Restas, 2013).

When a firefighting manager identifies a fire, he imagines what would happen if he applies the usual tactics to fight it. If the scheme of solution matches, he accepts it, if not, he rejects it and thinks of the next most typical action. Thus, it is a recognition-primed, model-matching process, which can be followed by a quick and almost automatic decision. The above process is naturally not limited only to forest fire managers; it can be used more broadly to firefighting managers.

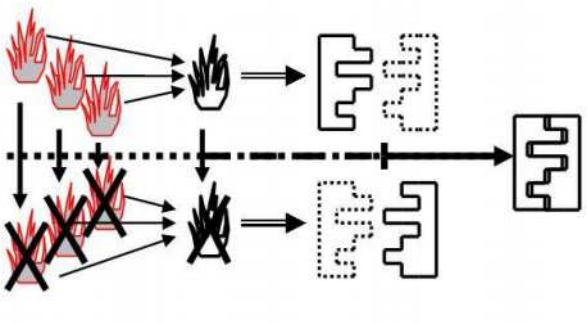

Figure 4. Aggregated scheme on fire and the evolvement of the lessons learnt from extinguishing it

The amalgamation of previous schemes into a given incident is shown in figure 5. The long-term memory of a firefighting manager, through practical experience, has the schemes of both different fires and their extinguishing characteristics. During another alert, information available and collected on a fire automatically generates the recollection of the scheme necessary to solve it, based on which a firefighting manager defines the firefighting tactics necessary. However, the results of association studies clearly point in the direction that at a given fire (problem) managers do not focus on the fire as a problem but rather on its immediate solution (Restas, 2014). From this, author makes the conclusion that a decision-maker will not follow the change of the characteristics of a fire, but the validity of solution scheme, that is, the dynamics of the implementation of the extinguishing process. This does not mean a contradiction with the previous, but rather a difference in views, the shift of emphasis of the focus of attention.

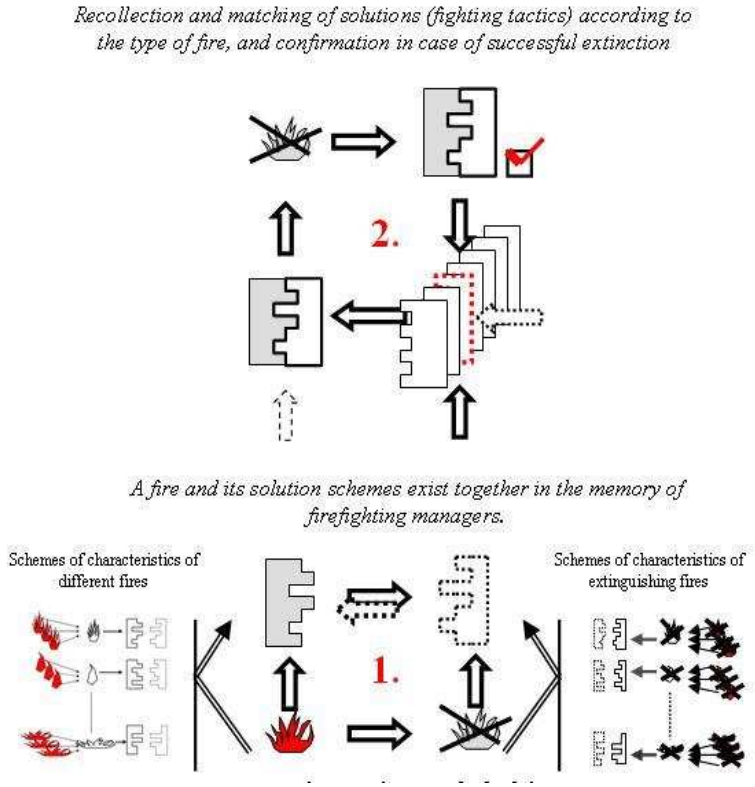

Figure 5. Decision-making mechanism of a firefighting manager

The difference in views, that is, the shift of emphasis means that a firefighting manager does not focus on the change of characteristics of a fire, but rather on the expected evolvement and dynamics of the scheme selected, i.e. extinguishing tactics. Based on the previous, these are, of course, inseparable from each other; however, author finds the dominance of the interventions trend in the results of association studies in the case of firefighters so strong that, based on it, author judges his above conclusion to be justified.

The above do not contradict Klein's model, they rather complement it. Klein, in his model, evaluates (imagines what will happen) the results of matching schemes by the decision-maker prior to performing action version, which, based on author's own experience, is so without doubt, however the aftermath of the decision, in author's opinion, is much more significant in case of firefighting managers. Since the problem immediately and automatically generates both the direction of the solution and start of the action version, rather the process itself is important in terms of efficiency, which is caused by the decision. The schemes based on experience certainly contain the information on the dynamics of the process of fire, so if it meets the expectations, we do not have to modify the original firefighting tactics. However, if the dynamics of the process does not suit the expected, the

change is inevitable in the performance of efficiency. Based on the above, the recognition-primed decision is not just an individual act before extinguishing the fire, but it is also the continuous accompaniment as needed. By doing this, author shares the view that the experienced decision-maker perceives the problem together with its solution, furthermore, author extends the continuous co-existence of the problem and of the whole process of solution of an emergency (firefighting and technical rescue).

Mechanisms complementing a recognition-primed decision

5.1. Triggers

Different triggers, internal resources ensure the operation of recognition-primed decisions. Klein, in his work, assumes 5 markedly distinct abilities, these are *intuition*, *imagination*, *perception of the invisible*, the *ability to formulate, metaphors* and *analogies* (Klein, 1999). In the joint work of Cohen, Freeman and Thomson (Cohen *et al*., 1996), draws the attention to the importance and benefits of critical thinking as criticism of actions planned by ourselves.

Despite the fact that one could assume, based on the previous issues, that recognition-primed decision-making enjoys exclusivity on a tactical level, it is absolutely not true. We can compare it with several fires or incidents, still, one of the essential features is that it protracts in time. It allows the decision-maker to think through the situation, collect information, develop action versions and consider. Not just forest fires but peat fires, or in many cases, fires of storage facilities or other hall-type buildings, burning for several hours or days and covering a large area are categorized specifically into the above types. During protracted decision-making, the recognition-primed processes, based on author's experience, proved to be irreplaceable assistance rather in solving partial tasks.

5.2. Analytical thinking

Killion sees the combination of recognition-primed decision-making with the analyzing and evaluating procedure in two ways (Killion, 2000). In both cases, the conditions are that adequate time should be available for analyzing the options. In the first case, prior to recognition-primed decisions, focusing on the given circumstances, we set up options and analyze them. In the second case, a more detailed analysis of the action version of our recognition-primed decision may take place. In the latter case, the spectrum of the task is obviously significantly narrower than in the first case. The two mechanisms, depending on the situation, can be harmonized or one of them may become predominant.

The observation of the elemental parts of multi-aspect decision-making shows that decision-makers divide complex problems to smaller and smaller partial problems until they become such a basic level problem that a decision-maker is able to solve even with little effort (Simon, 1960). This latter process can also be a recognition-primed decision-making, but logically we can find Duggan's view (2002), previously referred, at the end of thought list, according to which successful decision-makers not perceive a problem until they can solve it.

5.3. Critical thinking on tactical level

Cohen, Freeman and Wolf studied the possible decision support role of critical thinking on a tactical decision-making level (Cohen et. al., 1996). In their work, active naval officers and case reports were studied based on which they state that experienced emergency decision-makers, in new situations, using their previous experience, make decisions with help of recognition-primed mechanisms.

Cohen's model explains in detail the critical analytical strategies that contribute to the operation of recognition-primed thinking. Systematic situation models often based on informal narratives as schemes organize our information in cause and effect relationship in individual cases and underpin the development of recognition-primed thinking.

One of the most important elements of Cohen's model is the quick test. A quick test is a higher-level control mechanism for critical analysis and its accuracy. Its recognition strategies are formed, similarly

to other decision-making processes, by the success or failure experience of past events. The complex recognition mechanism comes to the fore when the demand on time and resources for critical analysis is overweighed. It is possible in three well-definable cases (Cohen *et al*., 1996). *A quick test considers the conditions in the light of the above factors, and if they appropriate, prevents recognition-primed decision, and focuses on critical thinking. When circumstances are not adequate, a quick test will allow for an instant reply.* (Cohen, 1996).

5.4. Satisfactory procedure mechanism

We have seen previously that a firefighting manager's time, just as the time of other decision-makers in an emergency to make a decision is limited. Since this time limit precludes the possibility to carry out the necessary analyses of the classic model, objectively the choice of an optimum option is not achievable for a decision-maker[1]. In response to the difficulties of the collection of information and the reduction of the costs in relation, a decision-maker does not strive for optimum results, but, depending on the circumstances, settles for satisfactory solutions.

The above process, unlike analytical thinking, is enforced by several factors. Some of these factors are the impossibility of obtaining all information necessary to select the best solution, or the shortage of time; the latter induces a compulsion of decision-making. The limited nature of the processing information available is also of significant influence. Filtering of information and by this the selection of response to the tasks is necessary because the capacity of our short-term memory is quite limited. According to Miller's studies, it allows the parallel processing of only 7 ± 2 bits of information at one time (Miller, 1956). If a firefighting manager made all the basic decisions, his decision-making capacity would be immediately exhausted at a complex firefighting task.

Despite the small capacity, thanks to recognition-primed mechanisms, correct decision is made in most cases (acceptable, given the effectiveness of firefighting). A firefighting manager, using his experience, in situations not requiring decisions different from the previous solutions, implement automatic measures, protocol procedures, thus continuously maintains his decision-making capacity. In this case, using his own experience, a firefighting manager is not interested in by which series of best elementary decisions he can eliminate fires, but only in satisfying the conditions of professional firefighting through the decisions made as a whole.

5.5. Decisions by exceptions

The aim of the application of the method is that the leadership responsibilities of managers should be drastically reducible; its essence is that we should only intervene into processes having permanent characteristics in majority, if they cross the pre-specified lower and upper limits. The method developed later (management by sensitive exception), so derived from the dynamics of the processes, the necessary interventions are now possible even before crossing the borders (Hoványi, 2002). The method of management (decision) by exceptions, based on author’s experience, is the greatest help for a firefighting manager to continuously maintain his decision capacity. It can appear in different ways, like protocol procedures, individual way of speaking, silence approval, peripheral vision, information-processing in zones.

The experience and competence of the persons performing a given activity allows that every firefighter make his basic decisions in his own field of work. This shows the arrangement in zones of information processing (figure 6). Of course, not every incident or moment requires response. This zone does not require action that is practically ignored by a firefighter, because it is a natural consequence of extinguishing. A significant part of problems outside the zone, as a result of a firefighter's decision in

[1] Except the single case when the random choice exactly coincides with the decision made with the method of analysis. Its magnitude can be identified through statistical methods.

that location, is solved by intervention (firefighting), this information now reaches the firefighting manager, but he usually does not require a decision yet. A firefighting manager manages the problems outside this zone that exceed the decision-making competence of subordinate firefighters. This originates in the fact that, on the one hand, based on the information from reconnaissance and radio traffic, he can create a comprehensive and dynamic picture of the entire process, the evolvement of fire or the efficiency of extinguishing, on the other hand, legislation entitles firefighting managers to take actions.

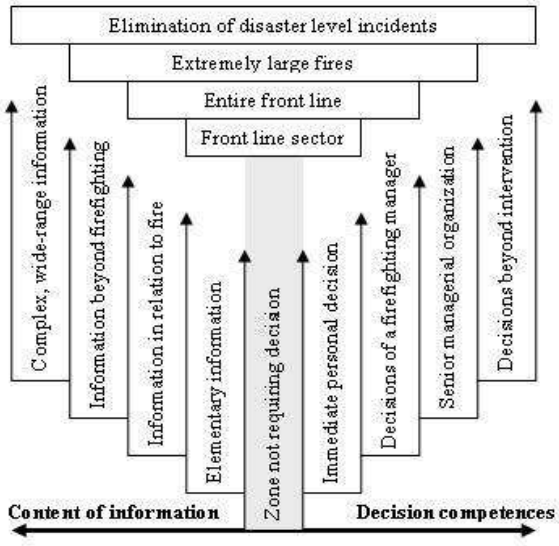

Figure 6. Decisions based on exceptions

5.6. **Creativity**

Creativity has many definitions. Munteanu, in one of his works, presents 35, which approach creativity in different ways, however, there is no single definition generally accepted or used, either (Munteanu, 1994). Analyses researching creativity show that there are three general directions of study (Csíkszentmihályi, 1996; Paprika-Zoltay, 2002). The first concerns the *nature* of creative thinking, the second one the *development* of creativity and the third one the *characterizing properties* of creative people. Amongst the properties, there is practically none, which would not be advantageous for efficient work in a VUCA environment describing the working conditions of a firefighting manager. Based on the above, author made the conclusion that the creative capabilities of a firefighting manager can be explicitly beneficial for facilitating the technically correct decisions relating to firefighting and technical rescue tasks.

Creativity can significantly increase professional efficiency of decisions made by firefighting managers in unexpected situations. This can be seen when firefighters are able to turn local conditions, in a moment, exploitable advantages. However, author found that a significant part of properties characterizing innovativeness do not prefer everyday work, free of interventions, in structured organizations, in respect of firefighting managers. This is confirmed by research findings as well, according to which it is explicitly problematic to follow strict rules for people producing creative results (The Reader's Digest Association Ltd., 1992). Maybe this is why it is a typical example that chief fire officers can safely trust the professional firmness of subordinates at incidents, in everyday life, even though the working relationships of managers and subordinates are burdened with tension.

5.7. **Heuristics**

Heuristics means that certain distortions are not incidental and unarranged errors, but the results of simplifying mechanisms, with which decision-makers make the complicated tasks manageable for

themselves, which cut the Gordian knot (Paprika-Zoltay, 2002). Based on researches related to the names Tversky and Kahneman, we distinguish 5 basic groups of heuristics (Tversky & Kahneman, 1974). These are representativeness, availability, fixing (imprint) and adjustment heuristics, retrospective distortion, as well as overconfidence and calibration. Studying the activities of firefighting managers, there are many examples of practical heuristics.
Overconfidence, based on author's judgment, is one of the greatest risk factors to the efficiency of decisions of a firefighting manager. A firefighting manager, quite often, stops searching for the necessary information earlier than sufficient, based on his experience, he trusts his own judgment, many times, assuming unnecessary risks. The extent of rational risk assumed during interventions should be always chosen proportionate to the given task; a risk assumable at a fire in a grain storage facility is incomparable with a fight for the life of a human being.
Researches show (Lichtenstein & Fischhoff, 1977) that overconfidence means that the division between actual and putative knowledge is around 50%. We are best able to judge the certainty of our decisions around 80% of knowledge, over this value, we underestimate our abilities. The above have shown that our actual knowledge does not grow parallel with certainty, the increase of our knowledge does not automatically mean the growth of self-assurance (Paprika-Zoltay, 2002). During firefighting (technical rescue), the characteristic VUCA environment exactly expresses that the actual knowledge of a decision-maker can only be partial, he can only be sure temporarily of the reliability of his knowledge. Aggregating the above, we can see that the risk of overconfidence continuously prevails in the decisions of a firefighting manager.

The complex model of decision-making of firefighting managers

In this article, author made efforts to examine and show the mechanisms promoting the more efficient decision-making of firefighting managers. Author demonstrated the linking opportunities of recognition-primed decision procedure and analogical thinking, pointing out the fact that the two do not exclude each other. If an intervention is protracted or longer time is available for the decision, many times, firefighting managers may achieve more efficient firefighting by using the latter.
If not enough time is available for analyzing and evaluating decision-making, recognition-primed procedures receive a greater role. Critical thinking uses recognition procedures, during which the decision-making process can be accelerated or analyzed with the help of a quick test and depending on the time available. The quick test, considering the circumstances, hinders recognition-primed decision and prefers critical thinking. However, when the circumstances are inappropriate for critical analyzing thinking, the quick test allows immediate reply.
Despite the limited decision capacity, thanks to recognition-primed mechanisms, in most of the occasions, correct decision is made by firefighting managers. Time limit precludes the possibility for the firefighting manager to carry out analyses necessary for the classic model, therefore, the selection of the optimal possibility is objectively not attainable by the decision-maker. The decision-maker is not striving to achieve ideal results, as a response to the difficulties of collecting information and reducing costs in relation, but depending on the circumstances, he is satisfied with the its satisfactory solution.
By reducing the time available for decision-making and for maintaining decision-making capacity, a firefighting manager applies the management (decision-making) method based on exceptions in numerous situations. Its essence is that several moments of interventions proceed protocol-like, thus, they need not be controlled all the time; on the other hand, not all the phases of the processes require direct management decision.
During the study of creativity, author has concluded that there is no such a feature characteristic of the working circumstances of firefighting managers that would not be advantageous to perform efficient work in a VUCA environment. Therefore, it is sure that the creative capabilities of firefighting managers can be explicitly advantageous to facilitate the professionally correct decisions on

firefighting and rescue tasks even if a significant part of the characteristics of innovativity does not favor the performance of an everyday work free of interventions with respect to firefighting managers. Heuristics are not random-like errors or specific distortions facilitating our everyday activities. These are the results of simplifying mechanisms, through which decision-makers can make difficult tasks manageable for themselves. Besides the benefits of heuristics, the greatest challenge for a firefighting manager can mean the inherent erroneous distortions, which surely often help, but their uncritical acceptance, in certain cases, can end up in fatal dangers.
The declared objective and sense of the decisions of firefighting managers is the efficient implementation of emergency interventions. It is symbolized by the principles of firefighting with structured division, on the top of which we clearly find the saving of human lives.

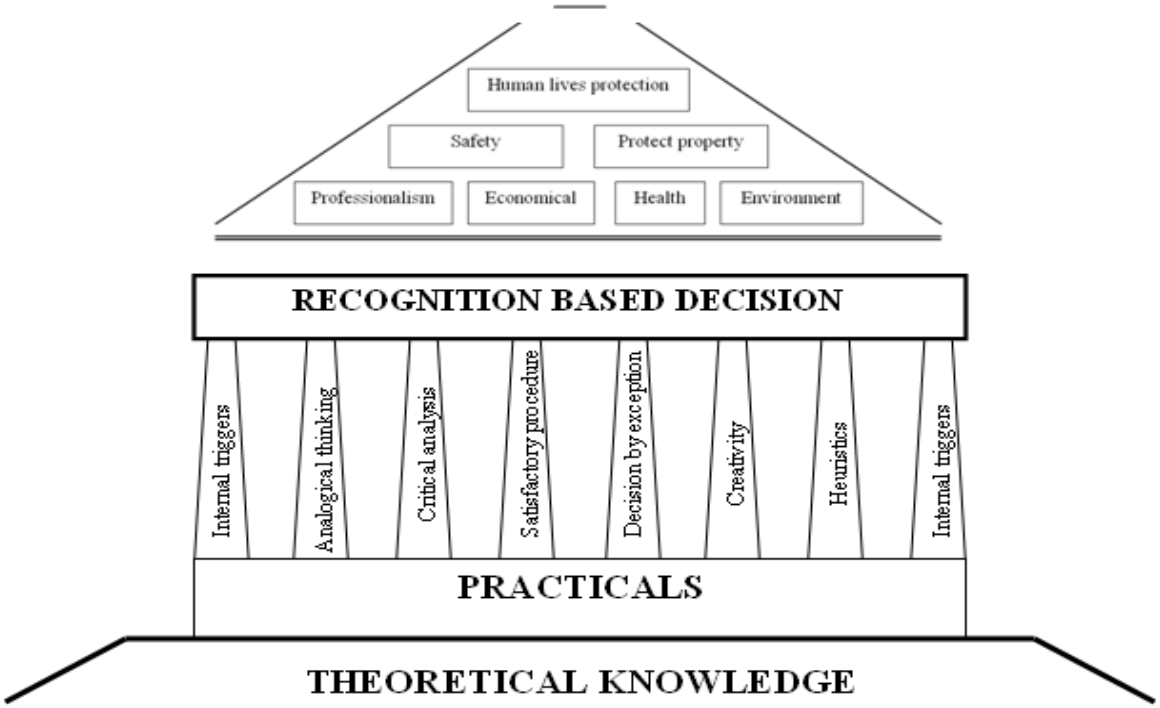

Figure 7. Complex model of decision-making of firefighting managers in emergencies

Firefighting managers certainly have less time to make their decisions compared to the time interval of classic decisions, so, their decision mechanism is strongly based on recognition procedures due to the peculiar environment (VUCA), and the limited process possibility of simultaneous pieces of information. The competence of firefighters is based on the unity of theoretical knowledge and practical experience. Building on practical experience, the different mechanisms like analogical thinking, critical analysis, satisfactory procedure, decisions based on exceptions, creativity and heuristics, together with the internal triggers, hold as pillars and make recognition-primed decision procedure of firefighting managers operational. Author illustrates the above as a complex system of emergency decision-making of firefighting managers in figure 7.

Introduction

The PREFER FP7 project aims at responding to major fire prevention needs in Southern Europe. The Mediterranean area is systematically affected by uncontrolled forest fires with large impact on ecosystems, soil erosion, slope instability, desertification trends, and local economies as a whole, with a negative mid-to-long term prospect because of Climate Change. In this scenario, the need to improve the information and the intelligence support to forest fire prevention is widely recognized to be relevant. Fire prevention is still the most cost-effective strategy when compared to firefighting and extinguishing that are costly, local, and triggered only in response to already ongoing crises. The PREFER project intends to contribute to responding to such a pragmatic need of Southern Europe's forests by: 1) providing timely multi-scale and multi-payload information products based on exploitation of all available spaceborne sensors; 2) offering a portfolio of EO products focused both on Pre-crisis and Post-crisis forest fire emergency cycle in the EU Mediterranean area; 3) preparing the exploitation of new spaceborne sensors available by 2020 (e.g.: Sentinels) and 4) contributing to the definition of User requirements for the new EO missions.
The paper is devoted to illustrate the results of the R&D activity and the results of the preliminary validation of the project products.

Methods

The main objective of the PREFER project is to set up a space-based end-to-end information services to support prevention/preparedness and recovery phases of the Forest Fires emergency cycle in the EU Mediterranean Region (Figure 1). The satellite data The PREFER Service portfolio consists of two main services (see Table 1):

1. Information Support to Preparedness/Prevention Phase" (ISP) Service, and
2. Information Support to Recovery/Reconstruction Phase" (ISR) Service

Hereafter the peculiarities of such information services are listed:

- They will be based on an harmonized set of user requirements, defined by the different users from Portugal, Spain, Italy, France and Greece, also taking into account the different legal frameworks existing in such countries.
- They will be as general as to be usable in the different countries of the Mediterranean Region.
- They will be demonstrated by an interoperable service provision infrastructure (based on OGC / INSPIRE), that will allow easy access to the information.
- They will be complementary to the products provided by the GMES Land and Emergency services of the GMES Initial Operations.
- They will be complementary to the products provided by the EC JRC EFFIS (European Forest Fires Information System) System.
- They will be based on the exploitation of the data from the GMES space infrastructure.
- They will optimise integration of different data: EO, Digital Terrain Models, socio-economic data, in-situ data, meteorological data.

The PREFER consortium has the ambitious objective to start up the formation of a cluster of research institutes, industries and SMEs focused on the provision of space-based information services and products in support to Forest fires emergency management in the Mediterranean Area.

Figure 1. In gray the countries where the PREFER project partners are located and in red the project test areas.

Service: Information Support to Preparedness/Prevention Phase	**Service: Information Support to Recovery/Reconstruction Phase**
Seasonal Fuel Map	Post-fire Vegetation Recovery Map
Seasonal Fire Hazard Map	Burn Scar map HR Optical and SAR
Seasonal Exposure (Vulnerability & Economical Value) Map	Burn Scar Map VHR
Seasonal Risk Map	Biomass Burning Aerosol Map
Daily Fire Hazard	3D Fire Damage Assessment Map
Prescribed Fires Map	Damage Severity Map

Results

This paragraph is devoted to describe more in detail the PREFER products providing, for those that are at a most advanced stage of development (namely: burn scar map, damage severity map and daily fire hazard), a description of results of the preliminary validation procedure. Figure 2 provides an example of one of the products which has been developed in the project. In particular, it shows the accuracy in the estimate of the burned areas reachable by using a suitable automatic algorithm applied on a high spatial resolution satellite images compared with the results routinely provided by JRC's EFFIS (European Forest Fire Information System) system.

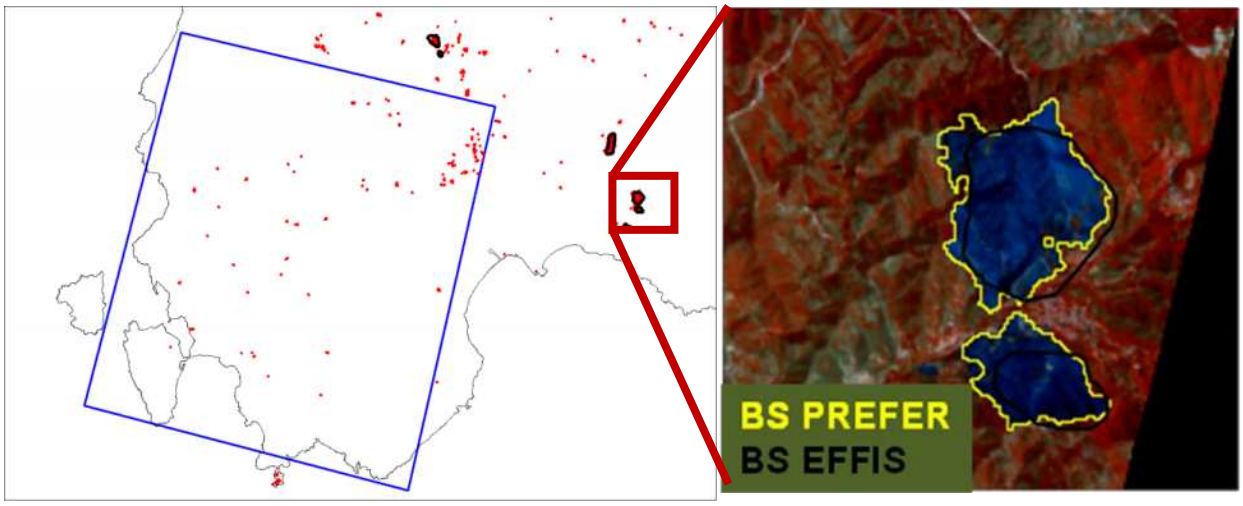

Figure 2. An example of the PREFER product burn scar. The PREFER product based on Landsat is compared with the same product provided by the EFFIS system of JRC.

Figure 3 provides an example of the damage severity map computed for a case study regarding a fire occurred last summer (2013) in Sardinia. The area of interest, Golfo Aranci, has been selected because of its relevance as SCI (Site of Community Interest). A couple of Landsat 8 images (pre and post fire) of the area were used for the computation of the damage severity index. Presently, three indices have been selected for the estimate of the fire severity, namely:

1. the well known dNBR (differential Normalized Burn Ratio) defined as follows (Key and Benson 1999, 2002):

$$dNBR = NBR_{pre} - NBR_{post}$$

where NBR_{pre} and NBR_{post} are the NBR indices computed on the pre and post-event images, according to the López García and Caselles relationship:

$$NBR = \frac{NIR - MIR}{NIR + MIR}$$

The dNBR provided a continuous scale of difference that could be related to a magnitude of ecological change, which in turn offered a conceptual model for burn severity: the greater the detected change caused by fire, the higher the severity.

2. a combination of indices called BSI which is composed of the three indices dNDVI, dNBR and dNDII:

$$BSI = (dNDVI + dNDII + dNBR)/3$$

$$NDII = \frac{NIR - SWIR}{NIR + SWIR} \quad NDVI = \frac{NIR - RED}{NIR + RED} \quad dNDII = NDII_{pre} - NDII_{post} \quad dNDVI = NDVI_{pre} - NDVI_{post}$$

This index, according to some tests made on fires occurred in Sardinia seems to be able to improve the fire damage severity estimation.

3. the DSI (Damage Severity Index) defined as:

$$DSI = MNBR_{pre} - MNBR_{post}$$

based on an optimized version of NBR called Modified Normalized Burn Ratio (MNBR) expressed as:

$$MNBR = \frac{NIR - \frac{1}{1.68} MIR}{(0.7 - NIR)^2 + MIR^2}$$

In the previous equation SWIR and MIR refer to the channels at 1.6 and 2.1 μm, respectively. Each one of the indices has presents some advantages and disadvantages summarized in Table 2.

Table 2. Comparison of the advantages and disadvantages of the developed indices.

Index	**Advantages**	**Disadvantages**
dNBR	Classical index; Tested in many cases; Thresholds known;	Saturation; Poor optimality; Sensitivity to external effects (Atmosphere, noise, etc…);
BSI	Composed by classical index; Increase of information considered respect other two;	Poor optimality; Sensitivity to external effects (Atmosphere, noise, etc…); Research of new threshold in calibration phase for damage assessment.
DSI	Optimized for change detection in burned areas; Increased sensitivity in changes due to fire. Using only two bands (less noise) Low sensitivity to external effects	Research of new threshold in calibration phase for damage assessment. Using only two bands (less information)

In figure 3 the damage severity maps computed, in an automatic way, by each one of the previously introduced indices have been compared with the damage level estimate done through the use of field data (MCBI, see below) and very high resolution images (Rapid Eye and Kompsat).
The index that best correlates with ground truth map is the DSI.

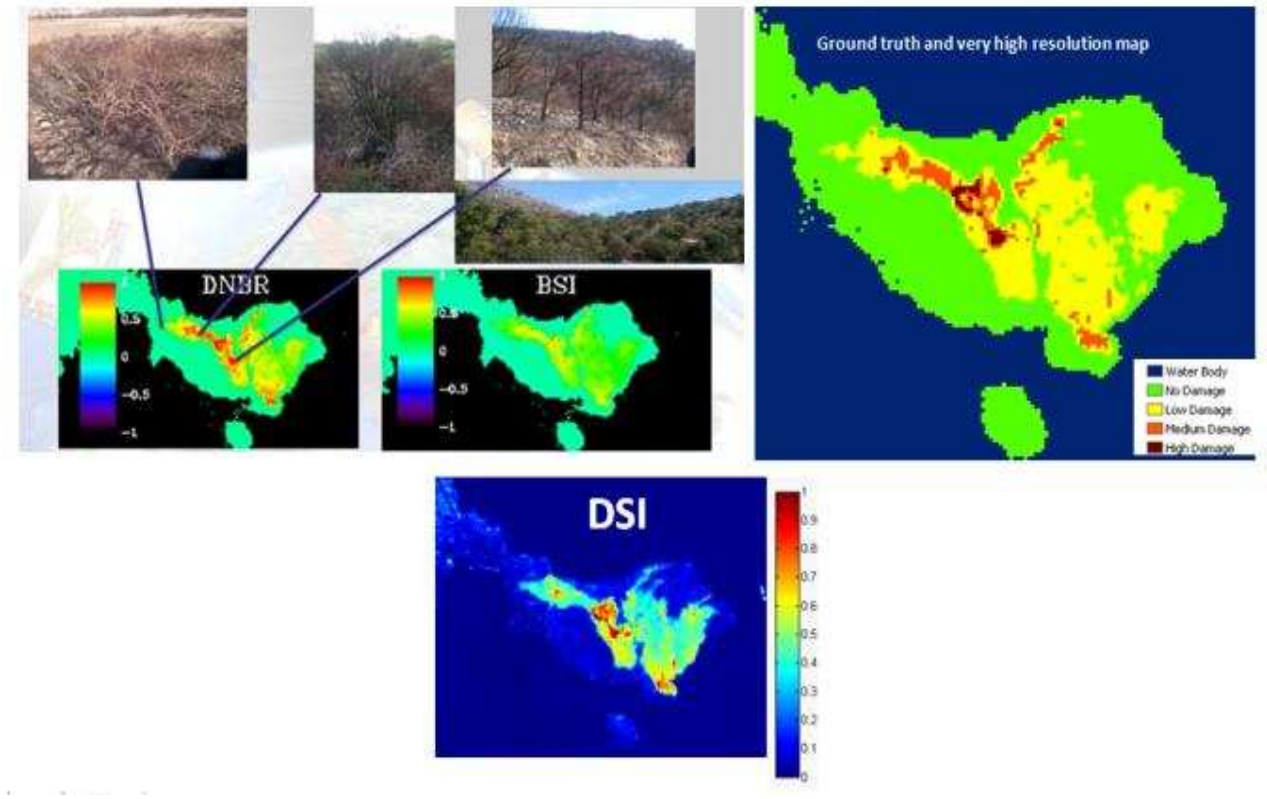

Figure 3. Comparison of the three indices with ground truth data.

The scale of the damage more used in the scientific international field is the CBI (composite burn index), a description of this parameter was given in Key and Benson 2006. In CBI, synthetically, the vegetation is considered made of 5 possible strata: 1) substrates, 2) herbs, low shrubs and trees less than 1 m, 3) tall shrubs and trees from 1 to 5 m high, 4) intermediate trees, 5) big trees.
The CBI was an innovation in the field of damage estimation because it provides an overall view of the damage associated with a number that varies continuously in a established range (0-3), this is a great advantage if we want to connect CBI to satellite observations.
However, we lightly changed the CBI definition for making it more consistent with our definition of damage. In particular, when the plots do not contain all strata, the missing strata have to be considered not damaged if these strata are upper than the existing strata and completely damaged if the missing strata are lower than existing strata."
Another change that we have made to CBI, is the reduction of the strata from 5 to 3: 1) herbs, low shrubs and trees less than 2 m, 2) tall shrubs and trees from 2 to 4 m high, 3) big trees. This new version of CBI is named Modified Composite Burn Index (MCBI).
Figure 4 shows an example of the third product recalled above, the Daily Fire Hazard Map (DFHI). This index is based on the FPI (Fire Potential Index) derived by Burgan (Burgan, 1998) for U.S. and takes into account the JRC experience (Lopez *et al*., 2002). The model requires the NDVI to compute the *Relative Greenness*, meteorological data (air temperature, relative humidity, cloudiness and rainfall) for estimating the Ten Hours Time Lag Fuel Moisture (FM10hr) and a fuel map to estimate the percentage of dead vegetation. The relative greenness (RG) or vegetation stress index represents how much green is a pixel, with reference to the range of historical observation of the NDVI used (Burgan, 1993). This quantity allows the estimate of the percentage of green fuel, as function of the fuel model assigned to each pixel.

The *Ten Hours Time Lag Fuel Moisture* has been selected as the quantity representative of the humidity available in the dead vegetation (Nelson, 2000). Such a quantity can be computed by using the meteorological parameters and the relationship described by Lopez (Lopez, San-Miguel, 2002).
However, the classic definition of FPI does not allow to take into account the effect of solar illumination conditions in determining the moisture content of the dead vegetation, therefore its proneness to burn. Actually, in Lopez *et al*. 2002 is declared that the *emc* values were corrected to take into account the solar heating but the way how this is obtained was not explained. Therefore, in order to introduce such parameter we decided to apply the formulas used for estimating the vegetation evapotranspiration rate, ET_0, and to use the computed values as a sort of weight for obtaining the *FM10hr* term for similar vegetation types characterized by a different solar *aspect angle*.
ET_0 has been computed by using the Penman-Monteith formula (Allen *et al*., 1998), modified according with FAO:

$$ET_0 = \frac{0.408 \cdot \Delta \cdot (R_n - G) + \gamma \cdot \frac{900}{T} \cdot u_2 (e_s - e_a)}{\Delta + \gamma \cdot (1 + 0.34 \cdot u_2)} \quad (5)$$

where ET_o is the reference evapotranspiration [mm day^{-1}], R_n the net radiation available at the vegetation [MJ m^{-2} day^{-1}], G the heat flux [MJ m^{-2} day^{-1}], T the daily mean temperature at 2 m [K], u_2 the wind velocity at 2 m [m s^{-1}], e_s water vapour saturation pressure [kPa], e_a actual vapour pressure [kPa], e_s - e_a the deficit of saturation pressure [kPa], Δ the slope of the vapour pressure curve [kPa $°C^{-1}$], γ psychometric constant [kPa $°C^{-1}$]. Therefore, the needed meteo data are: the mean temperature and humidity, the wind speed, the net solar radiation computed, in our case by using slope and aspect angle retrieved from a DEM of the area of interest. However, the whole process to obtain the quantities needed can be found in (Allen *et al*. 1998). Anyway others relationship, like these of Hargreaves (Hargreaves, 2003) and Thornthwaite (Thornthwaite, 1948), can be used for computing the same quantity.
Since also the presence of water in the alive vegetation can be considered relevant in determining the fire regime, the problem of estimating the vegetation water content, by using satellite images, has been dealt with. This estimate is made through an index called the *Equivalent Water Thickness* (EWT)**.** We adopted the expression given by Ceccato (Ceccato, 2002) which allows to estimate the value of EWT as a function of GVMI (Global Vegetation Moisture Index), although this index has been defined for the sensor SPOT/VEGETATION. Therefore, it was necessary to compute new coefficients allowing to apply the Ceccato EWT relationship to MODIS images. This was made by carrying out an extended series of simulation by using PROSAIL software. The new parameters have been computed by simulating more than 650000 profiles by using PROSAIL.
The results obtained by means of the simulation have been used for adapting the coefficients of the Ceccato model to the MODIS sensor and, above all, to the Mediterranean vegetation.

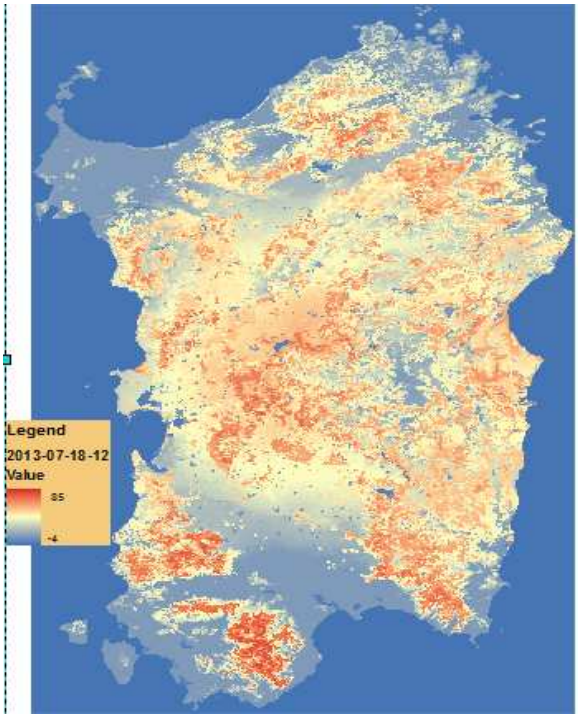

Figure 4. Example of DFHI index computed on the Sardinia region for the day 18 July 2013 at 12:00 UTC.

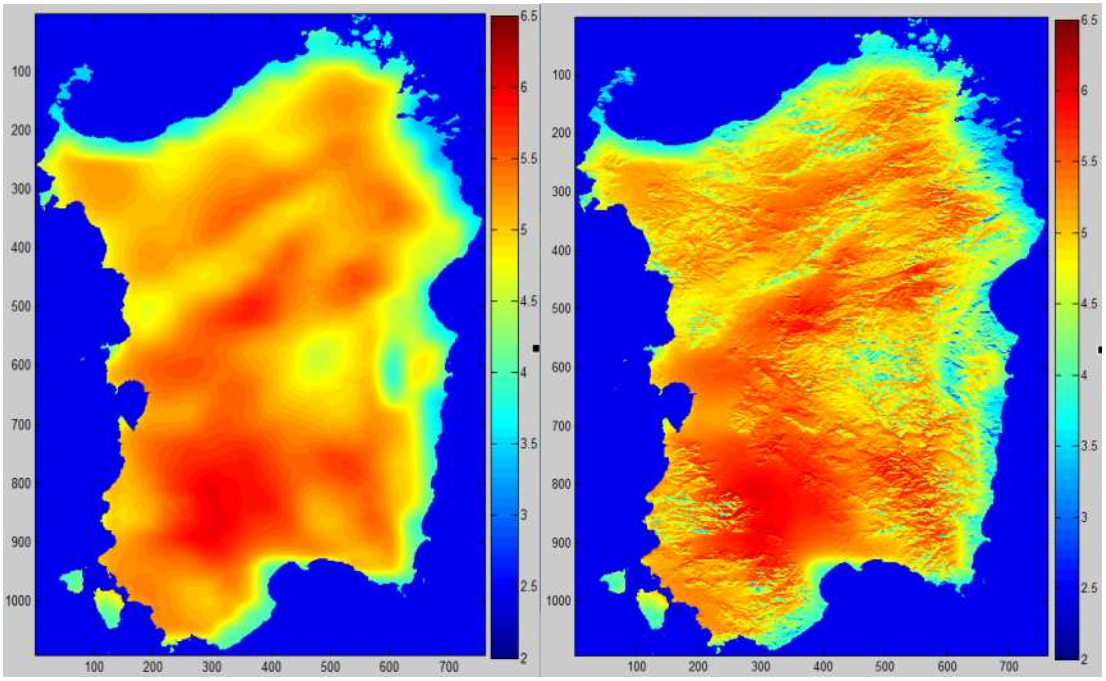

Figure 5. Comparison between the evapotranspiration (ET_0) maps computed by assuming a flat surface (right map) or taking into account the topography (left image) for the Sardinia region.

The solar illumination conditions are taken into account for estimating the DFHI by using ET_0 as a way for correcting the air temperature values used for retrieving the emc parameter. This has been done as follows:

- the Rn term (eq. 5), depending from the local aspect and slope of the surface with respect to the sun, allows us introducing the effect of the illumination conditions. In fact, we can estimate ET_0 assuming a flat surface and using the known meteorological parameters. See Figure 5 (right), as an example for Sardinia. Then, we can estimate the same quantity taking into account

the topographic characteristics of the area of interest (Figure 5, left). From eq. (5), written as function of T, it is possible to estimate the temperature (equivalent temperature) value capable to provide that ET_0 value computed taking into account the topographic effects.

In other words, a LUT has been computed containing 6 parameters: temperature, humidity, latitude, day of the year, available radiation and ET_0. For each pixel, we enter the LUT looking for the row of the table that minimizes the difference between the actual humidity and the one reported in the LUT, between the actual Rn and the one reported in the LUT and the actual ET_0 and the one reported in the LUT. The corresponding temperature represents the temperature that takes into account the illumination conditions present in the pixel as consequence of its slope and aspect.

Conclusions

The FP7 PREFER project objectives originate from the circumstance that, notwithstanding the improvements in the efficiency of the fire fighting, the phenomenon is not showing any tendency to decrease. Therefore, the European Commission has recently adopted a Communication on the prevention of natural and man-made disasters that focuses on the concept that a common approach is more effective than separate national approaches: for example, developing knowledge, linking actors and policies, and efficient targeting of community funds to prevention. In fact, the prevention is still the most cost-effective strategy, when compared to fire fighting and suppression, able to efficiently mitigate this major environment threat. PREFER intends to contribute at responding to such a pragmatic need of southern Europe's forests by: providing timely information products based on the exploitation of all available spacecraft sensors, offering a portfolio of products focused on pre- and post-crisis forest fire emergency, suitable for the users in the different countries of the European Mediterranean area.

Therefore PREFER will set up a regional service, able to process and distribute the information to end users. The service will be ready for operational deployment at the end of the project, as a new powerful tool at the disposal of the authorities in charge of forest fire management in the Mediterranean area.

Abstract
Landscape-scale fires are a regular feature of semi-arid south-western Australia where the dominant vegetation types are shrubland and eucalypt woodland. Fuel discontinuity limits the spread of fire in some eucalypt woodlands under moderate weather conditions, but fires can spread extensively in woodland under severe fire weather conditions. This paper reconstructs the spread of five large fires ignited by lightning that each burnt more than 90 000 ha. Fires remained active for up to 70 days after ignition until they encountered areas of sparse fuel associated with salt lakes and previous burn scars, or were extinguished by rain. Fire perimeters were mapped using daily NOAA AVHRR and MODIS satellite imagery and used to determine periodic growth in fire area. Weather conditions associated with each fire were examined using observations from a limited number of sites. Fire growth was episodic and strongly associated with periods of high temperature, extreme dryness and strong winds. An event of extraordinary fire growth was identified during the 1994 Forrestania fire which increased in area by more than 350 000 ha during a 24 hour period. The influence of weather on fire spread is being examined using re-analysis data from the European Centre for Medium-Range Weather Forecasting (ECMWF) Interim Re-analysis project ERA-1 which provides spatial and temporal data coverage not otherwise available due to the sparse observation network. South-western Australia provides a unique opportunity to examine factors influencing the duration, scale and growth characteristics of fires burning in semi-arid landscapes unimpeded by fire suppression. High intensity fires can cause widespread mortality of mature woodland trees with recovery to a mature structure taking several centuries, and the role of fire in development and persistence of eucalypt woodlands is currently a topic of scientific interest. This study forms part of a broader examination of the extent of active fire management, including prescribed burning and fire suppression, appropriate in these landscapes.

Keywords*: large fires, semi-arid landscapes, lightning ignition, Mediterranean woodlands, satellite imagery*

Introduction

Landscape-scale fires are a regular feature of remote semi-arid areas in south-western Australia where the dominant vegetation types are shrubland and eucalypt woodland. This region of Western Australia is recognised as being of global significance for biodiversity conservation and supports the largest remaining area of intact Mediterranean climate woodland on Earth, known as the Great Western Woodlands (Watson *et al*. 2008, DEC 2010). The semi-arid landscapes of south-western Australia provide a valuable opportunity to understand factors influencing the duration, scale and growth characteristics of fires burning unimpeded by suppression activities. Weather conditions conducive to the ignition and spread of fire occur from October to April in most years, with regular occurrence of severe fire danger resulting from high temperatures, low relative humidity and strong winds associated with the development of pre-frontal troughs during the summer months (McCaw and Hanstrum 2003). Lightning is a common source of ignition during late spring and summer, and fires may be left to burn without intervention for periods of weeks and sometimes months in remote areas where the human population is small and there are few assets threatened by fire. Patterns of fire spread in the landscape

are strongly mediated by vegetation type and fuel structure, time since fire, and by the location of natural barriers to fire spread including rocky outcrops and extensive salt lakes (O'Donnell *et al*. 2011a). The occurrence of very large fires (eg. >100 000 ha) has been linked to climatic patterns that facilitate more extensive spread of fire in eucalypt woodland communities (O'Donnell *et al*. 2011b, O'Donnell *et al*. in press). Large fires appear to be driven by inter-annual variation from extremely wet periods to drought periods that promote increased fuel mass and continuity of ephemeral grasses and small shrubs.

Improved understanding of factors controlling the occurrence and scale of fires in semi-arid woodlands and shrublands would benefit land management programs that seek to conserve biodiversity and cultural heritage values (DEC 2010, Prober *et al*. 2013) and to maintain biomass carbon stocks in long-lived woody vegetation (Berry *et al*. 2009). High intensity fires can cause widespread mortality of mature woodland trees, with recovery to a mature structure taking up to several centuries (Gosper *et al*. 2013a, b). There is also a need to predict the spread of fires that have potential to impact on communities and settlements, infrastructure such as powerlines and pipelines, and on regional transport corridors vital for communication and economic activity.

This paper reconstructs the spread of five large fires ignited by lightning that developed with little or no effect of fire suppression activity. Our study seeks to better understand the dynamics of large fires by documenting patterns of fire spread and examining weather conditions associated with periods of rapid fire growth. We also identify and discuss topics that will be investigated further as the study develops.

Methods

Study area

The five fires examined in this study occurred in or close to the Great Western Woodlands which are bounded on the western and southern sides by the interface with cleared agricultural land, and on the northern and eastern sides by the limits of eucalypt woodland associations and the transition to rangelands held under pastoral lease and subject to extensive grazing by cattle and sheep (Figure 1). Outside of the major regional centre of Kalgoorlie and the towns of Southern Cross and Norseman, the area is sparsely populated by residents of remote pastoral stations, mines and communities of traditional owners. Only a small proportion of the area has been subject to grazing by introduced cattle or sheep, and the vegetation generally retains its natural species composition and structure.

Mean annual rainfall declines across the Great Western Woodlands from 400 mm in the south-west corner to 250 mm at the northern limit (Fig.1). Land surfaces are of great antiquity and derived from Archean granite and gneiss of the Yilgarn craton intersected by formations of greenstone and banded ironstone (Beard 1998). The surface of the Yilgarn plateau is gently undulating at elevations between 200 and 500 m above sea level, with occasional higher points on rocky ranges and granite outcrops. Drainage is occluded with extensive salt lakes indicating the alignment of ancient paleo-drainage systems. Salt lakes are typically bare of vegetation and larger lakes (>1 km wide) are a major barrier to fire spread other than by airborne firebrands.

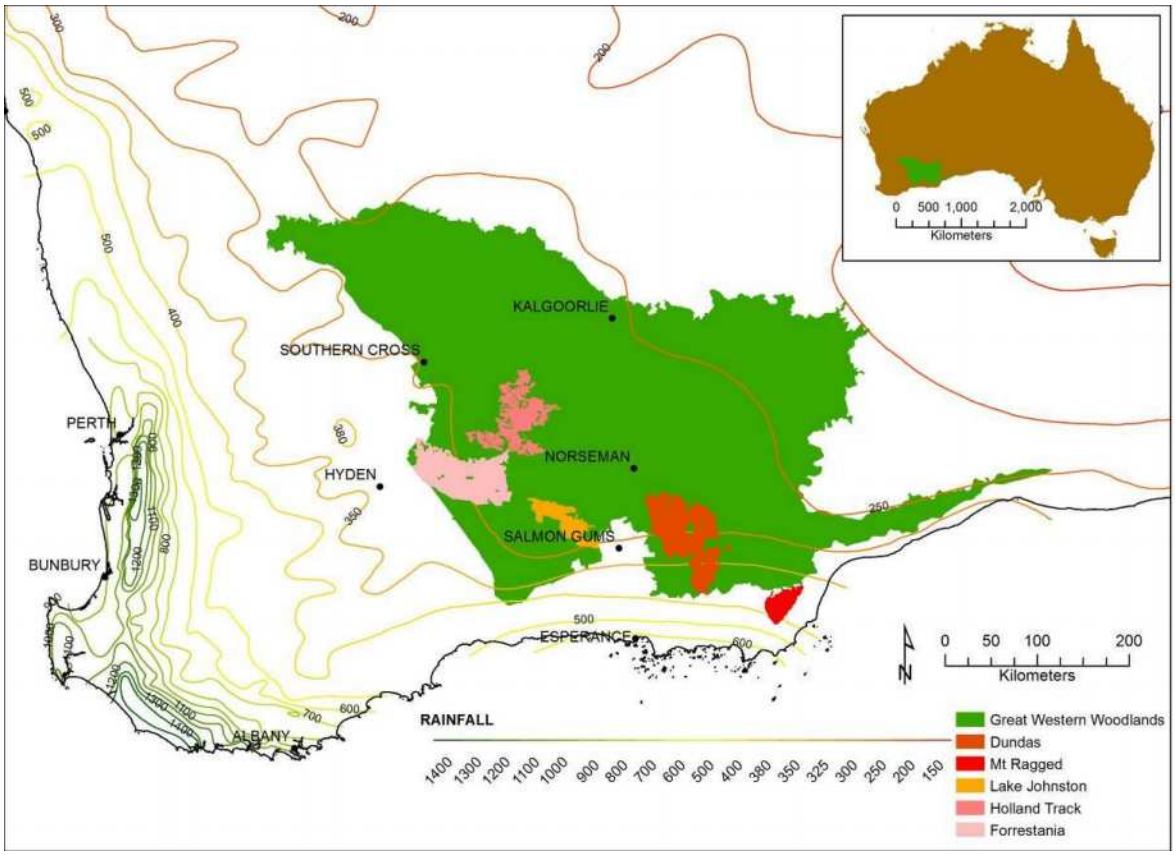

Figure 1. Location of the Great Western Woodlands in south-western Australia

2.1. Re-constructing fire growth from satellite imagery

The date and location of ignition, duration of fire activity and final area burnt for the five fires examined in the study are presented in Table 1. Fire perimeters were mapped from sequential satellite imagery dating to a minimum of every second day during the period of fire activity, subject to image availability and cloud coverage. Images were analysed daily during periods when fires were active and fire perimeters changed significantly from one image to the next. Imagery from the AVHRR sensor on the NOAA-11 and NOAA-12 satellites was used to map the perimeters of the Lake Johnson, Dundas, Mt Ragged and Forrestania fires. The NOAA-11 satellite was operational from 1998 to 2004 and the NOAA-12 satellite from 1991 to 2007. The AVHRR sensor acquired data in five bands (red, near infrared and three thermal bands) with an image resolution of 1.09 km. This satellite imagery data is suitable for detecting active fires (Lentile *et al*. 2006), particularly where fires are large in size and much of the area was burnt at high intensity resulting in significant change in vegetation cover, as was the case for these fires. Fire perimeters were digitised in ERDAS ER Mapper software and subsequently imported into ArcMap for final data manipulation. This analysis utilised archived NOAA imagery held by the CSIRO Earth Observation Centre (http://www.eoc.csiro.au/cats/) and Western Australian Land Information Authority (http://www.rss.dola.wa.gov.au/newsite/noaaql/NOAAsearch.html).

Progression of the 2004/05 Holland Track fire was derived from MODIS constellation imagery. Imagery from both the Terra satellite (launched 1999) and the Aqua satellite (launched 2002) was used, and contains 36 bands at varying resolutions from 250 to 1000 metres. Natural colour displays using bands red, green and blue were created and used to interpret burnt areas. Digitizing of fire perimeters was undertaken in ArcMap. The archive of MODIS data was accessed from the

Western Australian Land Information Authority Firewatch service (http://firewatch.landgate.wa.gov.au/landgate_firewatch_public.asp).

Table 1. Details of large fires reconstructed using satellite imagery

Fire	Ignition date (dd/mm/yyyy)	Ignition location (Lat./long.)	Duration of fire activity (days)	Final fire area (ha x 10^3)
Lake Johnston	19/12/1990	-32.7/120.7	36	151
Dundas	20/12/1990	-32.6/122.3	70	478
Mt Ragged	6/01/1991	-33.3/123.5	53	93
Forrestania	21/01/1994	-32.2/119.3	9	466
Holland Track	5/12/2004	-31.8/120.2	37	311

Weather

The network of weather observation sites representative of the Great Western Woodlands is sparse and restricted to larger settlements mostly located on the margins of the area including Southern Cross, Hyden, Kalgoorlie and Salmon Gums, with Norseman being more centrally located (Figure 1). Automatic weather stations capable of continuous recording began to be installed at these sites from the mid-1990s but did not exist at the time of the Lake Johnson, Dundas, Mt Ragged and Forrestania fires. Balloon sondes launched daily at Kalgoorlie provide atmospheric observations above the surface level. The ignition points of all fires examined for this study were at least 75 km from the closest weather observation site, and in some case much further. In selecting weather observations representative of each fire important considerations are how well the observations reflect the location of the fire relative to pre-frontal troughs and cold fronts advancing from the west, and relative to coastal influences that may moderate extremes of temperature and dryness but be influenced by sea breezes from the Southern Ocean.

Re-analysis data from the European Centre for Medium-Range Weather Forecasting (ECMWF) Interim Re-analysis project ERA-1 provides spatial and temporal coverage of weather data not otherwise available due to the sparse observation network in the study area and is being utilised as an additional source of information for fire reconstructions. Re-analysis data are available 3 hourly on a 75 km grid worldwide and provide basic variables (T, T_d, wind speed and direction) from 1979 onwards. Wain and Kepert (2013) used ERA-1 re-analysis data to develop a comprehensive and nationally consistent climatology of fire weather parameters for the whole of Australia including derived indices for fire danger and atmospheric stability that can provide important insights into factors influencing fire dynamics.

3. Results

The five fires examined in our study spanned the southern half of the Great Western Woodlands, with the 1991 Mt Ragged fire in the Cape Arid National Park at the southern extremity of the woodland region (Fig 1.). Three of the fires occurred during the summer (Dec-Feb) of 1990/91 resulting in a burnt area of 722 000 ha. Individual fires ranged in final size from 93 000 ha for the Mt Ragged fire to 478 000 ha for the Dundas fire. The Lake Johnston and Dundas fires were ignited by lightning from dry thunderstorms on 19 December 1990, and the Mt Ragged fire was ignited by lightning on 6 January 1991.

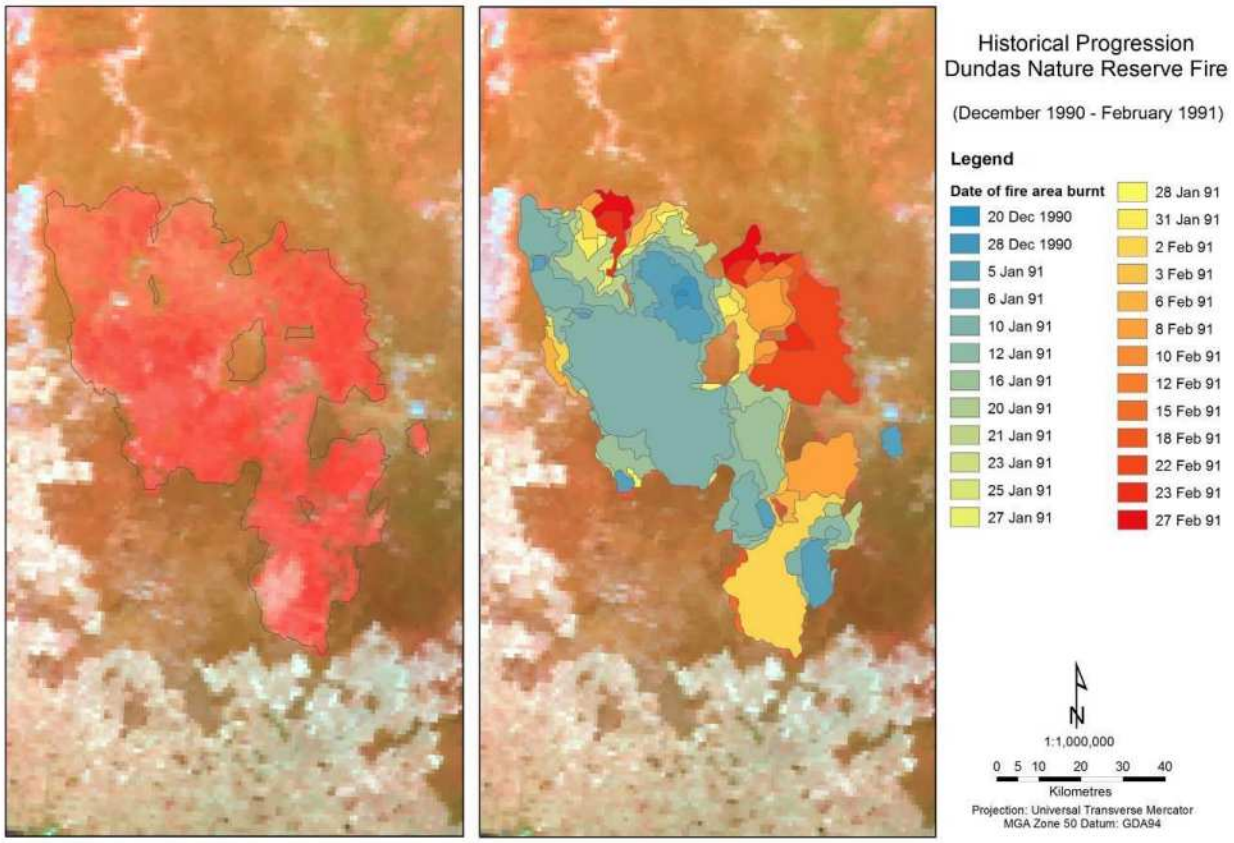

Figure 2. Reconstruction of the Dundas fire from AVHRR satellite imagery between 20 December 1990 and 27 February 1991 showing (a) burnt area and (b) periodic spread

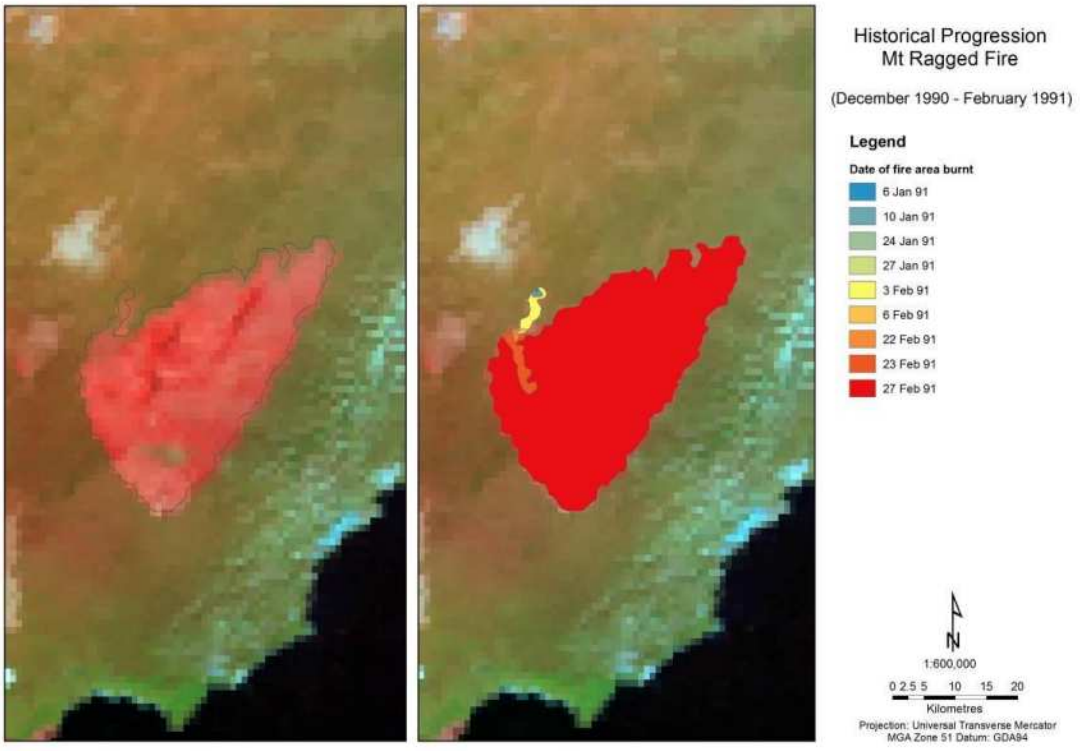

Figure 3. Reconstruction of spread of the Mt Ragged fire from AVHRR satellite imagery between 6 January and 27 February 1991 showing (a) burnt area and (b) periodic spread

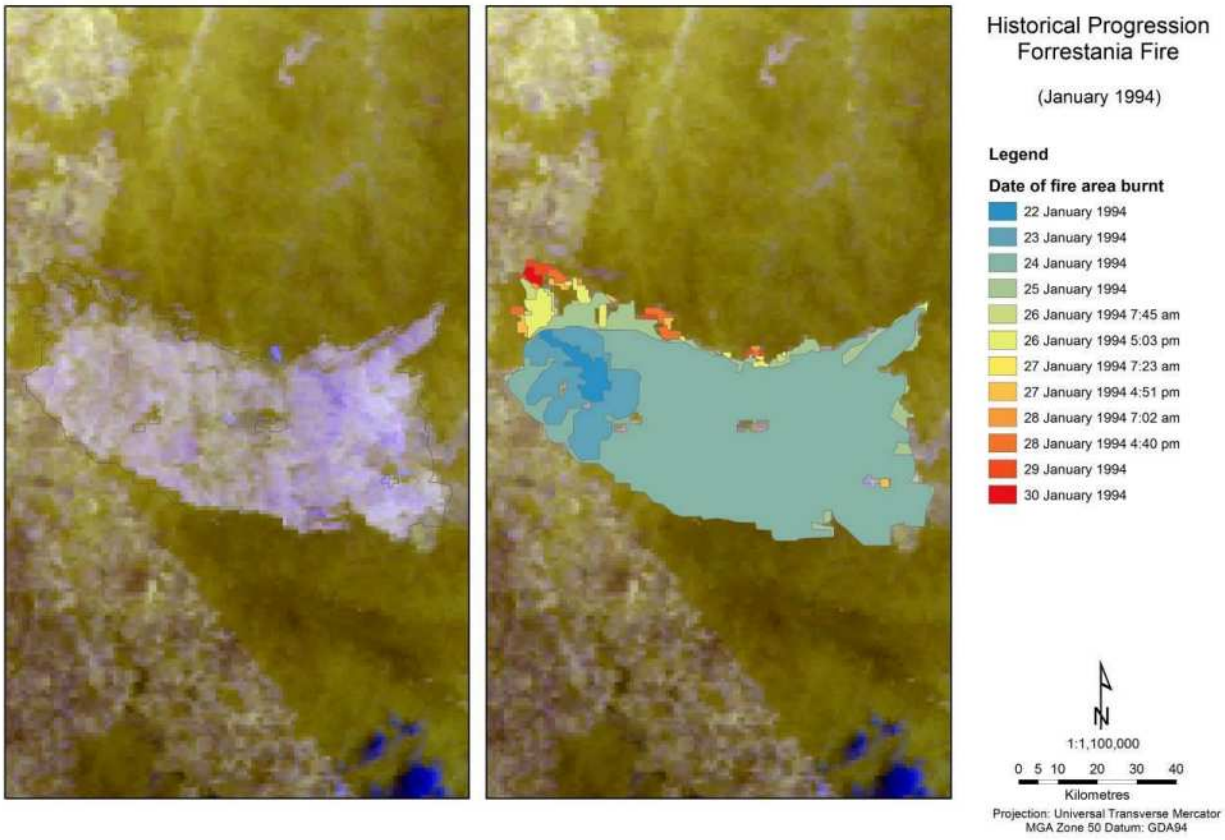

Figure 4– Reconstruction of spread of the Forrestania fire from AVHRR satellite imagery between 22 and 30 January 1994 showing (a) burnt area and (b) periodic spread

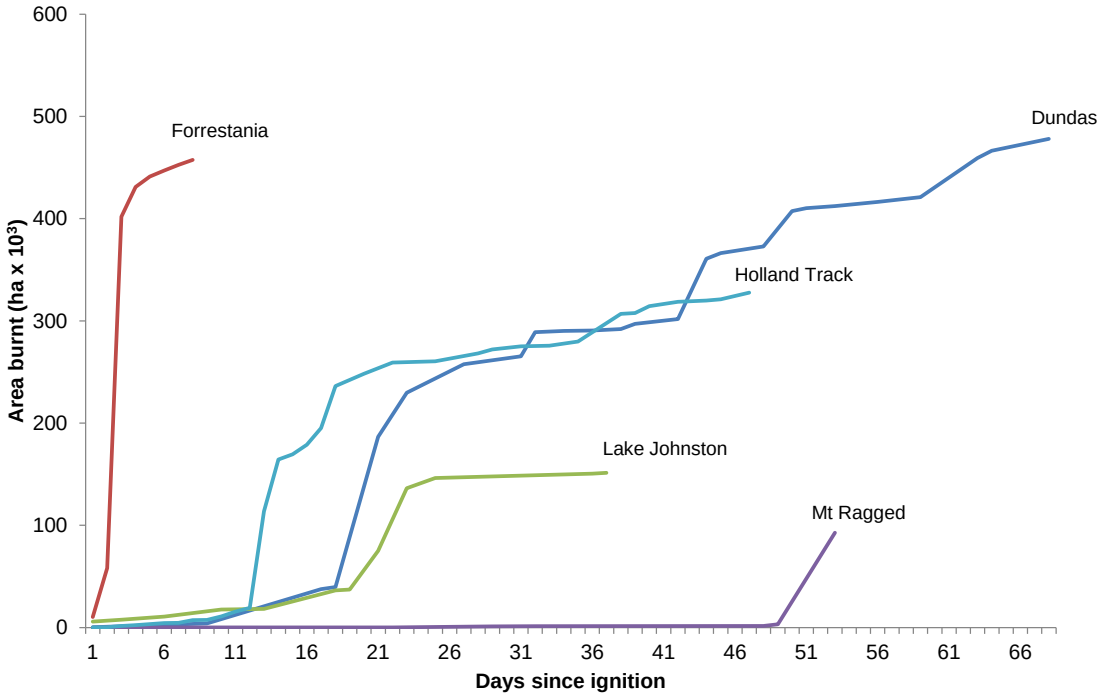

Figure 5. Increase in area burnt following ignition for five large fires

Fire reconstructions from satellite imagery show that the Mt Ragged and Dundas fires continued to grow through until late February 1991, with corresponding active periods of 53 and 70 days (Figs 2 & 3). The 1994 Forrestania fire burnt a very large area (466 000 ha) but was only active between 22 and 30 January, with the major spread event taking place on 24 January (Figure 4). The Holland Track fire was ignited by lightning on 5 December 2004 and remained active for 37 days attaining a final burnt area of 311 000 ha.

Fires exhibited different patterns of growth and development (Figure 5). The Lake Johnston and Dundas fires developed at a similar rate to each burn about 40 000 ha by 6 January 1991. Both fires then exhibited major spread between 7 and 9 January increasing in size by more than 100 000 ha under the influence of dry north-westerly winds and very high temperatures; a maximum temperature of 41°C was recorded at Salmon Gums on 8 January. The Lake Johnson fire travelled a distance of approximately 60 km to Peak Charles where its further spread was constrained by extensive salt lakes. The Dundas fire continued to develop and exhibited further periods of major spread to the south between 28 January and 3 February, and towards the north-east in mid-February. These spread events were also associated with periods of very high temperature (>42°C) and strong northerly to westerly wind. The Mt Ragged fire exhibited a quite different pattern of development following ignition on 6 January 1991. This fire remained small (<200 ha) throughout January and then grew to 1500 ha in early February, under the same weather pattern that drove the expansion of the Dundas fire. A further period of very high temperature and northerly winds increased the fire size to 3250 ha on 23 February. The major fire spread event took place on 27 February, initially under north-westerly winds through an area burnt previously by a lightning caused fire in 1983, and then under the influence of a strong south-westerly flow that extended the northern flank of fire. Fire growth on 27 February was estimated to be approximately 90 000 ha.

The Forrestania fire was ignited by lightning on 22 January 1994 and grew to approximately 10 000 ha within the first day of spread. Back-firing from the interface with the cleared agricultural land on 23 January increased the fire area to approximately 58 000 ha, with the pattern of the back-firing evident from the remote sensing imagery. An event of extraordinary fire growth took place on 24 January during which the fire increased in size by more than 350 000 ha under the influence of north-west and westerly winds. The head of the fire spread up to 80 km and reached the extensive salt lake at Lake Johnston. Upper air observations from Kalgoorlie show a dry adiabatic atmosphere to more than 5 km and wind speeds of 46 knots at the 900 hPa (1000 m) level (Figure 6). Growth of the Forrestania fire on the subsequent five days was relatively small in extent and confined to the northern flank of the fire.

The Holland Track fire was ignited by lightning on 5 December 2004, and underwent an initial period of growth for 10 days similar to that of the 1991 Dundas and Lake Johnston fires (Figure 5). Fire size increased by almost 100 000 ha on 17 December, after which time the rate of growth followed a similar trajectory to that of the Dundas fire. Some limited suppression activity including track construction and back-burning was undertaken on the Holland Track fire and this may have influenced its pattern of development during later stages.

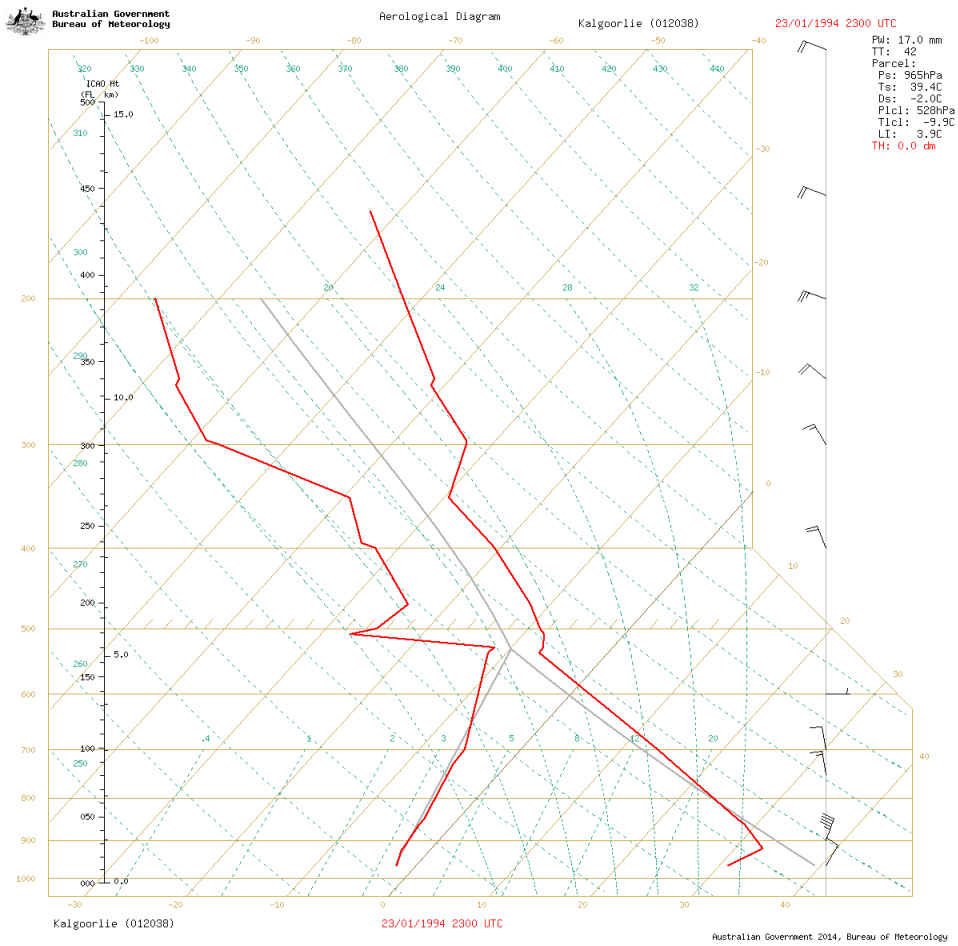

Figure 6. Aerological diagram for Kalgoorlie for 0700 hr Western Standard Time on 24 January 1994

Discussion

The fires examined in this study are of a size significant at the scale of the Australian continent, and potentially at a global scale. Indeed, the rate of growth of the Forrestania fire may represent one of the largest fire spread events documented for a single fire on one day. The scale of area burnt and rates of fire development are comparable with those documented for Black Saturday 7 February 2009 in south-eastern Australia which burned over 450,000 ha and resulted in 173 human fatalities (Cruz *et al*. 2012). The Kilmore East fire was the most significant of these fires, burning 100,000 ha in less than 12 hours and travelling a distance of around 55 km under northerly winds before being forced northwards by the passage of a cold front. Understandably, fires burning in remote areas of Australia that do not pose a direct threat to human life or economic activity attract little attention from the community or from fire researchers. However, these large remote fires warrant detailed study because of their environmental impacts on a range of values including biodiversity, atmospheric emissions and carbon storage in long-lived woody vegetation. They also offer insights into dynamic processes of fire spread that are rarely available in more densely populated landscapes.

Further work will be undertaken for this study to examine in greater detail the weather patterns associated with periods of major fire spread and to investigate the association between fire growth and existing fire danger indices used in Australia. We also intend to examine how fire spread is affected by broadscale patterns of vegetation and time since previous fire.

Rekindles or one-σ quality in forest fire fighting: validating the pressure on firefighters and implications for forest fire management in Portugal

Abstract
A long time after many business activities started struggling for six sigma quality in their operations, in Portugal, fire suppression operates at a one sigma quality level with disappointing performance results expressed by too many rekindles – re-work caused by defects in the suppression process. Indeed, they represent a high burden on wildland fire suppression resources, but despite the relevance of this phenomenon in Portugal, related research is still scarce.
Seeking to contribute to address this gap, the purpose of this study was to organize and provide an overview of the problem of rekindles in Portugal, and to verify whether evidence exists that the high proportion of rekindles in Portugal is related to the double duty of Portuguese firefighters to perform initial attack and mop-up operations.
Our study included informal meetings, formal recorded interviews, dispatch centre visits, actual rekindle observation, and an analysis of the National Forest Authority database.
From the study of genealogies of rekindles, we concluded that 17.2% additional forest fires (rekindles in successive generations) had their origin in only 7.4% of primary fires. Through regression analysis, we found that their proportions increase in days with more occurrences, preliminarily supporting the hypothesis of premature abandonment of mop-up operations, as a result from the pressure to immediately attack starting fires by the same crews.
A more detailed analysis of two representative districts highlighted specific organizational and natural challenges to successful mop-up efforts and provided further evidence of the hazardousness of rekindles. Finally, we suggest management practices to mitigate this problem and increase the level of quality of forest fire suppression in Portugal.

Keywords*: wildfire, rekindle, mop-up operations, reburn, initial attack, suppression*

Introduction

A complex and hazardous part of forest fire are rekindles, or reignitions, that reburn an area over which a previous fire has passed, but has left fuel that later ignites due to latent heat, sparks, or embers (NWCG 2011). Throughout the 2010 summer, Portugal had 14,551 primary wildfires, of which 17.2% rekindled into an additional 2,497 fires, leading to a total of 17,048. That summer accounted for 94.7% of the wildland annual burnt area of 132,241 ha. However these figures may be more severe. Several authors suggest that the number of rekindled forest fires is higher than that officially reported (ANIF 2005; Lourenço and Rainha 2006). Expert-judgment elicitation in field interviews performed by the authors points to the double. Even assuming that the available information is correct, the number of rekindles is too high (Beighley and Hyde 2009). This is a concerning situation that has been getting worse over the years (ANIF 2005), and results from ineffective mop-up operations (Murdock *et al.* 1999; ANIF 2005; ISA 2005; Lourenço and Rainha 2006; Lourenço 2007; Beighley and Hyde 2009), despite effective initial attacks (ANIF 2005; Lourenço and Rainha 2006; Lourenço 2007). Although there is a danger of fatalities during the mop-up stage (Alexander *et al.* 2007), this danger is even higher in a rekindle scenario (NWCG 2005). Finally, ineffective mop-ups and lack of surveillance

(Lourenço 2007) result in rekindles that often become large fires (ANIF 2005; Lourenço and Rainha 2006; Lourenço 2007). These are usually bigger than the wrongly judged extinguished primary fire, with larger burnt areas and considerable damage (ANIF 2005), even when the initial perimeter was just tens of meters (Lourenço and Rainha 2006).
After the disastrous fires of 2003 (Fernandes 2008), repeated two years later, the government commissioned a technical strategy (ISA 2005) to address this problem. In 2006, a modified version (shifting the emphasis from prevention to an increase in suppression capability) was approved and published (C.M. 2006) as the national strategy for forest protection against fires (Beighley and Hyde 2009). The plan recognizes the impact of rekindles and establishes mitigation as one of the priorities, with a goal of 1% by 2010 defined as an accepted value for the rekindle rate (Oliveira 2011). However, this goal was never achieved (AFN 2011) and the national figures are still much higher than, for instance, the USA 2004-2008 rekindle annual averages, which vary between 2 and 6% (Ahrens 2010).

Methods

For this study we use data kindly provided by *Autoridade Florestal Nacional* (AFN). This wildfire dataset, although having undergone several changes throughout the years, has been relatively stable in the last 12 years. The current version gathers information regarding the location of the fire, date and time (i.e., alert, ignition and extinction), burnt area, type of event, and causes. The events could be false alerts, fires in agricultural lands, or wildland fires (forests and shrublands). Information about the nature of the fire (single or reignition) is recorded since 1984 (Pereira *et al.* 2011). We focused our attention on 2010 because this is the first year for which more complete data on rekindles is available. For instance, it is now possible to know, for each rekindle, the specific fire whose bad mop-up originated it.
The country mainland is divided in 18 main administrative regions (districts), their corresponding municipalities (278 counties) and 4,050 parishes. There are significant geomorphologic, climatic and demographic differences between the northern and southern parts of Portugal (Pereira *et al.* 2011). Fire policies, suppression and prevention efforts are organized at the district level. They are therefore too heterogeneous, and we chose them as units of analysis.
Rekindles represent a high burden on suppression resources. Our goal (and hypothesis) was to find whether there was evidence that in days with more ignitions, the firefighters are compelled to prematurely abandon fire mop-up operations, thus promoting more rekindles. In other words, we wanted to know if the high number of rekindles was associated with the pressure to immediately combat all the new fires, to prevent them from becoming big fires. To accomplish this, we conducted a linear regression study, considering two variables. We consider as explanatory variable the number of fires that were simultaneously fought in each day (active fires). For the first component of the dependent variable, we counted the number of fires with a bad mop-up in that same day, i.e., the fires erroneously declared extinct, and origin of some later rekindle. However, because it is expected that bad mop-ups increase with adverse climatic conditions and the number of fires in each day, we divided this component by the number of active fires in that day. To count the number of fires with a bad mop-up in a particular day, we performed a detailed treatment of the database to uncover the genealogies of rekindles, identifying for each rekindle the bad mop-up that originated it. We used Microsoft Excel® and MapPoint Europe 2011® for the pivot tables and maps, IBM SPSS Statistics 19® for descriptive statistics, and STATA/IC 12® for regression analysis.

3. Results

Among the districts with a relevant number of rekindles, only one – Viana do Castelo – did not present a statistically significant positive correlation between the proportion of bad mop-ups and the number of active fires. The plot of the relationship between the two variables (**Erro! A origem da referência não**

foi encontrada. 1, left) displays no discernible trend; however it shows very clearly a persistently very high proportion of bad mop-ups. In our contacts with experts, a key explanation that was put forward for this result was the fact that this is the district in the country with the lowest ability to mobilize volunteer firefighting efforts, which leaves mop-up activities permanently understaffed. Another potential cause is the fact that the district has a very large mountain area, where wildfires are more difficult to control, resulting in higher burnt areas and perimeters, and therefore higher probabilities of rekindling.

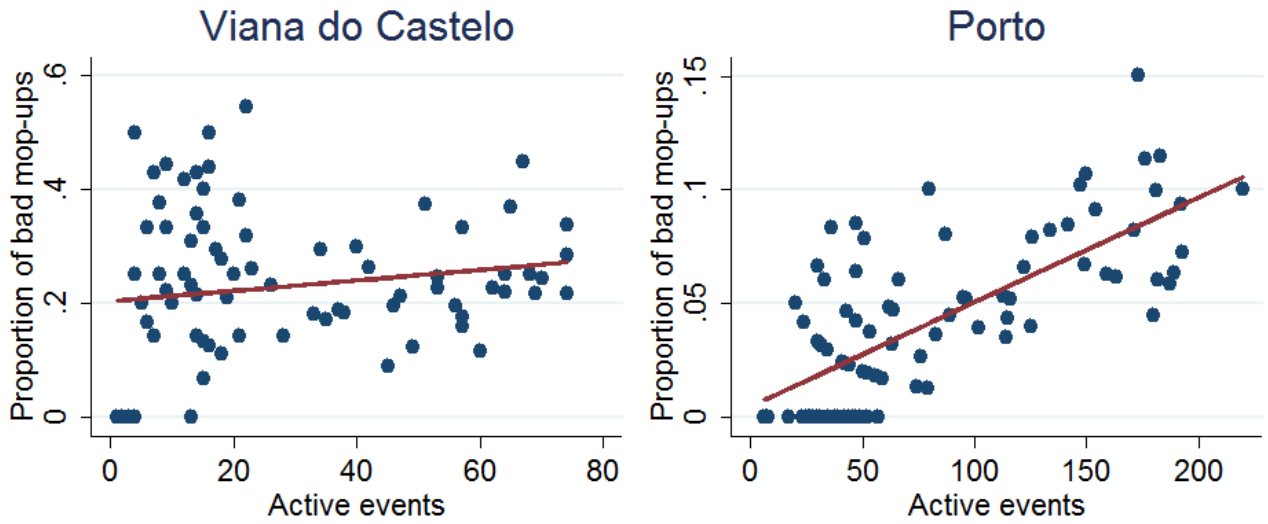

Figure 1. Plots of values and fitted values for Viana do Castelo and Porto.

The district where the effect of suppression pressure on bad mop-ups is clearer is the district of Porto; the correlation is high and the plot (**Erro! A origem da referência não foi encontrada.** 1, right) shows a distinct trend of increase in the proportion of bad mop-ups with the increase in active events. The district of Porto has a historical trend of a very high number of forest fires, which remained through 2010, with a very high proportion of forest fires with a burnt area below 1 ha – 90.6% of the six thousand incidents (Pacheco 2011). This very high number of incidents puts a huge pressure on the suppression system, which not only works at constantly very high levels of capacity utilization, but also is constantly being requested for initial attack of new fires or rekindles.

Starting from a literature review and the results of our fieldwork to identify, organize, and relate the set of physical, natural, technical and organizational factors that influence the occurrence of rekindles, we used data analysis and descriptive statistics to present evidence of the size and impact of the problem of rekindles in Portugal (Pacheco *et al.* 2012). A key contribution of our work resulted from a simple linear regression analysis of the relationship between active events and the proportion of bad mop-ups to active events. A statistically significant positive relationship was found for six of the seven districts with a relevant number of rekindles. Finally, a more detailed view of rekindle dynamics in the districts of Viana do Castelo (the only district with a non-significant regression) and Porto (the district with the higher significant correlation) highlighted specific organizational and natural challenges to a successful mop-up effort and provided further evidence of the hazardousness of rekindles. As future work, we plan to extend this study to new data that is becoming available for more recent fire seasons, and analyse the performance of alternative organizational architectures for suppression efforts, with specialized teams assigned to the different suppression tasks.

Risk assessment to achieve fire adapted communities in the US

Keywords: Risk Assessment, Cohesive Strategy, WUI

Extended Abstract

The US Cohesive Strategy on Wildfire Management has established three primary goals: 1) Fire Adapted Communities, 2) Fire Resilient Landscapes, and 3) Safe and Effective Fire Response. Risk assessment has been put forward as an organizing framework to achieve these established goals. However, there is considerable uncertainty in identifying the most effective way to reach the goals and how the goals complement or compete with each other in reducing potential future losses to human development and natural resource values from wildfire while recognizing the critical ecological importance of wildfire within fire adapted ecosystems.

In this presentation we focus on the application of a wildfire risk assessment framework to achieve fire adapted communities. To start we identify the sequence of events and necessary conditions that lead to Wildland Urban Interface (WUI) disasters, and outline a structured framework to examine the risk components that influence expected wildfire losses with particular emphasis on goal 1, Fire Adapted Communities. WUI disasters where numerous structures are destroyed with potential human fatalities typically follow a common sequence of events (see Figure 1). Environmental conditions related to the location of the community relative to potential severe wildfire behaviour, numerous homes susceptible to ignition, and high severity fire weather overwhelm and limit the effectiveness of firefighting resources resulting in WUI fire disasters.

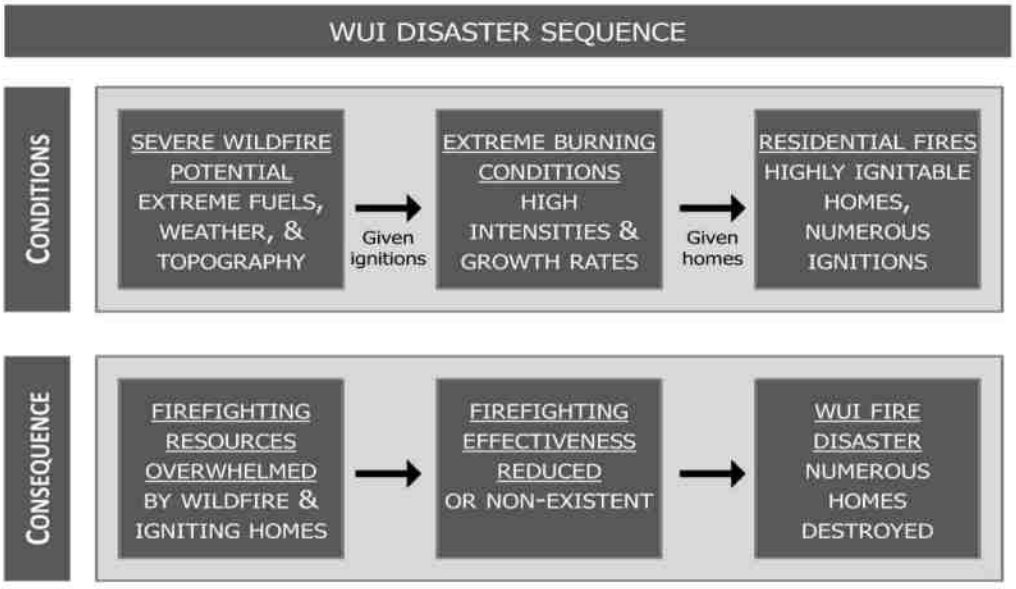

Figure 1. The WUI disaster sequence (taken from Calkin et al. 2014).

Evaluation of risk mitigation options to eliminate WUI fire disasters begins with the questions of what the appropriate wildfire management objectives are, how risk mitigation options realistically vary in terms of cost, the likely effectiveness if those options, and the appropriate identification of who bears the responsibility. Figure 2 presents a conceptual framework of mitigation objectives and methods to achieve those objectives in reducing the risk to life and property within the WUI.

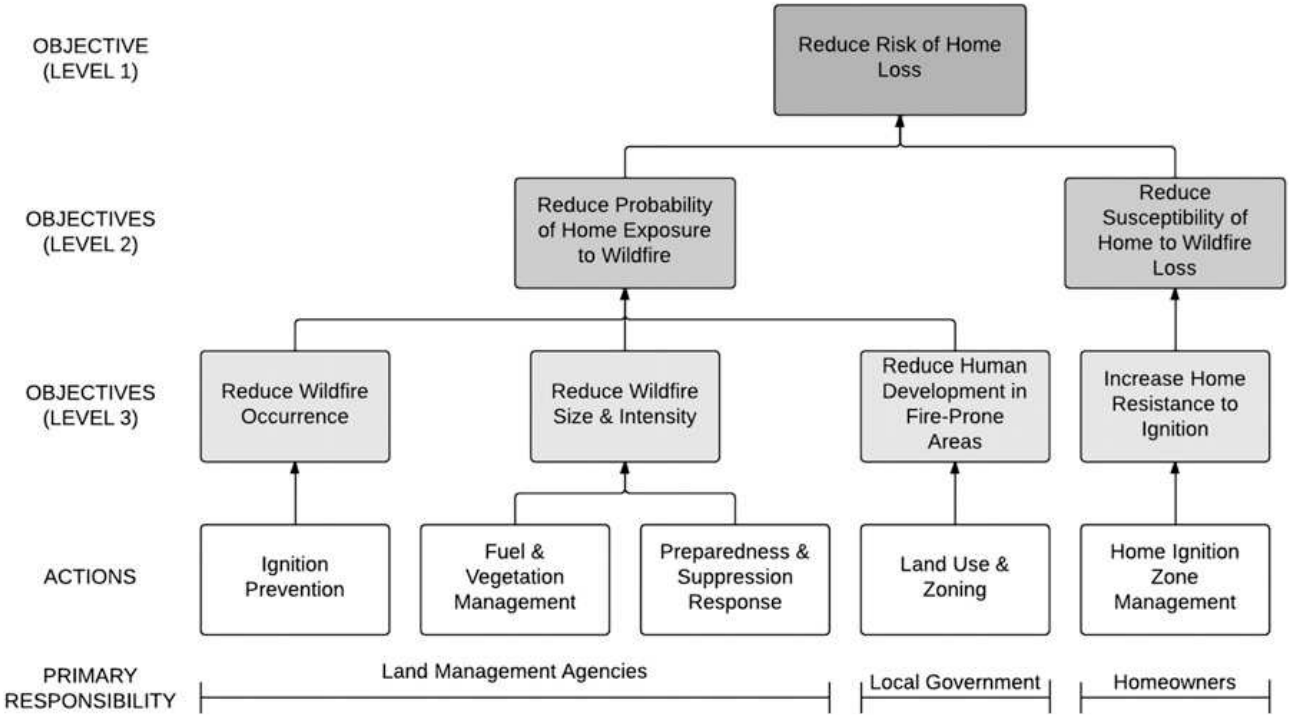

Figure 2. Conceptual framework of risk reduction to reduce risk to life and property.

Public land management agencies with wildfire management responsibilities in the US have focused significant attention on efforts to reduce the size and intensity of wildfire through aggressive suppression efforts and fuel treatment programs that focus effort within and adjacent to the WUI (US Public Law 108-148, 2003). However, extensive research has demonstrated that the destruction of residential structures is defined by the conditions of the structure itself and a 30 m buffer that surrounds the structure (see for example Cohen, 2000, 2010); an area which is typically private land. Public land agencies face several challenges in implementing aggressive fuel treatment programs near populated areas include limited budgets, sensitivity to smoke from prescribed burns, and concern that escaped prescribed fires may increase risk to the community (Calkin *et al*. 2011). Additionally, most WUI fire disasters occur under extreme wildfire conditions when suppression resources fail to contain the fire. Therefore, the ability of traditional fire management response to limit WUI fire disasters is limited.
We suggest the current paradigm that views wildland urban interface disasters as a failure of wildfire control needs to be reframed to recognize the inevitability of wildfire and that these disasters can best be prevented by focusing on the home ignition conditions. This is not to suggest that public land agencies do not have a significant role in achieving fire adapted communities. Significant investments in fuels treatments are necessary to maintain the environmental quality and landscape amenities that draw people to these environments. Application of these concepts will require engagement and risk sharing from all parties involved in fire management within the WUI. However, the described approach presents an opportunity to effectively and efficiently achieve fire adapted communities within the US.

Abstract
According to the literature, MODIS burned area product MCD45 has been shown to have low reliability in the tropical Andes, with omission errors around 50%. Instead, Landsat images can provide good results but current processing methodologies are very time consuming. This study presents a new method for the tropical Andes, based on spectral unmixing applied to MODIS and Lansat images, with the aim of improving the methods currently available to estimate burned area in the region. Results show that the technique is not appropriate for MODIS images, which have not enough spatial resolution distinguishing between burned and unburned pixels. However, spectral unmixing applied to Landsat images lead to results with only 20% of omission errors and 9% of commission errors.

Keywords*: tropical mountain cloud forest, linear unmixing, Peruvian Andes, MODIS, Landsat TM5*

Introduction

The Andes are one of the most biologically rich regions on the planet, where the occurrence of fires is believed to be increasing. In the Andean region of Cusco there are, on the one hand, high mountain pastures where the use of fire by local communities for agriculture and livestock as well as for cultural and religious practices is common (Sarmiento & Frolich, 2002). On the other hand, there are the tropical mountain cloud forests, ecosystems of high ecological value but extremely sensitive to fire which, due to climate change, are being increasingly affected by fires (Cochrane, 2003). However, the fire regime and the emissions associated with the combustion of biomass in the region are still relatively poorly understood, mainly due to the lack of systematic national fire monitoring policies but also due to the characteristics of the region with very remote areas of difficult access. Remote sensing can therefore become a very effective tool for the estimation of burned areas in these regions.
There are numerous studies in the literature on the detection of burned area scars from satellite images, but there are really very few studies focused on the Tropical Andean region (Bradley & Millington, 2006; Oliveras, Anderson, & Malhi, 2014; Román-Cuesta *et al*., 2014). Moreover, all of these few studies also agree that the majority of remote sensing products currently used have a high degree of underestimation in the detection of the number and area of fires in this region. Several reasons can be argued to explain this underestimation (Bradley & Millington, 2006), mainly: spatial resolution of imagery, topographic effects causing shadows on the image, climatic seasonality which affects fuel moisture contents and cloud cover, local fire characteristics (most fires in the tropical Andes are small and of short duration) and the spatial and temporal scales of human activity in managing the grasslands. Oliveras *et al*. (Oliveras *et al*., 2014) observed a remarkable underestimation of fire ignitions and burned area from MODIS fire products. Particularly, their data suggested that the MODIS burned area product (MCD45) failed to detect not only small burn scars but also large burn scars, probably due to the limitation of this global algorithm to overcome issues of cloud frequency and shadows caused by

the complex topography of this region. These authors have therefore suggested that a calibration would be needed for the Tropical Andes in order to improve the performance of these products. The use of higher resolution images such as the ones provided by the Landsat thematic mapper could also be a solution, but current processing methodologies are very time consuming, of difficult validation and limited by the temporal resolution of the Landsat imagery.

The basic unit of a satellite image is the pixel that varies in size depending on the image's resolution. Regardless its resolution, a pixel is not usually homogeneous, because the signal measured by the sensor is always a mixture of the electromagnetic radiation of different constituents that are in pixels. Recognizing that pixels are combinations of different components has introduced the need to decompose quantitatively these mixtures. The basic premise of the mixture modelling techniques is that in an image most of the area is dominated by a small number of different materials that have relatively constant spectral properties. These materials (eg water, soil, metal, vegetation, etc.) are called *endmembers* and the fractions appearing in a mixed pixel are called *abundances*. The endmembers are elements considered spectrally pure. The spectral decomposition or spectral unmixing is thus the procedure by which the measured spectrum of a mixed pixel is decomposed into the endmembers and their corresponding abundances. During the last decades, several methods have been proposed to solve the mixture problem (Atkinson & Tatnall, 1997; Brown, Gunn, & Lewis, 1999; Carpenter, Gopal, Macomber, Martens, & Woodcock, 1999; Guilfoyle, Althouse, Chang, & Member, 2001; Nascimento & Dias, 2005; Wang, 1990). Among all methods, the most widely used is the spectral mixture analysis (Adams, Smith, & Johnson, 1986; Keshava & Mustard, 2002) using linear models (LMM) and non linear models (NLMM). The question of whether linear or nonlinear processes dominate spectral signatures is still an unsolved problem (Somers, Asner, Tits, & Coppin, 2011). The linear approach has proven to be a useful technique for the interpretation of remote sensing data variability and a powerful mean of converting spectral information on products which may be related to the abundance of natural materials on the surface (Keshava & Mustard, 2002). Nevertheless, it does not include the possible interactions between the endmembers present in a pixel, which may lead to results with absolute errors of up to 30%. The NLMM, although it considers the possible interactions between endmembers and thus reduces the error, has a much higher computational cost (Adams & Gillespie, 2006). For this reason, the use of LMM is much more extensive in the literature.

The key to achieve good results in spectral mixture analysis is an accurate selection of type and umber of endmembers (Elmore, Mustard, Manning, & Lobell, 2000; Tompkins, Mustard, & Forsyth, 1997). The most common way achieving this is the use of iterative testing with different combinations and sets of endmembers (Franke, Roberts, Halligan, & Menz, 2009; Somers *et al*., 2010). Once the endmembers have been determined and the number of spectral bands available is known, if a LMM is used, an overdetermined system of linear equations have to be solved in order to obtain, for each pixel, the respective abundances of the endmembers. The solving method used must ensure the minimum error of the solution. Generally, the selection of this method is arbitrary, for example (Ball, Kari, & Younan, 2004) use the singular value decomposition, (Adams *et al*., 1995) use the Gramm-Schmidt orthogonalization, (Chen, Jia, Yang, & Matsushita, 2009; Du, 2004) use quadratic programming, (Settle, 2006) uses maximum similarity and (Anderson *et al*., 2005; Barducci & Mecocci, 2005) use the least squares regression analysis.

This study aims to develop a systematic and reliable methodology for obtaining accurate data on burned area scars for the Tropical andes, by using unmixing modelling on remote sensing images from different satellites (MODIS and Landsat).Following the work performed by Anderson *et al*. (Anderson *et al*., 2005), we used three types of endmembers (soil, vegetation and water), performing a specific study to characterize them (Somers *et al*., 2011) for the study area.

Study area

The study area, of about 2.8 million hectares, is located on the eastern slope of the southeastern Peruvian Andes, at altitudes over 2000 meters above sea level (see the red line in Figure 1), and is characterized by very steep gradients both longitudinally and latitudinally. The coordinates used to delimitate the study area were: -12° S, -14°S, -69.5° W, -73.2° W

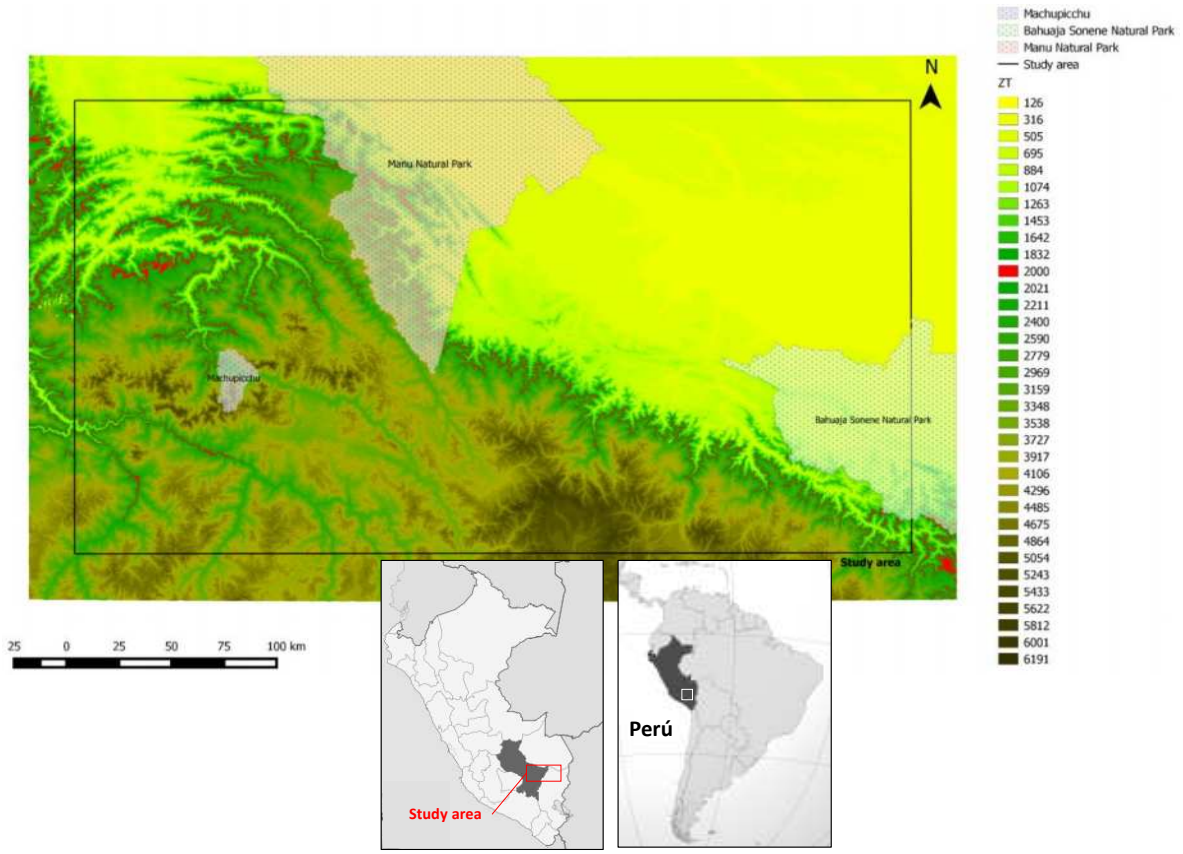

Figure 1. Location of the study area. Colour legend indicates altitude in meters a.s.l.

Methodology

3.1. Data

Three different sets of data were used: MODIS to develop the linear unmixing model, the ASTER Global Digital Elevation Model (GDEM) to develop an elevation mask over 2000 m a.s.l. at the study area and the Landsat TM5 for validation purposes.

MODIS instruments are onboard satellites Terra (EOS AM), launched in late 1999, and Aqua (EOS PM), launched in mid-2002; both following the Earth polar orbit and covering its entire surface every 1 to 2 days. MODIS instruments provide high radiometric sensitivity (12 bit) in 36 spectral bands, ranging from 0.4 to 14.4 microns wavelength, with spatial resolutions ranging from 250 to 1000 m (http://modis.gsfc.nasa.gov/about/design.php). Here, following the previous work of Anderson *et al*. (Anderson *et al*., 2005) we used the MOD09 product (MOD09GQ and MOD09GA) for obtaining the reflectance in the following wavelengths: band 1 (620-670nm), band 2 (841-876nm), band 3 (459-479nm), band 4 (545-565nm), band 5 (1230-1250nm), band 6 (1628-1652nm) and band 7 (2105-2155nm). Bands 1 and 2 correspond to MOD09GQ and have a spatial resolution of 250 m, while the other bands correspond to MOD09GA and have a spatial resolution of 500 m. We also used the product MODIS 250 m land-water mask (MOD44W) to help us making a mask of water bodies. Images from

MODIS were reprojected to WGS84/UTM18 using the Modis Reprojection Tool (MRT) free software (https://lpdaac.usgs.gov/tols/modis_reprojection:tool). MRT was also used to standarize pixel size to 250 m resolution in the three MODIS products (MOD09GQ, MOD09GA and MOD44W). For each MODIS product, we downloaded tiles h10v10 and h11v10 (that cover the study area) for the period January 2000-December 2012.

Aster is an earth observing sensor developed in Japan to be onboard the satellite "Terra". It is in operation since December 1999. Aster GDEM is a product from NASA and the Japan's Ministry of Economy, Trade and Industry, released on June 2009 and giving a complete mapping of 99% of the earth surface with a 30 m theoretical resolution. Previously the most comprehensive map was the NASA's Suttle Radar Topography Mission (SRTM) that covered 80% of the Earth's surface with 90 m resolution. Aster GDEM images can be obtained on the website: http://gdem.ersdac.jspacesystems.or.jp/search.jsp. The ASTER images corresponding to the study zone (S13W074- S14W074- S13W073- S14W073- S13W072- S14W072- S13W071- S14W071- S13W070- S14W070) were used to create an altitude mask to the MOD09GQ and MOD09GA reprojected images. After, another mask has been created by means of the MOD44W images to eliminate all water pixels. MODIS images used in the subsequent analysis had therefore a uniform 250x250 m^2 pixel size, were referred to the WGS84/UTM18 system and only non-water pixels above 2000 m a.s.l. were considered. All the algorithms developed to characterize endmembers, to perform the linear unmixing and to obtain the burned areas were implemented with MATLAB®.

The Landsat TM5 (Landsat 5 Thematic Mapper, Landsat TM5) is a sensor flying aboard the Landsat 4 and 5 satellites, released in 1984 and decommissioned in June 2013. It performed a full observation of the Earth once every 16 days. This sensor provided information on reflectance in seven spectral bands: band 1 (450-520nm), band 2 (520-600nm), band 3 (630-690nm), band 4 (760-900nm), band 5 (1550-1750nm), band 6 (10400-12500nm) and band 7 (2080-2350nm). Band 6 corresponds to the thermal band and has a resolution of 120m, while the other bands have a resolution of 30m. Landsat images corresponding to Path/Row 03/69 and 04/69 (covering the study area) were obtained on the website: http://glovis.usgs.gov/. These images were used to test the applicability of the LMM technique on higher resolution scenes. Data provided by Landsat is not directly the pixel reflectance value but the Digital Number (DN), therefore they have been converted to reflectance following the steps described on: https://earth.esa.int/ers/sysutil/069c.html.

3.2. Endmembers characterization

Three types of endmembers were used in this study: vegetation, soil and water (also referred to as shadow).

Each endmember requires a characteristic reflectance value per spectral band. To test the dependace of this value on the image tile and on time of the year (dry/rainy season), we randomly selected one cloud-free image per month for each MODIS product (MOD09GQ/GA) and tile (h10v10 and h11v10) for the period February 2000 – December 2012 (i.e. 620 images). In each image three areas of 5x5 km^2 were selected, each area corresponding to pure vegetation, soil or water. The reflectance values for each of the three endmembers were statistically analyzed, individually for each spectral band and, as a function of the tile and whether it corresponded to the dry season (May to October) or to the rainy one (November to April). The results showed that no significant differences existed, neither among tiles nor among season. Therefore, mean global values for each endmember and spectral band were used (see Figure 2).

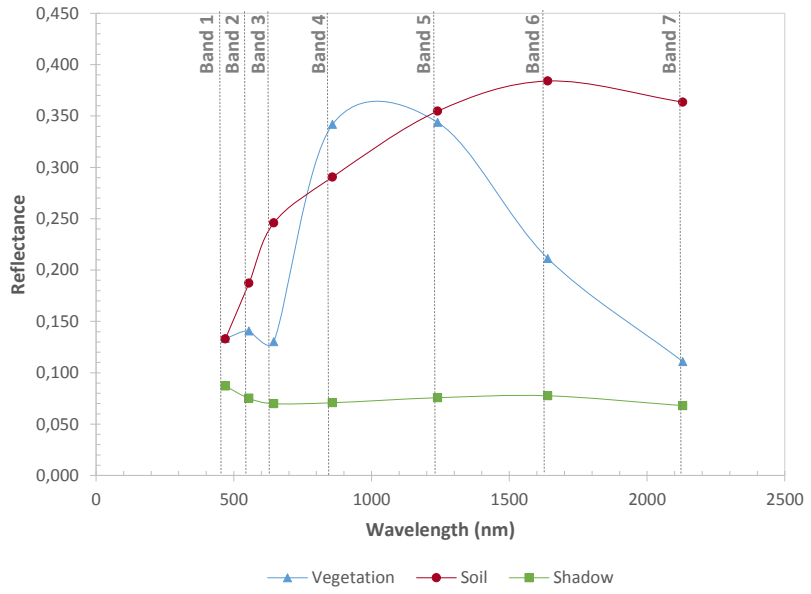

Figure 2. Reflectance values of the three endmembers used in the study as a function of the spectral band (from cloud-free images).

One of the main problems arisen in previous studies, that caused a low detection of the burn scars, was the large presence of clouds in the study area. To avoid that error, the endmembers were also characterized in those pixels identified as being medium cloudy –called "mixed"– and highly cloudy –called "cloudy"– (Figure 3).

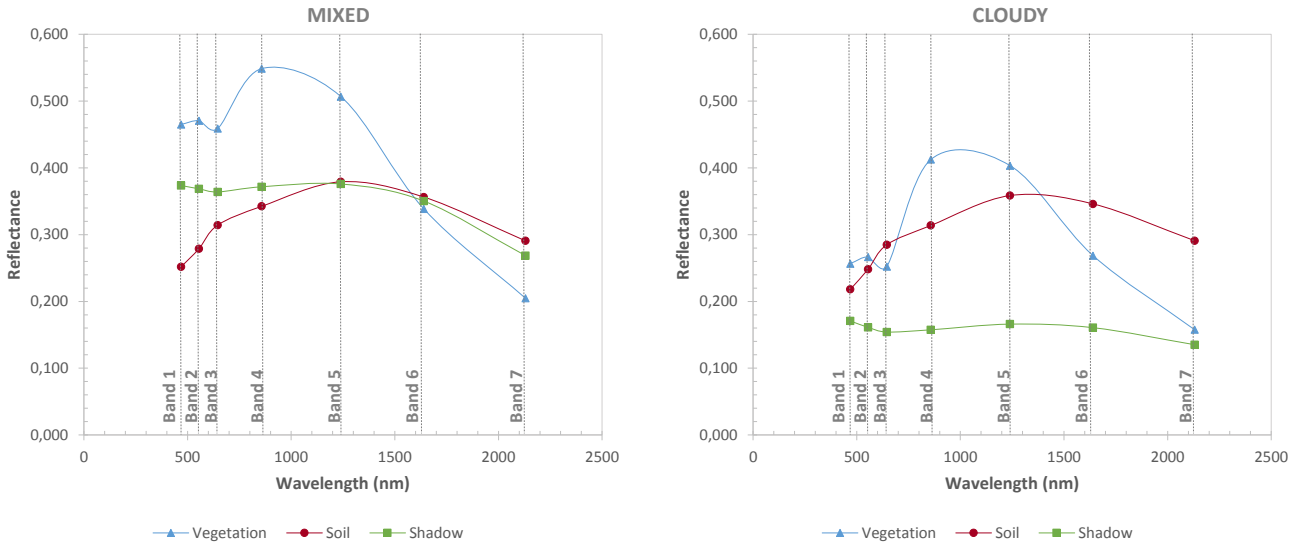

Figure 3. Reflectance values of the three endmembers used in the study as a function of the spectral band for pixels showing some degree of cloudiness. On the left values corresponding to mixed pixels; on the right values corresponding to cloudy pixels.

As it can be observed from the previous figures, there were clear differences between the reflectance of endmembers based on the degree of cloud cover. Being mixed pixels the ones that have the highest values and pixels free of clouds the ones that have lowest values.

3.3. Linear unmixing model

The LMM used in this study can be represented by the following equation:

$$r_i = a \cdot vegetation_i + b \cdot soil_i + c \cdot shadow_i + e_i$$

Where r_i is the reflectance of a pixel in the spectral band i; a, b and c are the proportions of vegetation, soil and shade respectively in this pixel; $vegetation_i$, $soil_i$ and $shadow_i$ are the reflectance values of the three endmembers in the spectral band i; e_i is the error of band i.

For each pixel, depending on whether it is clear, mixed or cloudy, a set of seven linear equations was obtained (one for each spectral band with the corresponding endmembers as a function of the cloudiness) with three unknowns (a, b and c) and two constrains: $(a, b \; and \; c \geq 0)$ and $(a + b + c = 1)$. The least squares regression analysis was used to solve this system of linear equations.

Once the relative abundances of the three endmembers are known for each pixel, the burned areas can theoretically be recognised as made of pixels having large proportions of shade. In section 4 we show the analysis of two known burn scars in the study area (described in section 3.4) in order to identify the thresholds in the shadow abundance that allow defining a pixel as burned.

3.4. Reference burn scars

Two previously known burn scars were used in this analysis. One corresponded to a fire occurred between the 2nd and 4th of July 2012 (named BS2012 from now on) covering around 129 ha and the other corresponds to a larger fire occurred at the end of August 2008 (named BS2008 from now on) with an area of approximately 1410 ha. Figure 4 shows these two burn scars superimposed over a Google Maps image of the zone together with a grid corresponding to the MODIS pixel size and distribution. Location of both fires in the study area is also given in Figure 5, the centre of BS2012 can be found in coordinates -13.23° S, -71.57° W; the centre of BS2008 can be found in coordinates: -13.81° S, -71.58° W.

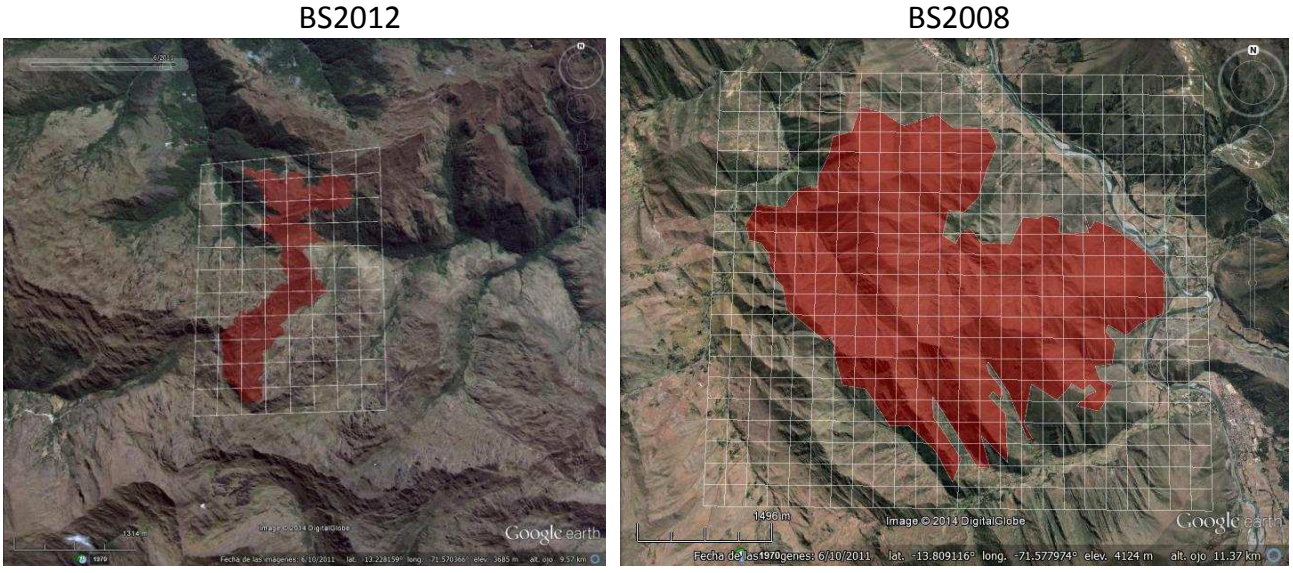

Figure 4. Area covered by the two burn scars used in this study. White line grid representing pixel size and number on the corresponding MODIS images.

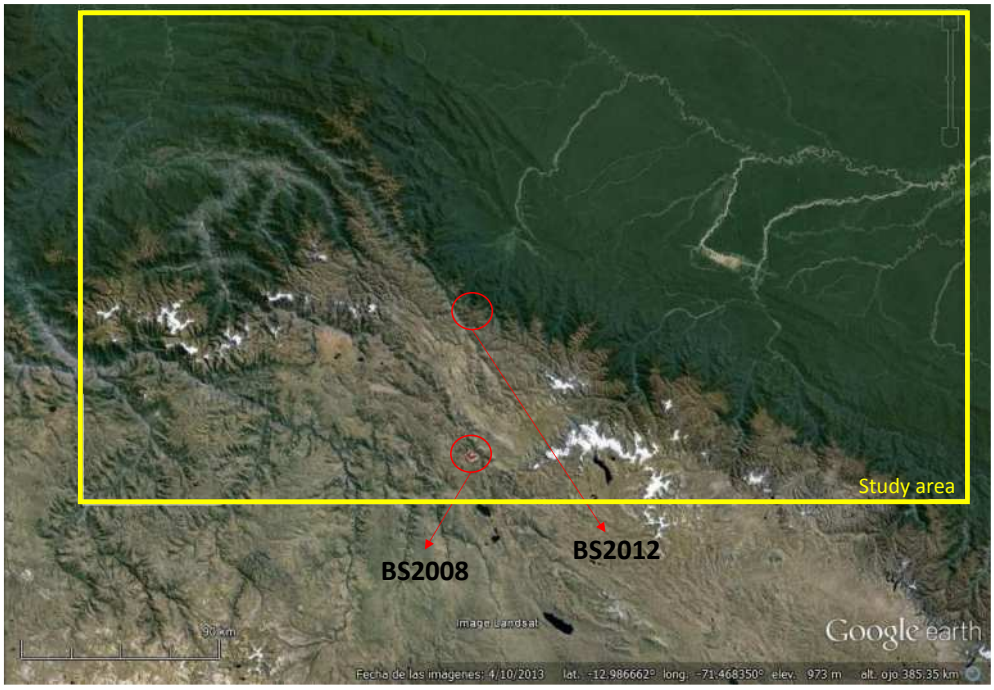

Figure 5. Location within the study area of the two burn scars used in this study.

Taking into account that MODIS pixel size is 250x250 m^2, BS2012 contained around 21 pixels while BS2008 contains around 226 pixels, which was a low number of data for any statistical analysis if only one image is taken. Therefore, 9 images corresponding to days previous to the BS2012 fire and 9 images just after the BS2012 fire were used to analyse the differences between burned and unburned pixels. In the case of BS2008, 5 images prior and 5 after the fire were used to extract the data.

Results and discussion

For each image previous and after the two fires analysed, BS2012 and BS2008, we obtained the abundances of the three endmembers considered: vegetation, soil and shadow. The frequencies of these abundances extracted from the images previous to the fire were plotted against the ones obtained after the fire. Because burned areas tend to have larger proportions of shadow (Anderson *et al.*, 2005), we expected to see differences in the abundances distribution previous and after the fire.

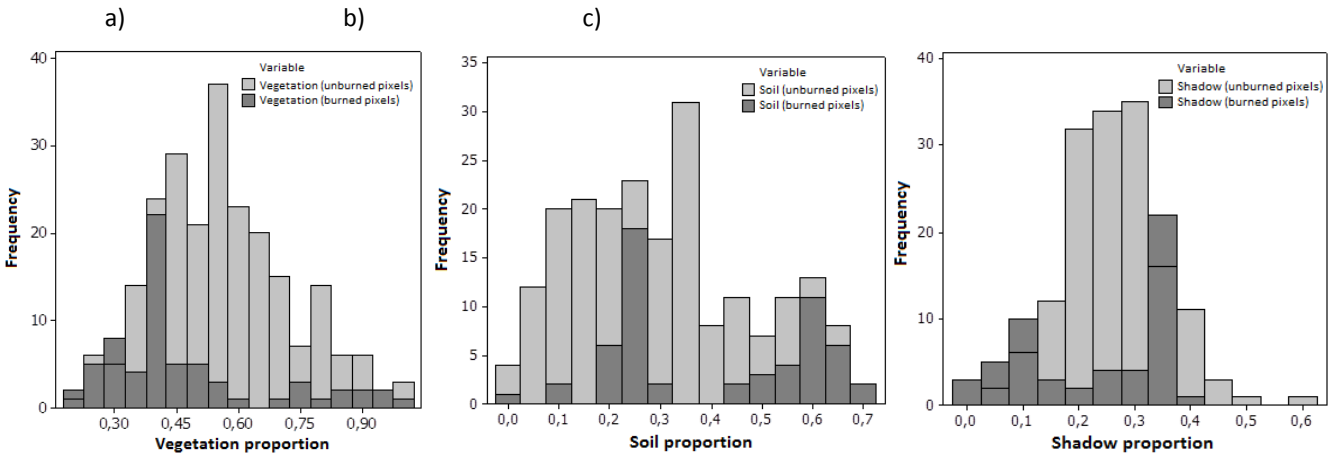

Figure 6. Frequencies distribution of the endmember abundances prior and after the fire BS2012: a) vegetation, b) soil, c) shadow.

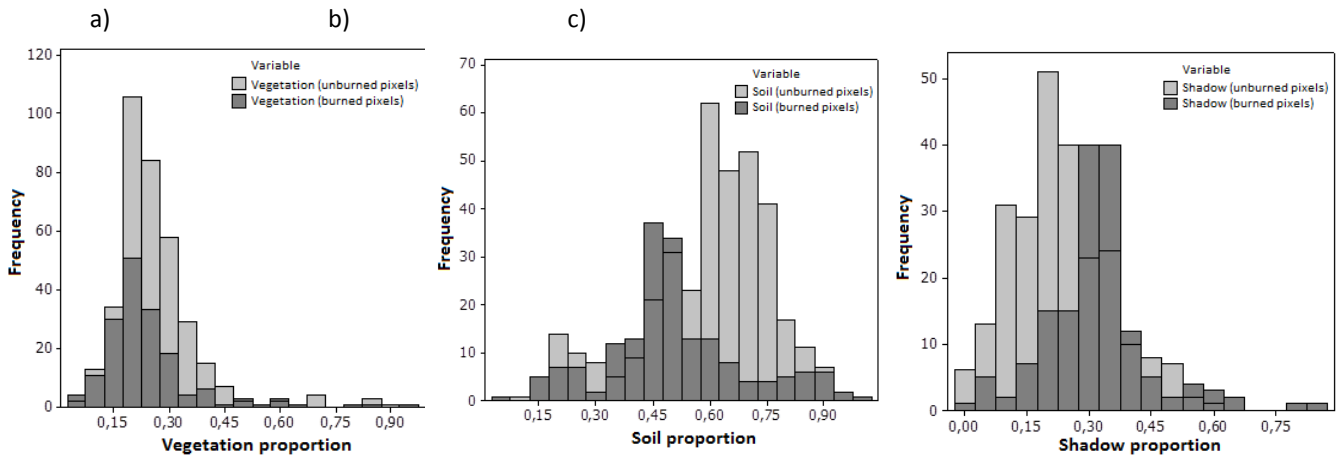

Figure 7. Frequencies distribution of the endmember abundances prior and after the fire BS2008: a) vegetation, b) soil, c) shadow.

Although vegetation abundances tended to diminish after the fire while soil and shadow abundances tended to increase, data dispersion was too large to enable us to distinguish a pixel from being burned or unburned according to its endmember proportion values (Figure 6). The large dispersion could be a result of the small size of the burn scar when compared to the pixel size, as there were many pixels that belonged to the burn scar boundary and were therefore half burned. Nevertheless, the same problem appeared inFigure 7, although in this case fire BS2008 was much larger and thus the boundary effect was smaller. These results show that that, even solving the problem of large presence of clouds in the area, linear unmixing method is unable to capture differences among MODIS reflectance values for burned and unburned pixels and therefore once again MODIS seems to fail to provide good data to obtain burn scar information in the study area. We hypothesized that MODIS spatial resolution was probably too low to capture with enough precision the differences in the reflectance values before and after the fire, taking into account the noise effect caused by the complex topography of the study area on the reflectance values.

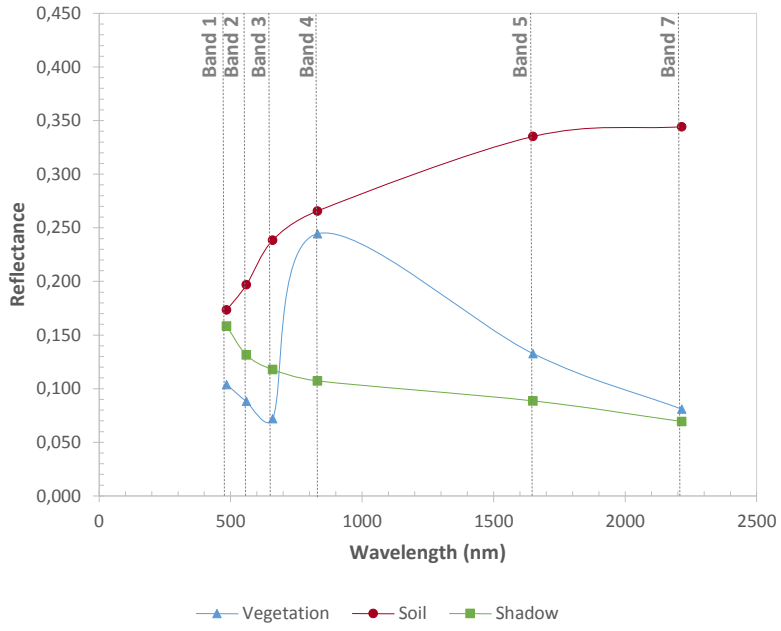

Figure 8. Endmembers characterization obtained from Landsat TM5 images.

To test this hypothesis the same method was applied to images provided by Landsat TM5. A new endmembers characterization was performed following the method described in section 3.2, but using Landsat data on the spectral bands 1 (485 nm), 2 (560 nm), 3 (660 nm), 4 (830 nm), 5 (1650 nm) and 7 (2215 nm), Figure 8 shows the results obtained. In this case, the study of the endmember abundances distribution before and after the fire was performed with BS2008 whereas BS2012 was saved for validation purposes.

Figure 9 shows the endmember proportion before and after the BS2008 fire obtained with Landsat images. Results for soil and shadow abundances, showed large dispersion and a great number of extreme values, therefore not being useful for burned/unburned discrimination purposes. However, vegetation abundances were clearly different depending on whether the pixel was or was not burned. Burned pixels had a vegetation abundance below 40% while unburned pixels have always a vegetation percentage above 40%. Using this criterion to distinguish between burned and unburned pixels, the method was applied to BS2012 in order to see if it was possible to detect the burn scar.

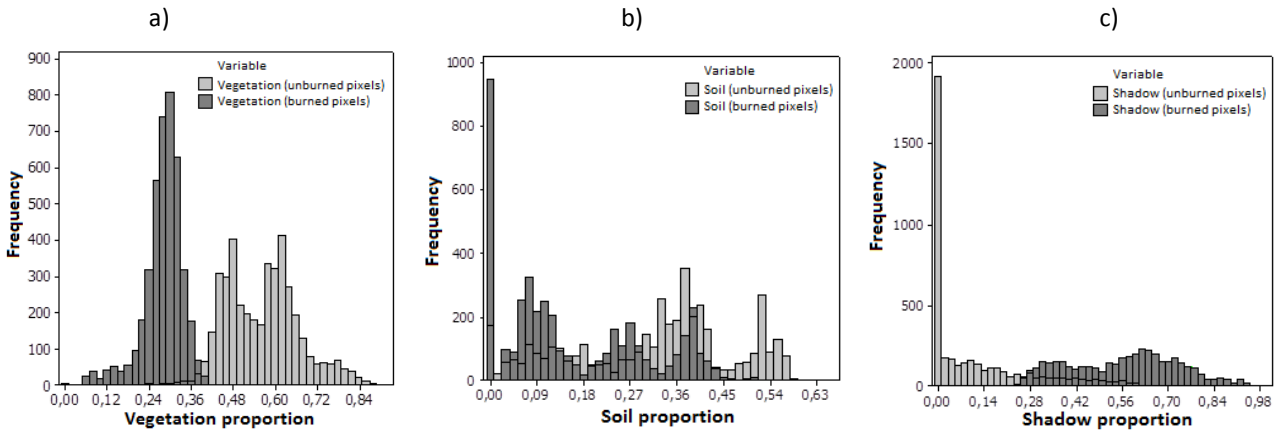

Figure 9. Frequencies distribution of the endmember abundances previous and after fire BS2008 using Landsat TM5 images: a) vegetation, b) soil, c) shadow.

Due to a number of difficulties that Landsat TM5 has been dragging since December 2008, no data was available for this sensor for the year 2012. Therefore, we used the images obtained by Landsat 7 ETM + that, despite the failure of one of their scanners, continues providing images. As it can be seen in Figure 10 (left and centre), Landsat 7 ETM+ images of the area were BS2012 was located show three black bands without data, due to problems with the sensor. This was transformed into three grey bands after applying the spectral unmixing model, corresponding to undefined pixels due to the lack of data. Despite this, the method was able to locate and draw the burn scar quite accurately.

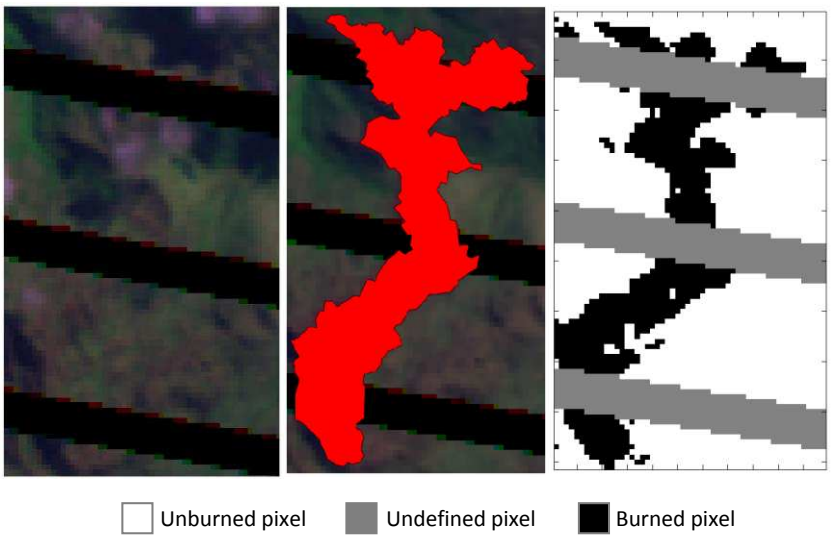

Figure 10. left: Landsat 7 ETM+ image prior to the BS2012 fire (16/06/2012); Centre: Landsat 7 ETM+ image after the BS2012fire (03/08/2012) with burn scar area superimposed; Right: image obtained with the linear unmixing model

An estimated value of 9% of commission error and 20% of omission error was computed for this fire, the only one for which the perimeter has been ground validated. Although omission error was still high, it significantly improved omission errors of 48% for the MODIS MCD45 burned area product in the study area (Oliveras *et al*., 2014).

Conclusions

The literature survey has shown that current methodologies to estimate burned areas in the tropical Andes need to be significantly improved. One of the methods that could provide better results is the spectral unmixing. This technique require the characterization of specific endmembers for the study area. In this paper a specific study to characterize the endmembers for the tropical Andes has been performed. It has shown that, for the study area, reflectance values of the endmembers are independent of the MODIS tile and of the season but change according to the degree of cloudiness.
MODIS images were not valid for the technique studied, probably due to their spatial resolution (250 m). However, Landat images, with 30 m spatial resolution, proved to be relatively accurate in the detection of burned area scars with spectral unmixing modelling. However, the complex topography and meteorology of the study area makes the development of any automatized technique for detecting burned area scars especially challenging, and further efforts are needed to achieve a reliable, standardized method that allows the accurate detection of burned area scars in the tropical Andes.

Abstract
Biomass burning is extremely important at the global, regional and local scales and has impressive impacts at the atmospheric, climatic, environmental and socio-economical levels. The temperate biome of the Mediterranean regions is characterised by rainy and mild winters followed by warm and dry summers that make the region especially prone to the occurrence of a large number of summer fire events. In this context, the 10-year (2003 – 2012) MODIS fire data, provided by the MODIS Fire Team (University of Maryland) is used to characterize the spatial and the temporal distribution of fire activity over western region of the Mediterranean basin, paying special attention to large fire episodes. Finally, an assessment of the role of meteorological conditions on large fire events is performed based on the analysis of low and mid atmospheric fields of geopotential, air temperature, relative humidity and wind.

Keywords*: Extreme fire activity; MODIS; Fire pixels; fire weather; atmospheric circulation patterns; Mediterranean*

Introduction

Biomass burning is an extremely important process from local to global scales with significant impacts at the atmospheric, environmental and socio-economical levels. Encompassing the lands around the Mediterranean Basin is associated to Mediterranean type of forests, woodlands, and shrub. This temperate biome is characterised by rainy and mild winters followed by warm and dry summers that make the region especially prone to the occurrence of a large number of fire events and to the onset of extreme episodes that account for the bulk of burned area in the whole fire season (Pereira *et al*., 2005, Trigo *et al*., 2006; Amraoui *et al*., 2010). The Western part of Mediterranean basin, which includes the Iberian Peninsula, Southern France and Sardinia in Europe and Northern coastal areas of Morocco, Algeria and Tunisia in North Africa, has been the most affected by vegetation fires in the last decades (Schmuck *et al*., 2013). In the above mentioned countries, fire ignition is strongly conditioned by human behaviour and socioeconomic activities (Costa *et al*., 2010). Nevertheless, natural factors like the morphology of the landscape, land use, land cover, weather and climate strongly affect wildfire activity (Amraoui *et al*., 2013). In fact, weather and climate have a profound influence on all stages and aspects of biomass burning from ignition, spread and behaviour up to severity and effects (Benson *et al*., 2008).
The vast majority of burned area in Mediterranean regions is due to a reduced number of extreme events that occur during a short period of time, and are associated to several atmospheric processes interacting at different temporal and spatial scales (Pereira *et al*., 2005). These facts motivate focusing attention on the extreme events of fire activity and on the role of weather conditions on fire activity during these cases.

In terms of accuracy and reliability, satellite information appears as a very appealing tool to monitor fire activity over the entire globe and have led to the development of a consistent long-term record of global fires (Justice and Korontzi, 2001) due to: (*i*) its homogeneity in space and time and (*ii*) its several advantages over classical databases of ground-based measurements where the computation of burned area or number of fire occurrences not only depend on the policies of the different countries but are also usually estimated by visual inspection (Pereira *et al*., 2011; Amraoui *et al*., 2013).
In this context, the Moderate Resolution Imaging Spectroradiometer (MODIS) on board the polar orbiting Terra and Aqua satellites of National Aeronautics and Space Administration (NASA) Earth Observing System (launched in 1999 and 2002, respectively) was the first instrument with spectral characteristics designed specifically for active fire detection (Kaufman *et al*., 1998) and, consequently, the MODIS active fire product (Justice *et al*., 2002) is the most consistent database of burned area and active fires at different spatial and temporal scales (Csiszar el al., 2005; Oom and Pereira, 2013).
The main objective of this work is to use the 10-year (2003 – 2012) database of the MODIS active fire product, composed by daily numbers of fire pixels: (*i*) to characterize the extreme fire activity episodes (hereafter EFAE) occurred over the Iberian Peninsula and the Northern Africa, throughout the year (extending the study to the months outside the fire season) and (*ii*) to characterize the associated meteorological conditions of these extreme events based on the analysis of low and mid atmospheric fields such as wind, air temperature, relative humidity, mean sea level pressure and geopotential.

Data and Methods

Active fire data

The fire dataset covers a 10-year period, from January 2003 to December 2012, of the MCD14ML Collection 5 active fire product (Justice *et al*., 2002), obtained from MODIS imagery data with a spatial resolution of 1 km at nadir. Fire detection is performed using a contextual algorithm that exploits the strong emission of mid-infrared radiation from fires and is based on brightness temperatures derived from the 3.9 and 10.5 μm channels (Giglio *et al*., 2003).
During the considered 10-year period, there is a grand total of 126 887 fire pixels detected in the study area. The spatial distribution of these fire pixels suggests the existence of two separated sub-regions with highest fire activity namely, the Northern and Western parts of Iberian Peninsula (hereafter NWIP) and the Northern Africa and South-Eastern Iberia (hereafter NAFR) accounting for about 57% and 40% of the grand total, respectively. This evidence is even consubstantiated by the impressive anti-correlation (- 99%) between relative number of fire activity in these two sub-regions (Figure 1).

Meteorological data

The meteorological conditions associated to extreme fire activity were derived using the horizontal fields of ERA-Interim data (Dee *et al*., 2011) provided by the European Centre for Medium-Range Weather Forecasts (ECMWF). The following meteorological data were extracted over the Western Mediterranean sector (30^0W – 20^0E, 20^0N – 60^0N), at 12 UTC, for the period of 30 years (1983 – 2012), and then projected onto a $0.75^0 \times 0.75^0$ latitude/longitude grid:

- mean sea level pressure (hereafter MSLP);
- air temperature at 2 metres height (hereafter T2m);
- wind speed and direction at 10 metres (hereafter W10m);
- air temperature, geopotential height and relative humidity at 850 hPa which corresponds to approximately 1 500 m of altitude (hereafter T850, Z850 and RH850, respectively); geopotential height at 500 hPa, in the mid atmosphere, at about 5 000 m of altitude (hereafter Z500).

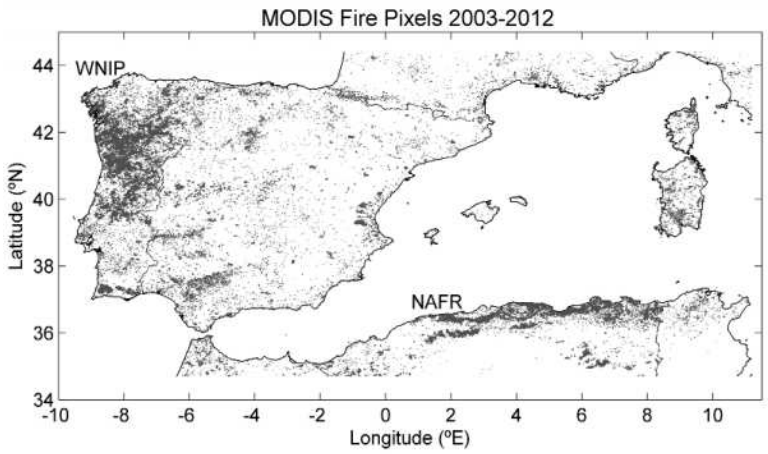

Figure 1. MODIS Fire pixels over Western Mediterranean region from January 2003 to December 2012.

2.3. Methods

The EFAE throughout the study period were identified by the use of two criteria: (*i*) at least 3 consecutive days with number of fire pixels above the 95th percentile; and, (*ii*) a minimum of 10 fire pixels per day in the same sub-region. These criteria led to the identification of a total number of 35 EFAE with the following spatial distribution: 31 of cases in NWIP; 3 events in NAFR; and 1 particular case that cannot be clearly classified in any of the previous clusters. It is worth noting that 18 of EFAE located in NWIP sub-region have occurred during summer period (May to October) and the remaining 13 episodes during winter period (November to April). On the other hand, all the 3 EFAE occurred in the NAFR sub-region were detected in the summer months (June, July and August).

An assessment of the role played by the meteorological conditions during the EFAE may be performed by analysing the associated horizontal patterns of meteorological fields. For this purpose, reference fields of meteorological variables were computed for each day of the year by averaging the respective 12 UTC meteorological fields for the same day over the entire reference period of 1983 – 2012. Daily anomalies were then computed as departures of each daily field from the reference field (for that day). Finally, composites and anomalies of the meteorological fields were derived by averaging the field's daily values and anomalies for the days of each EFAE.

Results

An exhaustive analysis of all meteorological variables listed in section 2.2 was performed for each day of the 34 EFAE. The spatial patterns of the obtained composites and anomalies allow stating that the atmospheric conditions were very similar for all days of EFAE in each sub-region and season which lead to the definition of three clusters of EFAE, namely NWIP-Summer, NWIP-Winter and NAFR-Summer.

The similarity between the meteorological patterns of each day of the EFAE associated to the same cluster, leads to present results of only one case for each cluster that illustrate the typical atmospheric conditions associated to extreme fire activity of the respective cluster. The chosen extreme episodes are: 11 – 18 October 2011, 21 February – 2 March 2012 and 27 – 30 August 2007 corresponding to the NWIP-Summer, the NWIP-Winter and the NAFR-Summer clusters, respectively. For sake of simplicity, only the anomaly composites of meteorological variables obtained for each EFAE will be presented (Figures 2 to 4).

The episode of 11 – 18 October 2011 (NWIP-Summer)

The anomalous synoptic conditions at the surface (Figure 2b) and at 850 hPa (Figure 2c) are characterized by an amplified Azores anticyclone extending from the Atlantic to Central Europe and by a sub-Saharan thermal low centred at South Algeria. The MSLP and W10m dynamical fields over the region are characterised by isobars with SE-NW orientation and geostrophic winds resulting from the convergence of NE winds over Europe and SE winds from the Northern Africa. This circulation pattern leads to strong North-Eastern and South-Eastern advections of continental dry and warm air, resulting in high surface air temperatures over the Western Iberia and in the extreme air temperature anomalies, exceeding 7ºC in both 2 metres height temperature and temperature at 850 hPa.

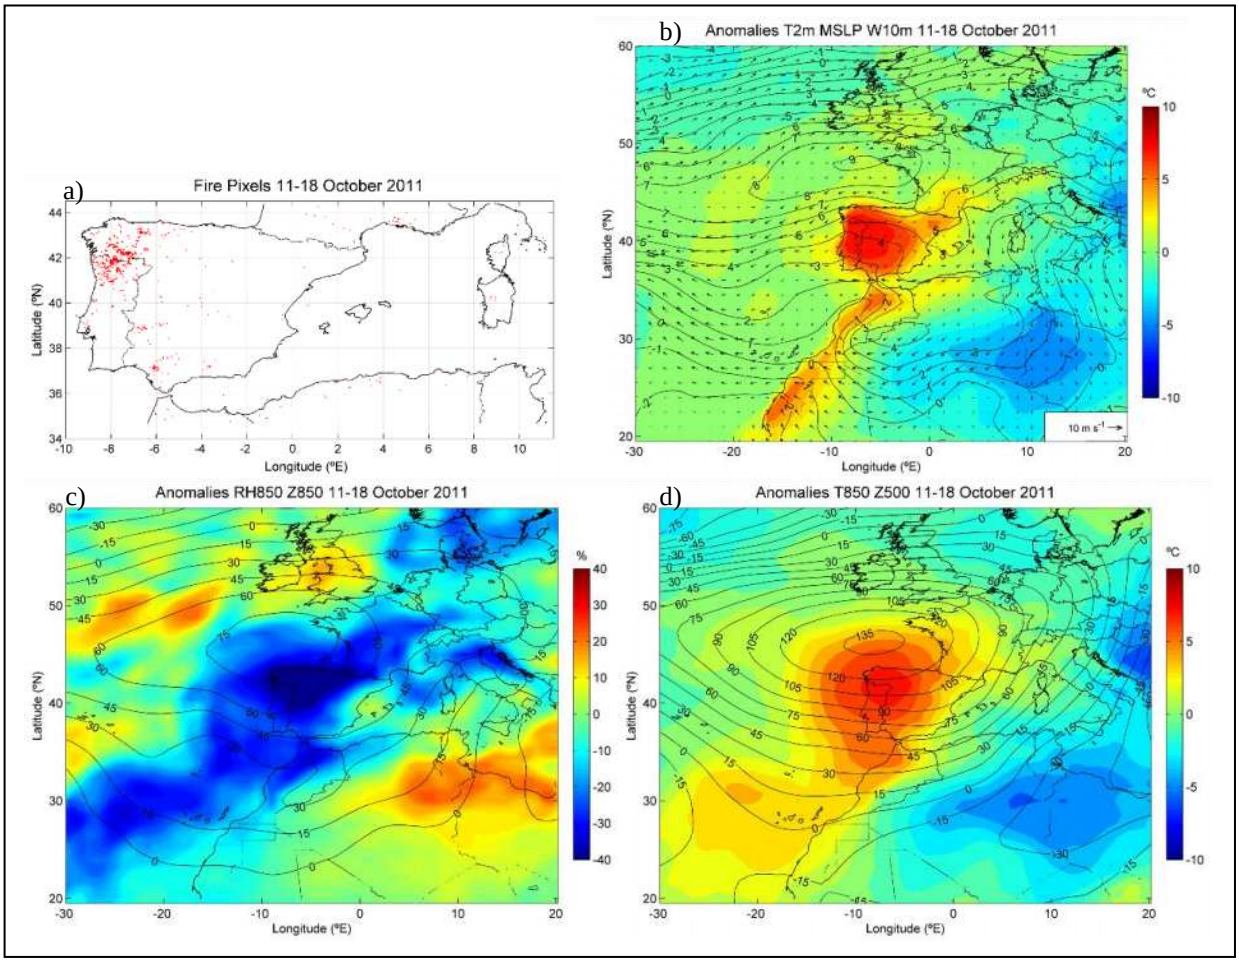

Figure 2. MODIS Fire pixels (red dot) over Western Mediterranean region detected during the EFAE of 11 – 18 October 2011 belonging to the NWIP-Summer cluster (upper left panel). The associated anomalies composites of multiple low and mid atmospheric fields are also shown: (b) air temperature (°C) at 2m height (T2m) mean sea level pressure (MSLP) and wind ($m \cdot s^{-1}$) at 10 m (W10); (c) relative humidity (%) at 850 hPa (RH850) and geopotential height (gpm) at 850 hPa (Z850); (d) air temperature (°C) at 850 hPa (T850) and geopotential height (gpm) at 500 hPa (Z500).

Relative humidity at 850 hPa level reveals the presence of very dry air over the Western and the Northern parts of the Iberian Peninsula reaching the impressive value of 25% with anomalies lower than -35%. Composite of the atmospheric flow at 500 hPa (not shown) reveals synoptic baroclinic activity with a pronounced ridge with axes in the Southwest to Northeast direction over the Atlantic Ocean and at Iberia, forcing warmer and drier air mass into the NWIP sub-region. The patterns of composite anomalies at 500 hPa level (Figure 2d), exhibit positive departures of 135 gpm enhancing

the subsidence of air into the Troposphere and reinforcing the increase of air temperature through adiabatic heating at lower levels.

3.2. The episode of 21 February – 2 March 2012 (NWIP-winter)

The synoptic conditions are characterized by an anticyclonic blocking activity over Eastern Atlantic which evolved in altitude into a predominant omega pattern located West of Europe and constituted by the huge high-pressure ridge and two troughs, the first one positioned over Central Atlantic at West of the Canary Isles, and the second one over Central Europe. It is worth stressing that the above mentioned anomalous circulation patterns at the low and mid-Troposphere levels exhibit positive departures of Z850 and Z500 reaching, respectively, to the impressive values of about 100 and 200 gpm (Figures 3c and 3d) North of the Iberian Peninsula.

The temperature anomalies over the sub-region are lower than the previous episode reaching values of about 3ºC for both the T2m ant T850 temperatures (Figures 3b and 3d). As in the preceding episode, relative humidity at 850 hPa level shows the presence of very dry air over the sub-region decreasing to the impressive value of 30% with anomalies lower than -40%.

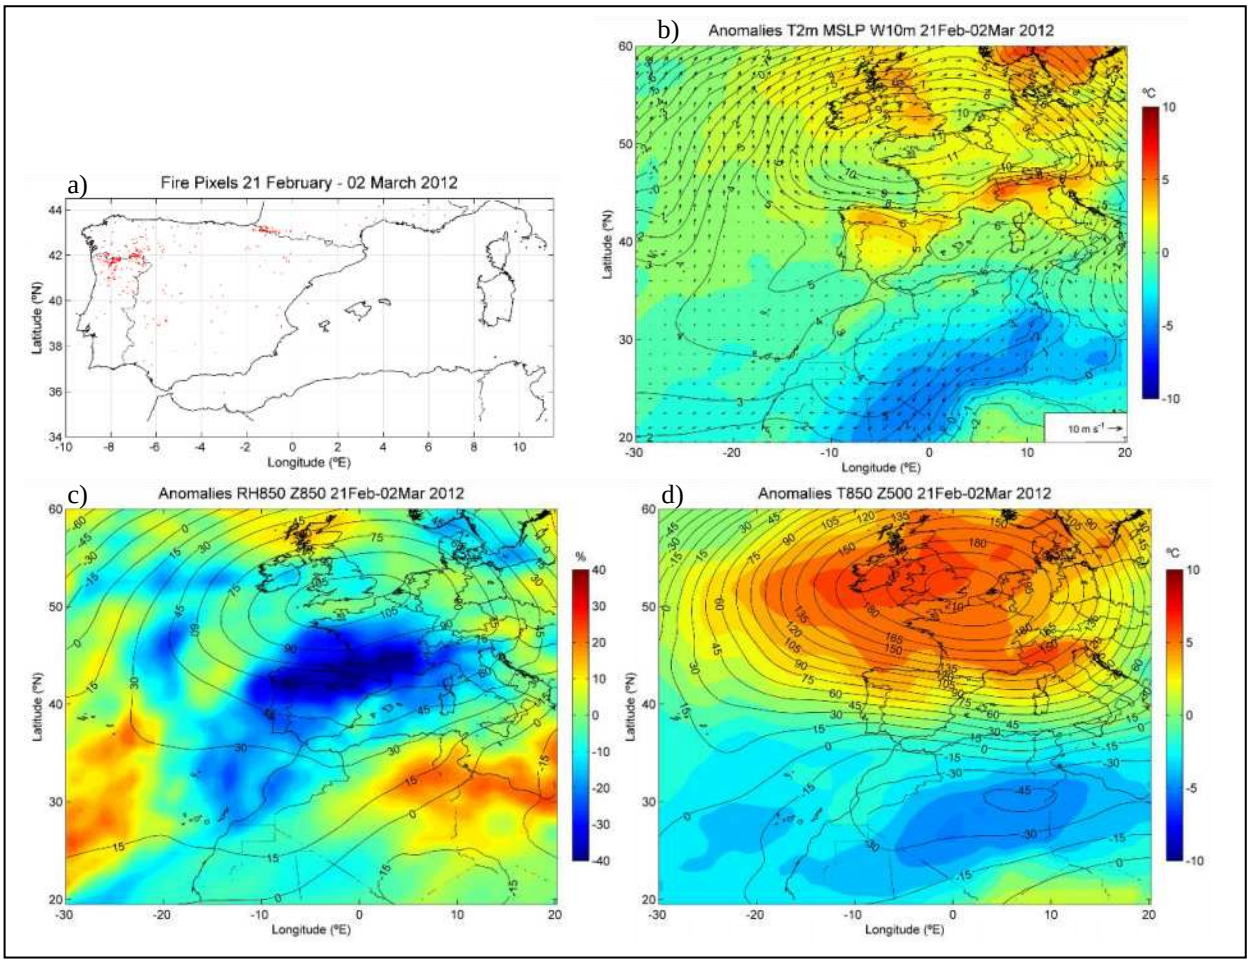

Figure 3. As in Figure 2 but respecting to the EFAE of 21 February – 2 March 2012 belonging to the NWIP-Winter cluster.

3.3. The episode of 27-30 August 2007 (NAFR-Summer)

The atmospheric conditions of the episode occurred during the month of August 2007 in North African sub-region is quite different from those obtained for NWIP during winter or summer periods. At the surface, the circulation is dominated by an intense Southerly/South-Easterly advection of very hot and

very dry Saharan air, brought to the region by the anticyclonic circulation centred over South Italy and the cyclonic flow due to the presence of a Saharan heat low centred over South-Western Algeria and to the Atlas Low located in Central Morocco. The associated high departure values of air temperature (above 7 ºC) obtained in both T2m and T850 (Figures 4b and 4d), and very low departure values of relative humidity at 850 hPa reaching the value of -25% (Figure 4c) are well apparent over this sub-region.

The atmospheric circulation at the 500 hPa level is dominated by a pronounced ridge whose axis is directed from Southwest to Northeast (not shown), affecting the Northern Algeria and Tunisia and bringing warmer and drier air mass to the region. It may be observed that the location of the referred ridge over Western Mediterranean basin is associated to positive departures of Z500 of about 60 gpm (Figure 4d), which delimit a region over Eastern part of Iberia and Northern Algeria and Tunisia, revealing a region characterized by enhancement of the air subsidence into Troposphere, leading to an increase of air temperature through adiabatic heating at lower levels.

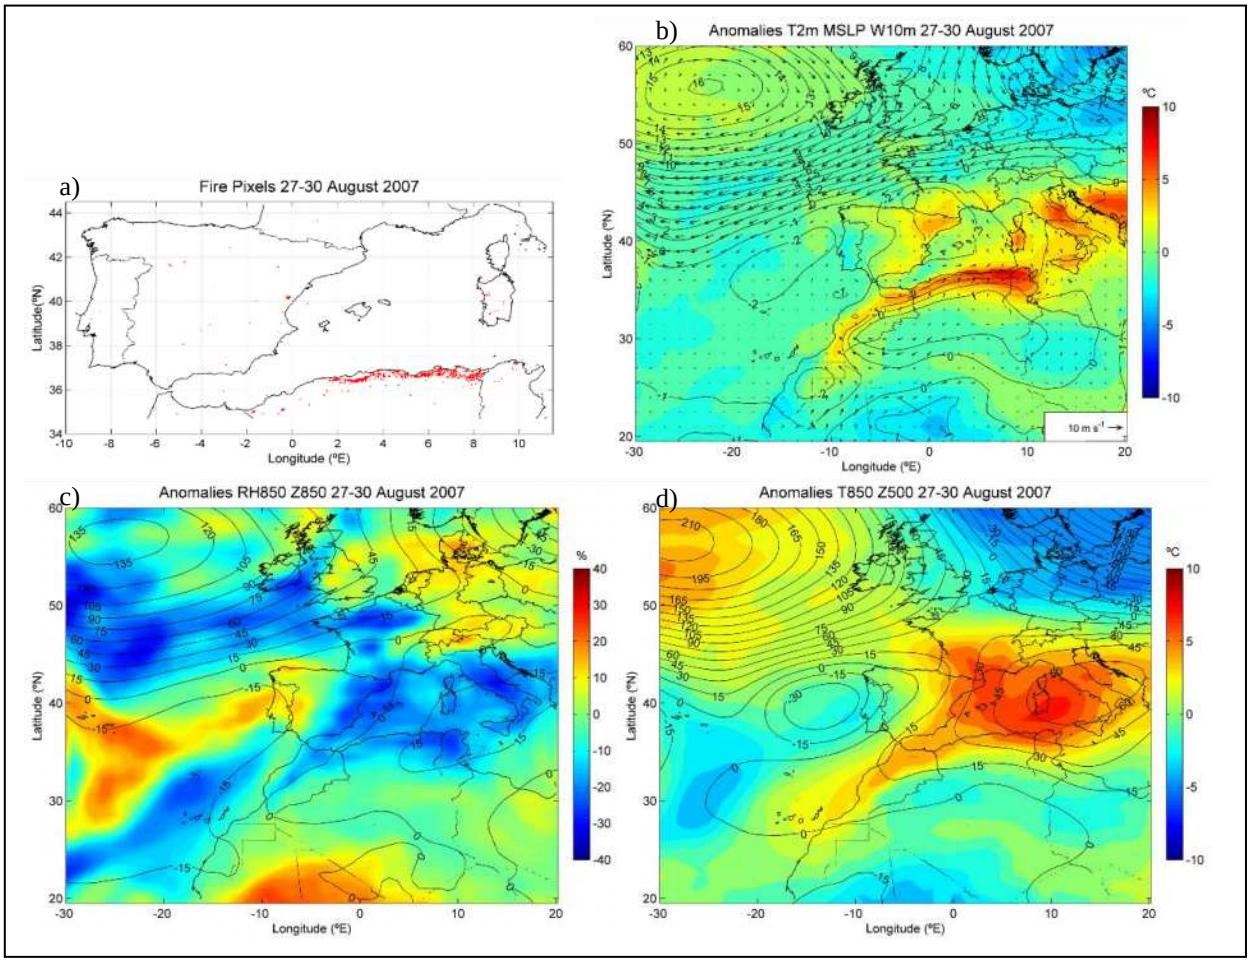

Figure 4. As in Figure 2 but respecting to the EFAE of 27 – 30 August 2007 belonging to the NAFR-Summer cluster.

Conclusions

The main objective of the present study is to identify and characterize the atmospheric conditions associated with extreme fire activity episodes occurred over Iberia and Northern Africa mainly because: (*i*) these regions comprises the European and North African countries most affected by fires

(Pereira *et al*., 2011, Schmuck *et al*., 2013); and, (*ii*) weather and climate proved to be the most important factor to the fire regime in the region (e.g. Rasilla *et al*., 2010; Amraoui *et al*, 2013).
The spatial distribution of fire pixels detected by MODIS over Western Mediterranean region during the 10-year (2003 – 2012) period reveals the existence of two sub-regions particularly affected by this natural hazard (Figure 1): the Western and Northern parts of Iberian Peninsula (NWIP); and South-Eastern Iberia and Northern region of Algeria and Tunisia, in North of Africa (NAFR).
The non-seasonal approach used in this study, based on the two criteria mentioned in section 2.3, allows the identification of the major extreme fire activity episodes over the region and the determination of the associated atmospheric patterns, applying the methodology previously validated for Portugal, Italy and Greece during summer (Pereira *et al*., 2005; Trigo *et al*., 2013; Amraoui *et al*., 2013). Thereby, the EFAE were identified in the two sub-regions: 3 episodes observed in the NAFR sub-region and occurred during summer season (June, July and August) and 31 episodes detected in the NWIP and occurred throughout the year even outside the summer fire season, 13 of them during the winter season (November to May) and the remaining 18 episodes during the summer season (June to October). Accordingly, all EFAE were grouped into 3 clusters depending on the sub-region and on the season of occurrence: NWIP-summer, NWIP-winter and NAFR-summer clusters. The similarity between the meteorological patterns of the EFAE associated to the same cluster, leads to present results of only one case for each cluster that illustrate the typical atmospheric conditions associated to extreme fire activity of the respective cluster.
The most important features of the meteorological anomaly fields associated with the presented 3 EFAE belonging to the 3 different clusters are the positive anomalies of T2m and T850 and the impressive negative anomalies of RH850 over most of the corresponding sub-region. It is worth noting that the temperature parameter (T2m) is not the most critical factor to the occurrence of vegetation fires during the winter season. For instance, the T2m of the EFAE belonging to the NWIP-Winter cluster presented in this study (21 February – 2 March 2012), reached a small value of 13ºC (with an anomaly that does not exceed 3ºC) over the NWIP sub-region corresponding to a typical value for the mentioned sub-region and season.
The atmospheric circulation patterns of the EFAE occurred in NWIP during summer and winter are essentially characterized by Eastern advection of air at surface and higher levels usually associated to the influence of the Azores high pressure system and the occurrence of heat waves episodes during summer and Atlantic anticyclone blocking events during winter which imply clear sky conditions and enhanced of radiative heating/cooling over the sub-region.
Atmospheric patterns responsible for the occurrence of EFAE in NAFR sub-region during summer season are dominated by very hot and dry South-Easterly winds (*Scirocco* winds), due to the anticyclonic circulation centred over South Italy, and by the cyclonic flow resulting from the presence of a Saharan heat low centred over South-Western Algeria and the Atlas Low located in Central Morocco. The atmospheric circulation at the 500 hPa level is dominated by a pronounced ridge affecting the Northern Algeria and Tunisia that brings warmer and drier air mass to the sub-region.
Finally, the identification and characterization of the atmospheric conditions associated with extreme fire activity episodes is of paramount importance for (*i*) the planning and management of fire prevention activities and fire suppression resources, because the time of occurrence and persistence of such conditions may be predicted with current weather forecasting systems for periods of days up to a 1 – 2 weeks and (*ii*) to improve future projections of fire activity based on estimated changes on their frequency, magnitude and duration for different scenarios of climate change (Dury *et al*., 2010; Pereira *et al*., 2013).

Abstract
A key factor in decision-making process during a wildfire incident is counting on the forecast of how the fire is likely to behave in different fuels, weather conditions and terrain. Wildfire models and simulators attempt to assist fire responders in gaining understanding of the fire behaviour. The main hurdle to overcome when applying such technologies at operational level is the lack of a complete model that describes wildfire governing physics and the trade-off between accuracy and computing time. A forecasting prediction must be delivered within a positive lead time and current physical models are far beyond this requirement.
Inverse modelling and data assimilation techniques offer a great potential of operational applicability in wildfires, coupling fire monitoring and fire behaviour forecast at real time. With this approach, a better description of the processes simulated by the fire behaviour models can be achieved when adding real-state information of the system, since discrepancies between simulated fire behaviour variables and observed variables are minimized. The use of this approach accelerates fire simulations without loss of forecast accuracy.
In this paper we explore the adaptation to real fire scenarios of a synthetic-data-based inverse modelling structure for fire behaviour forecast. Improvements are investigated to extrapolate the already existing algorithm to real data assimilation from IR aerial monitoring. The technique explores elliptical Huygens expansion coupled with simple -yet effective- semi-empirical wildfire models. The algorithm assimilates fire fronts positions extracted from airborne thermal imaging and additional available data as wind speed and direction or fuel characteristics. The invariants -set of governing parameters that are mutually independent and constant for a significant amount of time- are resolved by means of forward model and linear tangent minimization.
The technique has been adapted to be employed in large-scale mallee-heath shrubland fires experiments conducted in South Australia in 2008. Fires were filmed with a helicopter transported TIR camera. The IR images were processed to obtain the position of the fire perimeter at a maximum frequency of one isochrone every 10 seconds. The algorithm shows great capability to simulate fire fronts observations and opens the door to keep developing a fully automatic data assimilation algorithm with forecasting capacity.

Keywords*: inverse modelling, data assimilation, infrared imagery, shrubland fire behaviour.*

Introduction

Fire managers need to obtain real-time information as fast as possible in order to make quick potentially impactful decisions. They have to keep track of fire behaviour and suppression activities at all times with the responsibility of safeguarding physical integrity of all the individuals involved in the emergency. In response to this need, numerous activities have been recently under way to take advantage of new opportunities and technology for wildland fire management. Over the past few years several public wildfire agencies have been benefiting from different information technology tools that allow monitoring fire activity and fire brigades. A good example of such advances is the implementation of airborne fire monitoring apparatuses combined with global geo-positioning systems so that both fire and suppression resources can be tracked. With these systems, images of any interesting spot of the fire scenario can be obtained in the infrared (IR) and visible spectrum and

transferred in real-time to the commander work station of the fire incident, so that fire managers can have more readily available information for decision-making. However, the use of this systems is currently less cost-effective than it could, not only because of the specificity of all the compounds and the costs associated to the airborne platform (e.g. surveillance helicopters and aircrafts) but also because the information they provide is not exploited quantitatively, particularly, for forecasting purposes.

A key factor in decision-making process during a wildfire incident is counting on the forecast of how the fire is likely to behave in different fuels, weather conditions and terrain. Wildfire models and simulators attempt to assist fire responders in gaining understanding of the fire behaviour. The main hurdle to overcome when applying such technologies at operational level is the lack of a complete model that describes wildfire governing physics (Finney *et al*., 2013) and the trade-off between accuracy and computing time. A forecasting prediction must be delivered within a positive lead time (time ahead of the predicted event) and current physical models are far beyond this requirement. Inverse modelling and data assimilation techniques offer a great potential for operational applicability in wildfires, coupling fire monitoring and fire behaviour forecast at real time. With this approach, a better description of the processes simulated by the fire behaviour models can be achieved when adding real-state information of the system, since discrepancies between simulated fire behaviour variables and observed variables are minimized. The use of this approach accelerates fire simulations without loss of forecast accuracy (Mandel *et al*., 2008), (Jahn *et al*., 2011), (Rochoux *et al*., 2012).

In this paper we explore the adaptation of a synthetic data assimilation-based forecasting algorithm to deal with large scale real sensed data. The algorithm to be adapted is based on the identification of some invariants (model components that are constant for a given period of time and area, such as fuel depth, moisture content, packing ratio, etc.) that are determined through an optimization process during a given assimilating window. This technique has shown great performance when challenged with synthetic data (Rios, Jahn, & Rein, 2014) but its adaptation to a real case scenarios will require special attention. The real data that will be used are fire fronts isochrones obtained by airborne infrared imaging in mallee-heath shrublands experimental burns conducted in South Australia in 2008 (Cruz, McCaw, Anderson, & Gould, 2013; Pérez, Pastor, Planas, Plucinski, & Gould, 2011).

Data assimilation and inverse modelling

Data assimilation has been historically developed and applied in the weather forecasting discipline to combine observations with the models and improve forecasts with available sensed data (Kalnay, 2003). One of the most common strategies used to merge assimilated data with the model is by means of inverse modelling.

Inverse modelling is particularly appropriate for wildfires modelling due to large amount of unknowns in terms of environmental parameters, such as fuel physical properties (e.g. fuel elements distribution and thermal characteristics), weather inputs (e.g. wind profile, ambient temperature gradient and relative humidity) and terrain features (e.g. slope and aspect variability). There are numerous necessary variables to initialise a physical classical forecasting model and hardly ever can all be measured. By contrast, the inverse approach can use any kind of available data to improve the forecast if the forward model is tweaked accordingly.

Despite its great capacity for coping with complex problems with a large number of variables, still few authors have tried to apply it to the fire field. Among these, Jahn *et al*. (Jahn, Rein, and Torero 2011, Jahn, Rein, and Torero 2012) successfully pioneered this approach to forecast fires in enclosures using both simple and complex models (two zones models and Computer Fluid Dynamics, CFD models).

In the field of wildfires, Mandel *et al*. (Mandel, Beezley, Coen, & Kim, 2009) explored this technique to predict time-temperature curve of a sensor placed in the way of an advancing fire. They examined a reaction-diffusion equation and a semi-empirical fire line propagation model coupled with an

Eulerian level-set-based equation. Additionally, they coupled weather forecast information to the model demonstrating the powerful potential of data assimilation. Despite its potential, their implementation was found to be unstable due to the ill-definition of temperature measurements in a wildfire.
Following this work, Rochoux *et al*. (Rochoux, Delmotte, Cuenot, Ricci, & Trouvé, 2012b), (Rochoux, Emery, Ricci, Cuenot, & Trouvé, 2014) developed a data assimilation algorithm using ensemble Kalman filters and a state estimation approach. The forward model (named "Firefly") was composed of a Rothermel based propagation equation for rate of spread (RoS) and a level set approach to propagate the front. The algorithm was tested with synthetically generated data and with a controlled small scale (4 x 4 m) grassland experiment with spatially-varying fuel depth and temporally-varying wind speed and direction. One of the main drawbacks of the algorithm lies in the fact that the model deals with errors using Kalman Filters which implies the assumption that the errors are normally distributed. However, in fire, errors do not follow a Gaussian distribution (Johns & Mandel, 2008). Nevertheless, the approach reinforces the potential of data assimilation in wildfire forecasting.

Simple synthetic validation

As has been mentioned, the work at hand is the improvement an adaptation to a real data context of a forecasting algorithm developed by Rios *et al*. (Rios *et al*., 2014). The algorithm is based on Huygens light propagation principle applied to wildfires propagation (Richards, 1990), (Richards, 1993) together with Rothermel model (Rothermel, 1972) to compute RoS. The Huygens principle assumes that each node in the front acts as a new elliptical propagation ignition point. Each ellipse –firelet– has the main axis directed towards the wind-slope vector (assumed to be the main propagation direction) and the magnitude of its axis is defined by equations [1-3] (Figure 1). The curve that envelopes all the firelets is then the new fire front (Figure 2).

$$a(s,t) = RoS(s,t) \cdot \frac{1 + \left(LB - \sqrt{LB^2 - 1}\right)^2}{2 \cdot LB} \quad \textbf{[1]}$$

$$b(s,t) = RoS(s,t) \cdot \frac{1 + \left(LB - \sqrt{LB^2 - 1}\right)^2}{2} \quad \textbf{[2]}$$

$$c(s,t) = b(s,t) - \frac{RoS(s,t)}{\left(LB + \sqrt{LB^2 - 1}\right)^2} \quad \textbf{[3]}$$

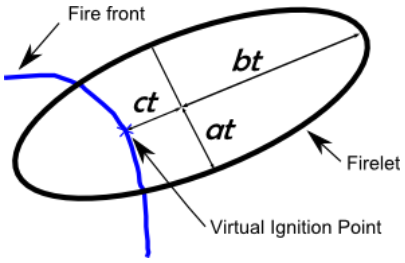

Figure 1:Firelet axis geometry

Where *LB* is the length-to-breadth ratio and is defined by Anderson *et al*. (Anderson, Catchpole, De Mestre, & Parkes, 1982) throughout an experimental correlation with the wind-slope vector and *s* is the front parameterization variable.

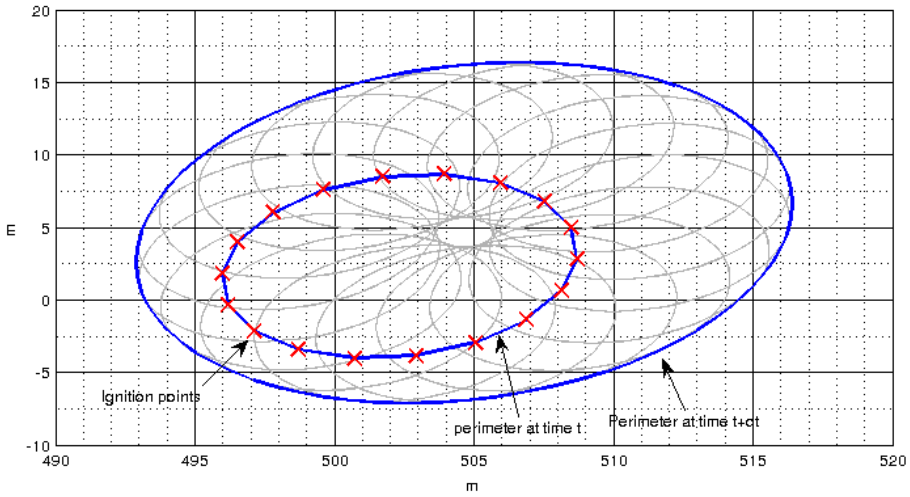

Figure 2. Illustration of the Huygens' Principle applied to fire spread. The fire front at time t is discretized into vertices (red crosses). Each of this vertex become the point source for local elliptical expansions (firelets). The curve that envelopes all the firelets is the new fire perimeter at time t + dt.

The optimization problem to find the invariants that best reproduce the assimilated fire fronts used a Tangent Lineal Model approach and an automatic differentiation of the forward model. To check the performance of the algorithm, different configurations of invariants were checked. In some cases, up to 4 invariants were estimated during the optimization loop and non-homogeneous fuel distribution together with temporally-varying wind direction and speed were used to recreate more real scenarios. The algorithm showed good capacity to identify the correct invariants and reproduce the assimilated fronts even when the first guested invariants value was 150% off the true value (see Figure 3). The computational process was fast and large lead times were achieved.

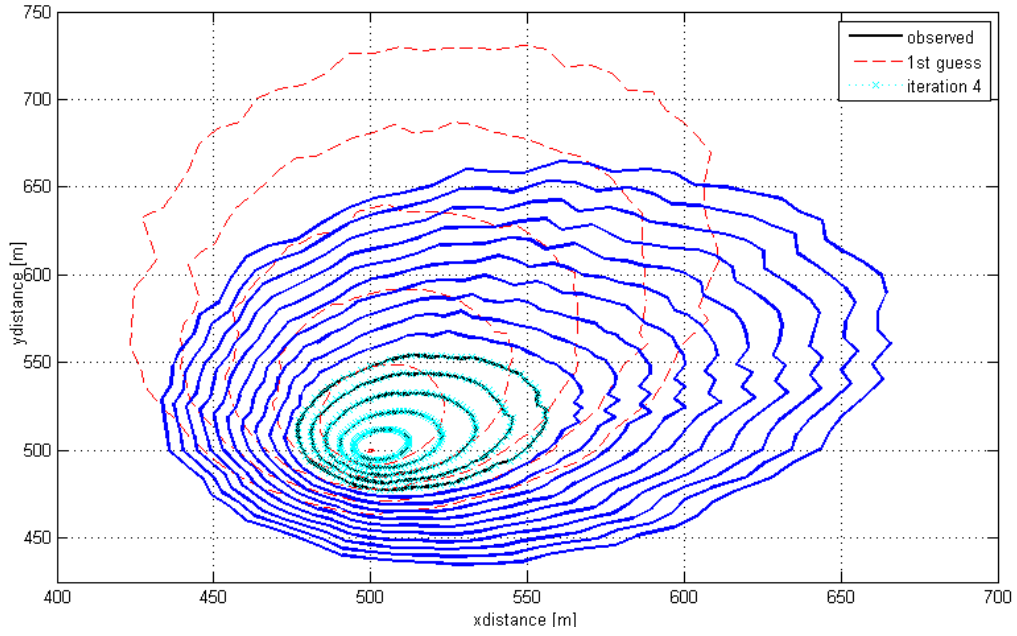

***Figure 3. Fire front convergence(dotted light blue lines) towards observed data (solid black line) after 4 iterations (after* Rios *et al.*, 2014)**

The complete flow diagram of the algorithm is presented inFigure 4. A first invariant's vector guess is needed to create the first forward model run. Together with the available assimilated fronts, the optimization loop identifies the most suitable invariants by means of automatic differentiation. When

a certain convergence is achieved the invariants are assumed to be properly estimated and a forecast can be delivered. This forecast will be valid as long as the invariants remain constant.

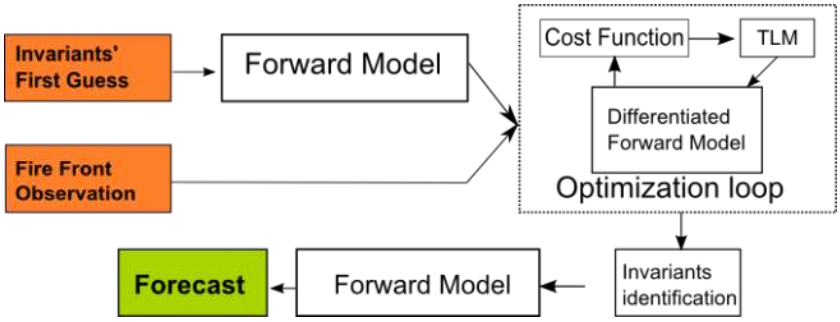

Figure 4: Diagram flow of the data assimilation algorithm. Orange boxes are input data whereas green box is the output of the algorithm.

Real data pitfalls

The use of real data to check the performance of the model rises some mathematical and computing problems that need to be addressed. First of all, a real fire front hardly is a closed curve, which is, however, one of the bases of the already existent algorithm (see Figure 3). There are many circumstances that may disable the fire to expand in all directions, e.g. line vs point ignition, perimeter interception by a firebreak, suppression activities, etc. Thus, the existing forward model has to be adapted to this reality and hence handle open ignition curves. For this reason, a new set of forward model differential equations needs to be implemented and integrated. Moreover, the simulated fire needs to stop on firebreaks (natural or suppression-made) or overtake them if they are inefficient. At this stage of our algorithm, when a simulated fire overtakes little fire breaks or vegetation has a great local change, the front creates sharp areas (see Figure 5) that have to be smoothed, hence improvements in terms of regridding and adding extra nodes on the perimeter have to be done. Due to this overtaking, the current code simulates front fingers that will overlap as fire propagates and recovers a convex shape (Figure 5), and because of that a filtering algorithm that correct this non-physical situations will need to be coupled to the model.

Regarding the assimilated data, in real scenarios data income concerning environmental parameters can be highly variable so the algorithm needs to be prepared to integrate data that are not regularly supplied on time and space.

Beyond the inherent algorithm difficulties, the use of the inverse modelling framework with real data also requires some additional remarks. While the assumption of the existence of some invariants parameters may remain correct for certain scenarios and time periods, it might not be such an invariant magnitude in the model that can reproduce the assimilated data, due to model simplicity. Therefore the forward model needs to be kept flexible enough to allow large adjustments and complex behaviours and front shapes. Similarly, the cost function optimization target value should not be kept too small since perfect convergence (i.e. perfect matching of simulated and observed fronts) might be impossible. Even in the cases where it converges close to zero, the correct invariant's value will not be known, and therefore the individual invariant convergence cannot be analysed as it was done in the synthetic data case.

Real case algorithm adaptation

In order to use our existing inverse modelling data assimilation structure with real sensed data some adaptation algorithms had to be implemented. This included new integration of the Huygen's expansion differential equations, a regridding algorithm, a loop clipping algorithm and a degridding algorithm.

3.1. Forward model equations

The previously implemented forward model equations did not allow the initial fire perimeters to be opened curves. Thus we implemented the integration of the differential equations originally developed by Richards (Richards, 1990) for the firelets enveloping curve defined by x and y coordinates:

$$\frac{\partial x(s,t)}{\partial t} = \frac{a^2 \cos\theta\left(\frac{\partial x}{\partial s}\sin\theta + \frac{\partial y}{\partial s}\cos\theta\right) - b^2 \sin\theta\left(\frac{\partial x}{\partial s}\cos\theta - \frac{\partial y}{\partial s}\sin\theta\right)}{\sqrt{\left(b^2\left(\frac{\partial x}{\partial s}\cos\theta - \frac{\partial y}{\partial s}\sin\theta\right)\right)^2 + \left(a^2\left(\frac{\partial x}{\partial s}\sin\theta + \frac{\partial y}{\partial s}\cos\theta\right)\right)^2}} + c\ \sin\theta \quad \textbf{[4]}$$

$$\frac{\partial y(s,t)}{\partial t} = \frac{-a^2 \sin\theta\left(\frac{\partial x}{\partial s}\sin\theta + \frac{\partial y}{\partial s}\cos\theta\right) - b^2 \cos\theta\left(\frac{\partial x}{\partial s}\cos\theta - \frac{\partial y}{\partial s}\sin\theta\right)}{\sqrt{\left(b^2\left(\frac{\partial x}{\partial s}\cos\theta - \frac{\partial y}{\partial s}\sin\theta\right)\right)^2 + \left(a^2\left(\frac{\partial x}{\partial s}\sin\theta + \frac{\partial y}{\partial s}\cos\theta\right)\right)^2}} + c\ \cos\theta \quad \textbf{[5]}$$

Where a, b and c are the firelet axis calculated with equations [1-3], θ is the wind-slope vector direction and s the curve parameterization parameter. These equations were numerically integrated using a Prediction-Corrector method based on central difference approximation.

3.2. Complementary algorithms

3.2.1. *Regridding algorithm*

As mentioned in section 2.2 a regridding algorithm was needed in order to avoid sharp zones formations due to firebreaks or rapid local fuel changes. The algorithm implemented, successively analyses the angles between three correlative segments. Then, if any of the two adjacent angles is larger than a given threshold a new node is inserted in the corresponding segment and the process is repeated until all the angles meet the condition. The effect of this step can be observed in Figure 5 (before applying the algorithm) and Figure 6 (after using it). In this case, the implemented open curve differential equations are used to propagate the front.

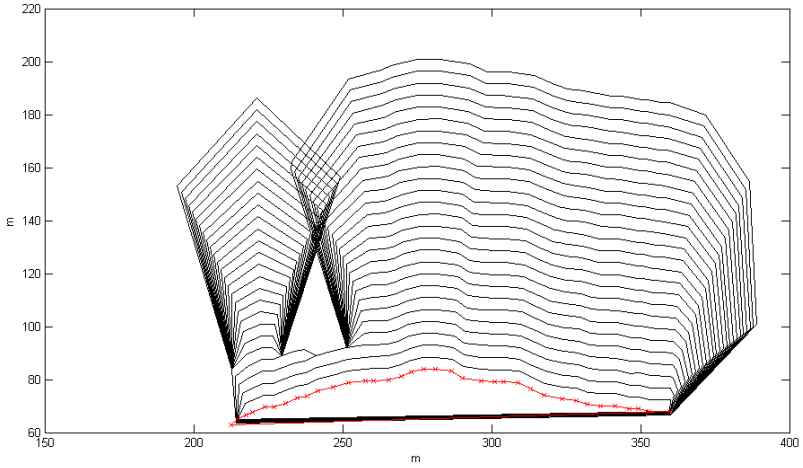

Figure 5. Propagation model showing pitfalls due to the presence of a firebreak (a rectangular 20x10m fire break is placed at coordinates [230, 90]). Line ignition (red crossed line), is taken from real fire data (shrubland experiments in South Australia 2008)

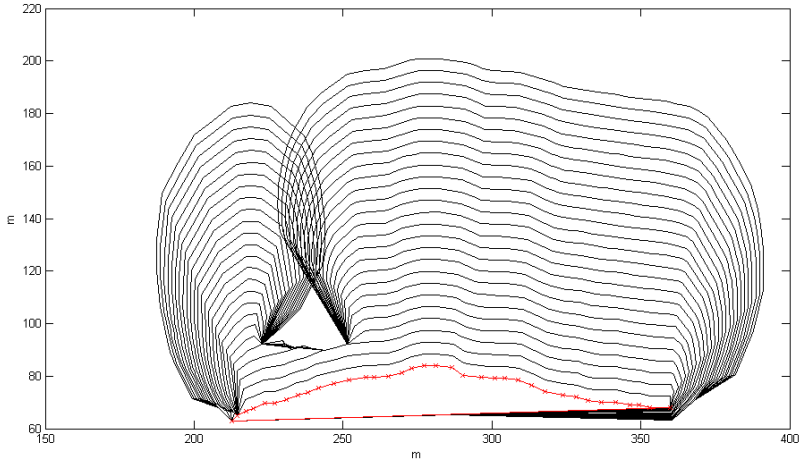

Figure 6. Effect of the regridding algorithm for the same front propagation around a firebreak as figure 5 for a threshold value of π/4 radians.

3.2.2. *Loop-clipping algorithm*

When the front became a convex curve and kept propagating, after overtaking a fire break or due to a local fire spread acceleration, our code created overlapping loops between two front fingers or even self-crossing loops. A loop-clipping algorithm was then implemented to avoid meaningless propagations such as fire propagating inwards in a self-crossing loop. The algorithm checks for intersections at any segment and identifies the section that has to be directly removed from the propagating front. Loop clipping can create sharp curves on the loop's intersection and therefore the regridding algorithm is again called afterwards.

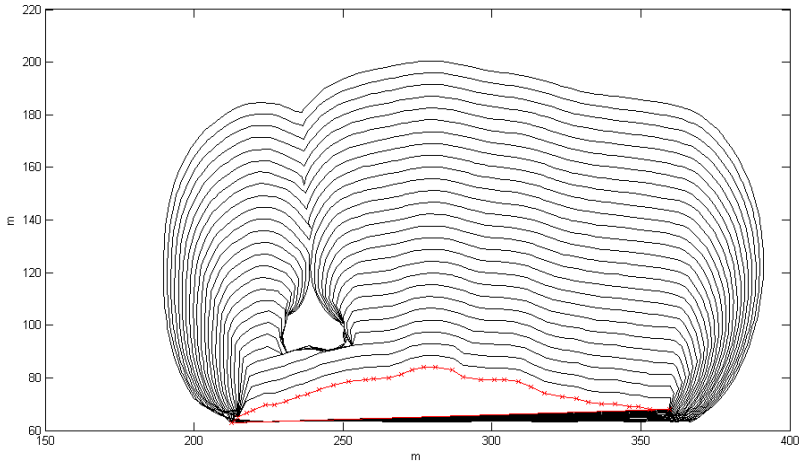

Figure 7. Effect of the loop clipping algorithm when applied to the same propagating case as Figure 6.

3.2.3. *Degridding algorithm*

After applying the mentioned improvements, as the forward model generated fire fronts and the loop clipping and regridding algorithms were run when needed, unnecessary nodes appeared in a non-curved region. To maintain performance and coherence a degridding algorithm had to be implemented. The algorithm looks for segments that are shorter than a given length (taken to be a multiple of the

spatial sensibility) and checks that the adjacent angle is smaller than this of regrinding algorithms. If both conditions are met, the node is removed from the front (Figure 8).

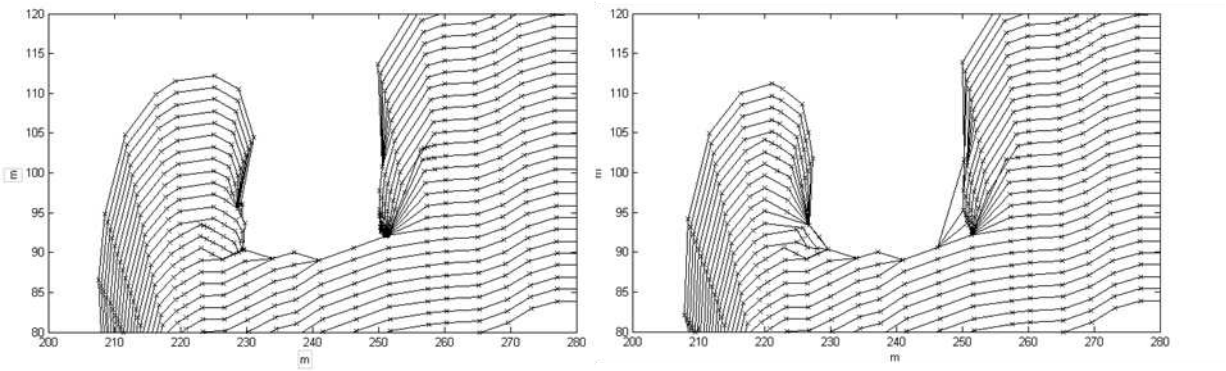

Figure 8. Around fire brake zones, the propagation algorithm creates regions of high and unnecessary node density (left figure). When the degridding algorithm is applied (right figure) those regions are reduced and the forward model can be run faster.

3.3. Inverse modelling

In our inverse modelling-data assimilation structure, a cost function that accounts for the discrepancies between modelled and sensed fire fronts has to be evaluated in each forward model run to determine the invariants. The best set of invariants are calculated by minimising this cost function. The cost function plays a central role in the algorithm. It has to be simple enough so its evaluation is not computationally expensive while it has to be accurate and drive the algorithm towards a meaningful convergence.

3.3.1. *Cost Function*

The cost function implemented in the previous algorithm used an angular discretization scheme to select the points on both, the model and the observed fronts. The summed up distance between each angularly related pair of points was then computed as the cost function value:

$$J(p) = \sum_{t=t_i}^{t_f} \sqrt{[\overline{y_i} - y_i(p)]^T W [\overline{y_i} - y_i(p)]} \qquad \textbf{[6]}$$

Where $\overline{y_i}$ and y_i are the observed and modelled front coordinates respectively, p is a given set of invariants value and W is a weight diagonal matrix that can be used to give more value to certain observations depending on their reliability and accuracy. In each cost function evaluation, all the available fronts are computed and summed up.

In the real data scenario the angular discretization is no longer valid due to the complex shapes. Thus, the cost function was modified by finding the Euclidian norm of a vector that connects each modelled segment mid-point with its correspondent assimilated front following the local propagation direction (perpendicular to the local curve slope). Since this distance is quantified for every assimilated fire front and the number of segments are not kept constant in each front as the perimeter expands, the total distance between each pair of isochrones is divided by the number of vectors. Figure 9 illustrates the Euclidian norm evaluation for four fire fronts assimilation. Note that some intersection vectors diverge due to the local geometry of the modelled front. In this cases, a filter is applied so vectors that are larger than the mean value plus/minus 2 times the standard deviation are removed. As both perimeters converge, the intersection vectors behaviour improves.

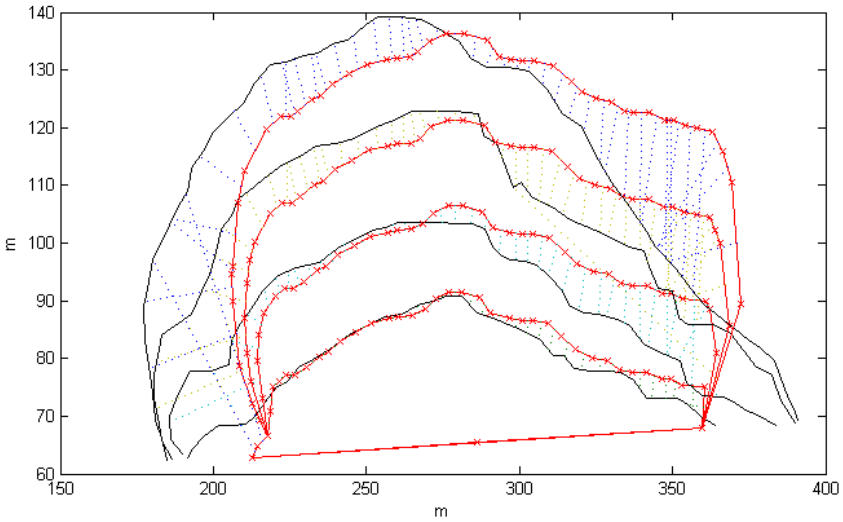

Figure 9. Paired isochrones of assimilated (black solid lines) and modelled (red dotted lines) fire fronts (real fire data from South Australia experiments 2008). The cost function is calculated by averaging the Euclidian norm of the lines perpendicular to the modelled front that intersect the corresponding observed perimeter.

3.3.2. *Tangent Lineal Model*

The optimization loop is the most critical part of the algorithm since it will affect the total computing time (and therefore compromise the lead time). The two main approaches to optimize the cost function are gradient-free and gradient-based algorithms. While the first group sweeps all the available domain and identifies absolute minimums, their algorithms are also more computationally expensive. The gradient-based algorithms assume an initial guess for the estimating parameters and use the gradient to drive the solution towards a minimum. They are particularly suitable for systems where variables are limited within a range of values. Using the later, and using a Tangent Linear Model local approximation for the forward model (based on Taylor's expansion series on the vicinity of the initial guess) the optimization step can be reduced to a linear system of equations that can be easily solved by using a QR factorization with column pivoting (Nocedal & Wright, 1999):

$$\sum_{t=t_i}^{t_f} H_i^T H_i \bar{p} = \sum_{t=t_i}^{t_f} H_i^T (\bar{y} - y_i(p))$$

Where $\bar{p}$ is the difference between an old and an updated invariant's vector, $(\bar{y} - y_i(p))$ is the discrepancy between the observed and the modelled fronts and the term $H_i^T H_i$is the Jacobian of the forward model. The most common numerical algorithm to calculate this term need to evaluate the forward model itself multiple times (a centred difference approach for example) which may dramatically increase the computational time. Alternatively, an automatic differentiation approach can be used to directly evaluate this term. This approach uses the chain-rule for derivatives to systematically derive the scripted code. Once this is done, the Jacobian term can be calculated with one run. If the process is repeated in a loop, the final invariant's vector is obtained when the term that contains the difference between the observations and the model converge. This algorithm is not yet implemented for the real data assimilation case due to the changes in the forward model equations. The automatic differentiation process has to include the correcting algorithms, and therefore is not straightforward. Moreover, since the complexity of the model increases, the adjoint model instead of the forward model is needed.

Model testing with real fire data

The improvements implemented so far in our inverse modelling – data assimilation structure were tested using real fire data coming from experimental fires performed in eastern South Australia in March 2008. Despite being within a framework of a scientific experimental burning program, fires exhibited real behaviour patterns as were performed in extremely severe weather conditions and plots dimensions were all above 6 ha. These experiments were conducted in Ngarkat Conservation Park (35º45'S, 140º51'E) which is constituted by a characteristic dune and swale system comprising large flat areas of mallee-heath shrublands (130 m a.s.l.). Fire behaviour in mallee-heath fuel types is characterized as being discontinuous and highly variable due to the heterogeneous characteristics of the various fuel layers that comprise mallee-heath fuel complexes (Cruz *et al*., 2013). Data used in this paper comes from the experimental burn performed in a 9 ha 8 year-old heath plot in March 4th 2008. This fuel complex was characterized by scattered small-leafed shrubs, organized in clumps, and a discontinuous litter layer partially buried by sand. The main fire carrying fuel layer was the discontinuous shrub canopy (1.5 m depth). Ambient conditions were temperature of 32 ºC and relative humidity of 25%. Wind speed (10-m open) averaged 15 km/h, with gusts up to 30 km/h. Wind direction was from south-south-westerly. Characteristic dead fuel moisture of the fuel complex was 7.7%. The fire was ignited with a 130-150 m long line and two minutes after ignition, flame heights were about 2-2.5 meters, with flashes up to 4 meters. The fire spread vigorously throughout the plot with sustained flames heights of 4-5 meters. Eight minutes after ignition, the main flame front hit the northern border of the plot, concluding a 350 m head fire run (Planas, Pastor, Cubells, Cruz, & Grenfell, 2011) The fire was filmed from an helicopter with a IR camera (AGEMA Thermovision 570-Pro, FSI-FLIR Systems). This camera operated within the 7.5-13 μm range and was equipped with a frame grabber to control and store sequences of IR images (240 x 320 pixel) onto a laptop computer at an approximate rate of 5 frames per second. The helicopter was hovering positioned so that the majority of the plot was in view for the duration of each fire, allowing fire behaviour to be recorded and monitored. Isochrones map (1 every 10 seconds frequency) and RoS map of this fire experiment were subsequently obtained applying a methodology for IR analysis developed with MATLAB® computing software and described elsewhere (Pastor *et al*., 2010).

Using the first observed perimeter as an ignition line, the forward model was run fed with the moisture content, wind speed and direction and fuel load and depth values. Figure 10 shows the comparison between 5 min of real burning fronts, sampled every 10 sec. and the modelled isochrones for the same period of time. While individual isochrones shape do not perfectly match all the observed fronts, the total distance travelled by the head fire is well predicted. Similarly, the left flank of the fire is properly predicted as time passes by. Taking into account that the plot had a high fuel discontinuity not added to the model, and also that the wind variation was neither considered, the simulations are reasonably accurate and support the need for and the suitability of an automatic data assimilation algorithm capable of identifying this factors difficult to obtain with enough accuracy during operational scenarios.

Conclusions

The required steps to adapt a data assimilating system to work with real sensed data have been investigated and implemented in a wind-driven short-term forecasting algorithm. Difficulties such as front concavity, fire breaks and fuel irregularities have been identified and addressed in the forward model. The assimilating capacity of the algorithm can be now explored by casting different invariants configurations and performing the optimization step with an automatic differentiation approach to ensure positive lead time. The preliminary check with airborne thermal images of a large scale experiment showed the capacity of the implemented forward model of reproducing head fire

propagation and overall fire growth with a reasonable accuracy and highlights the potential of an automatic assimilation algorithm implementation.

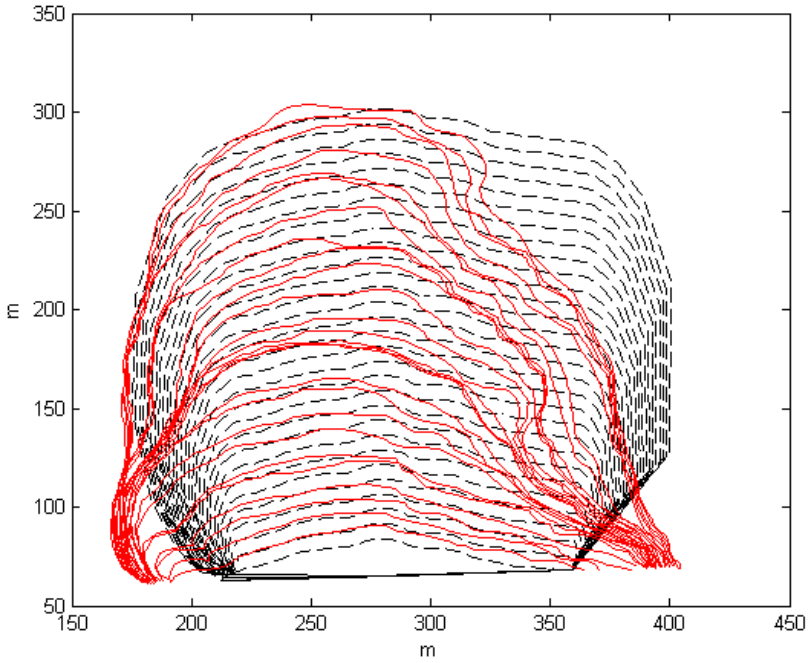

Figure 10. Modelled fronts (dashed lines) versus Ngarkat's plot "A" real perimeters (solid lines). Isochrones are plotted every 10 secons during 5 min. (i.e. 30 isochrons are depicted). The fuel depth is estimated of 1.3m and the wind is set to 3m/s.

Susceptibility of forest fire in urban area of Uba, MG, Brazil

Fillipe Tamiozzo Pereira Torres, Guido Assunção Ribeiro, Elias Silva, Sebastião Venâncio Martins

[a] *Universidade Federal de Viçosa, DEF, campus universitário 36570-000, torresftp@yahoo.com.br, gribeiro@ufv.br, eshamir@ufv.br, venancio@ufv.br*

Abstract

The aim of this study was to produce a map of susceptibility to fires in vegetation within the urban perimeter of the city of Uba, MG, Brazil, with the use of information related to topography, land cover and land use and the proximity of access roads and urban areas, using GIS techniques. From the validation of the generated cartogram, it was observed that 80 % of cases were located in areas of high and very high risk, 15 % in medium-risk and 5 % in areas of low and very low risk. Was observed in this study that the largest number of occurrences is concentrated near urban areas. In other studies, these authors found that, besides the favourable physical environment it is necessary a causative agent to fire occur. In area of very high or very low risk, the event will only occur from an initial cause or source of heat. This mapping will serve as a tool for establishing public policies to prevent power, acting in promoting awareness and control measures in the areas of highest risk.

Keywords*: Vegetations fires, susceptibility, map.*

Introduction

Fire is a growing problem in the remaining tropical forests in the world. Despite years of scientific study and all the media attention in relation to forest fires, the effects they cause to the environment have also been ignored (Silva *et al*., 2003).

Fires in vegetation generate various economic, landscape and ecological damage and can occur in protected or conservation areas, farms, roadsides, proximity to urban areas and reforestation areas, besides other places (Fiedler *et al*., (2006). Anyway, fires occur when several factors associated with combustion and fire propagation become favorable to the ignition and spread of flame (Nogueira *et al*., 2002).

There are two types of factors that determine the degree of fire danger. The constant factors that are represented by the type of fuel, which involves different types of vegetation and topography and the variable factors that are represented by atmospheric conditions (Torres *et al*., 2011). The slope, aspect and the use and occupation of land are examples of these variables.

According to Batista (2000), the topography influences the climate and determines the type of fuel. Considering that fire behavior is largely the result of climate and fuel available, it can be said that the topography also has a decisive influence on fire behavior.

Surfaces with different orientations and slope receive different amounts of solar radiation compared to a horizontal surface at the same location and time of year (Torres & Machado, 2011). The studies of Torres *et al*. (2010a) shown that the concentration of largest number of fires on the North (43 %), followed by Western a (27 %), East (18 %) and South aspect (12 %) with fewer occurrences. This is due the sun, during most of the year, culminates in Zenith north of the city, because of latitudinal position. This factor tends to raise the temperature in the North aspect influencing more fuel load and fire occurrences. Regarding the slope Ribeiro *et al*. (2007) shown that the increased of the fire intensity in this areas is due to the approaching flames and fuel compared with smooth areas, heating the fuel quickly.

According to Viegas (2004), the spread of fire in slopes is distinct from that in areas without slope due to the effect of additional factors such as convection and radiation behavior. If there is slope and the presence of wind, the propagation rate tends to increase.
In addition to relief, the fuel is crucial in the fire occurrence. Evaluating coverage torched in the city of Uba (MG), Torres *et al*. (2010a) observed that the most forest vegetation tends to hold moisture better than herbaceous, recording 80 % of the occurrences of fires in fields and pastures and 5 % in forests.
The type of material and their arrangement facilitate the ignition and spread of fire. The thinner material has lower ignition temperature and loses their moisture faster (Nunes, Soares & Batista, 2006), facilitates the start of the fire and accelerates its spread. Also according to these authors, the proximity and uniform distribution of the fuel particles facilitate the spread, also favoring the occurrence of fire on the fields, pastures, and urban vegetation areas.
On the other hand, bushes or trees intercept the radiation, reducing the temperature of the air and the fuel in its interior (Nunes *et al*., 2008). They also act as a barrier, preventing the free passage of air currents, reducing the wind speed inside. This reduces evaporation, making the drying of the fuel. Furthermore, transpiration of forest material provides an increase in relative humidity in the forested area.
However, it is not enough that the factors directly associated with the occurrence of forest fires are favorables, the initial flame is necessary to fire occurrence. Thus, any action to prevent forest fires should seek the elimination of its causes (Nogueira *et al*., 2002).
According to Soares and Cordeiro (1974), Soares and Santos (2002), Bonfim, Ribeiro and Silva (2003), Santos, Soares and Batista (2006), and Torres *et al*. (2010b), the main cause of fires is human activity, such as smoking, burning to clean, incendiary fires and recreation. Thus, next to roads and urban areas tend to be more susceptible to fire occurrences.
Because of the constant character of the listed factors (slope, aspect and land use), they become valuable in establishing susceptibility maps to fires. It is essential to know where the fires occur to determine the areas of high risk or high susceptibility (Soares and Santos, 2002) for these regions by establishing specific programs. The risk zoning or fire risk maps according to Batista (2000) have been used very effectively as a fundamental tool in the rational planning of resources for prevention and pre-suppression of fires on vegetation.
Faria, Silva and Goes (2003) affirm that the use of tools linked to a Geographic Information System (GIS), allows increase knowledge about the relationships between environmental phenomena, estimating risk areas, potential environmental and defining zoning. The cartograms generated provide a layer on the various components of the environment, such as slope, use and cover, soils, geomorphology, and others, besides to allow the overlap of the generated maps.
The aim of this study was to produce a map of susceptibility or risk to fires in vegetation inside the urban area of Uba city (MG), using informations related to relief, use and land cover. This mapping will serve as a tool for establishing public policies for prevention, acting in the public awareness of power as well as control measures in the areas of highest risk.

2. Methods

The Municipality of Uba is located in the physiographic mesoregion denominated Zona da Mata Mineira, Minas Gerais State, Brazil. It lies between latitudes 21°16' to 20°57' south and longitudes 43°07' to 42°57' west. Its length is approximately 40,750 hectares and its population is about the 101,466 inhabitants (IBGE, 2010).
The topography is represented by areas of strong wavy slope, comprising about 16,556 hectares (40.6 %) of its entire territory. However, other 11,354 hectares (27.9%) can be considered flat whereas 8,790 hectares (21.6 %) has an intermediate topography. The remaining area (4,050 hectares, 8.9 %) has a mountainous structure.

The vegetation type is compound by pasture cover an area of 75,51 %, followed by brushwood (capoeira) and woods with 16.2 % and agriculture with 4.9 %.
The susceptibility cartogram of fires was done using ArcGIS 9.3 software to generate the maps of Slope, Aspect and Use and Occupation of the soil. These maps were overlaid, allowing the determination of more susceptible areas to fires.
In this sense, to construct the maps of declivity and exposure of slopes was produced a Digital Elevation Model (DEM) (Figure 1) by interpolating the contours of 10 - 10m, extracted from Aerial Images Orthorectified range of 1:10,000, November 2005.

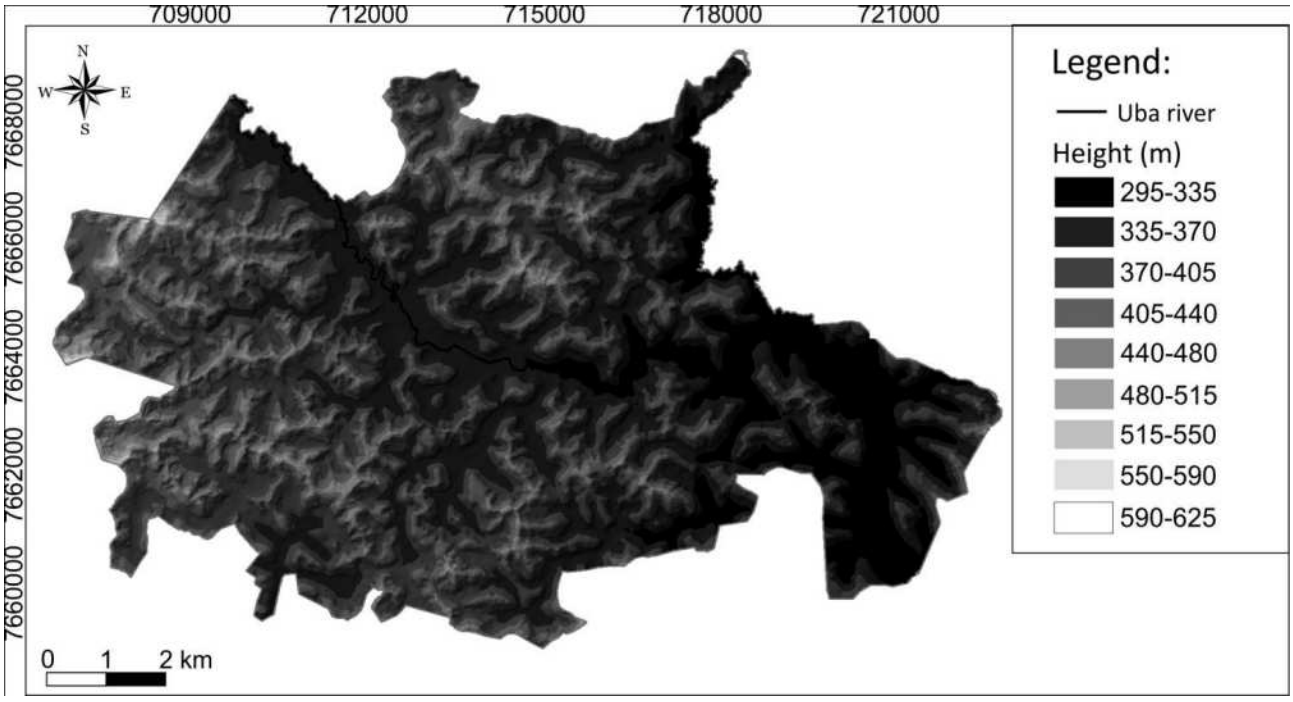

Figure 1. Modelo Digital de Elevação do perímetro urbano de Ubá – MG

The land use map was originated by visual interpretation of orthorectified images. They were vectored the major classes of land use in the urban area of the municipality: forest, brushwood (capoeira), pasture, agriculture, water bodies, exposed soil and constructed area. To check the classification performed in the laboratory, georeferenced points in the field were collected, thus ensuring the reliability of the data.
After generation of cartograms regarding declivity (Figure 2), Aspect (Figure 3) and Use and Occupation of the soil (Figure 4), the classes were analyzed relating to each of these maps. Grades were assigned to each of these classes according to weight of respective class of occurrence (Table 1).

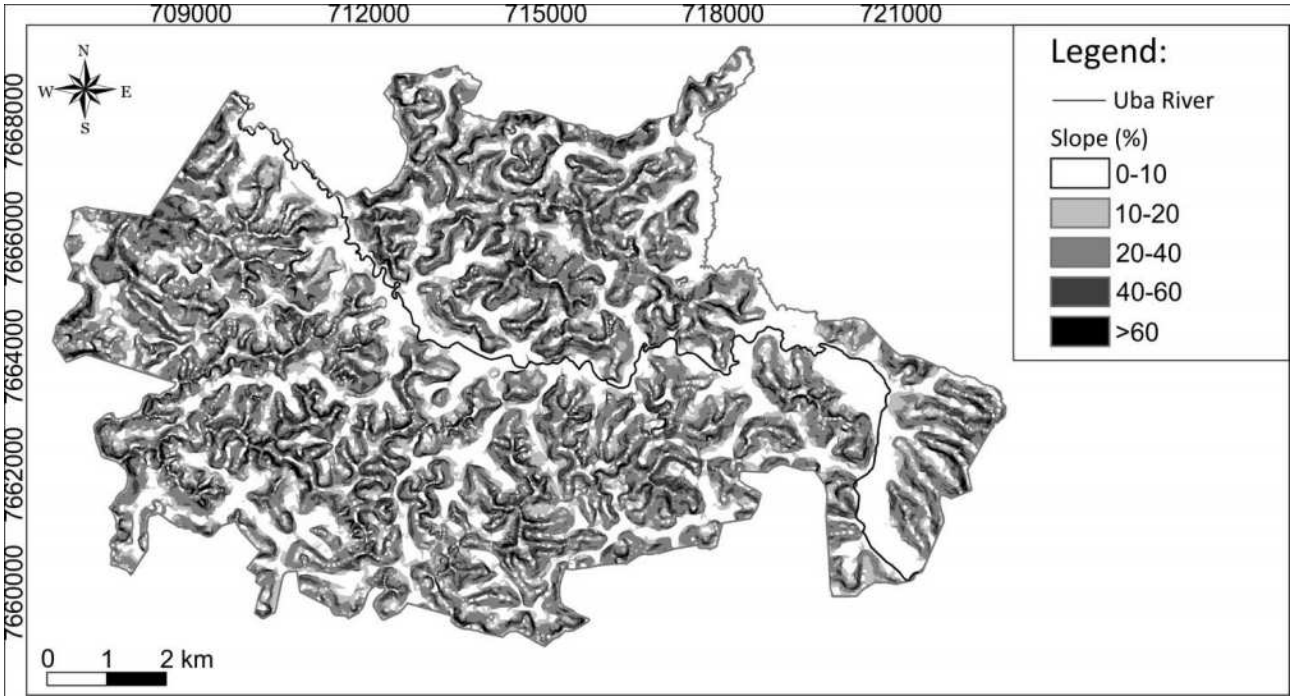

Figure 2. Slope of the urban perimeter Uba - MG

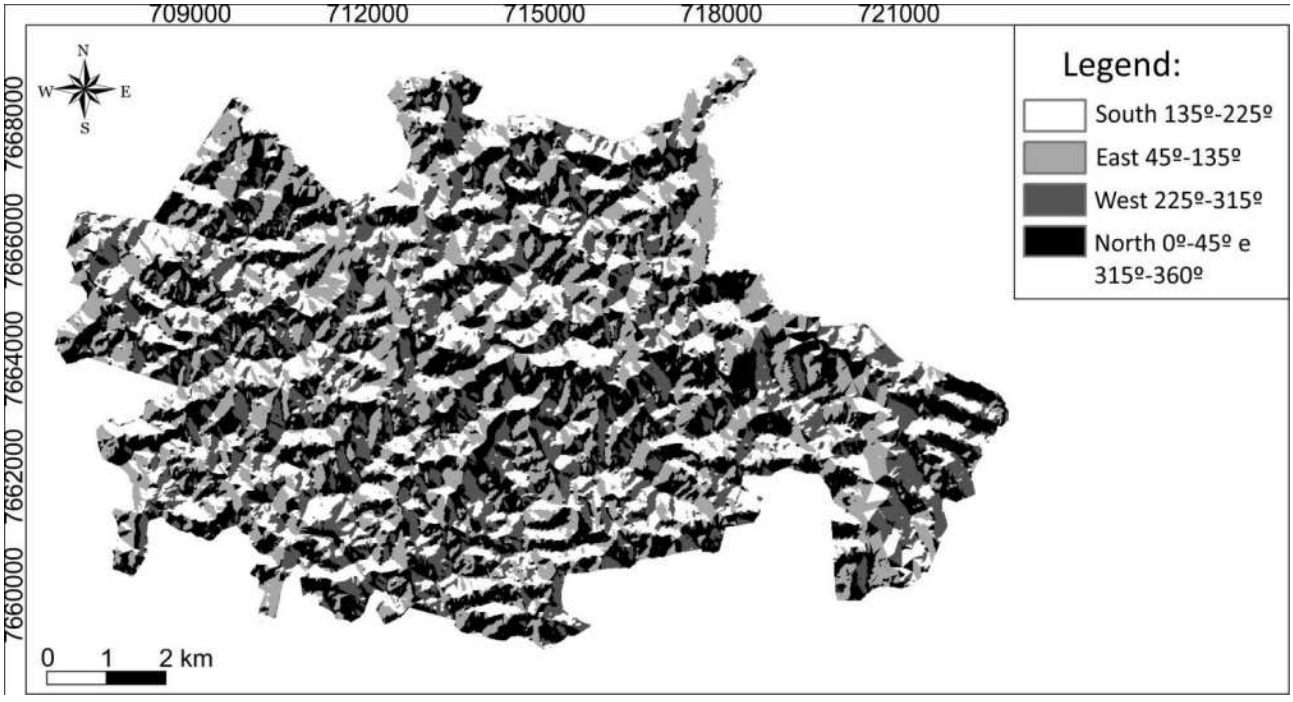

Figure 3. Exposition of the Sun aspects the urban perimeter of Uba - MG

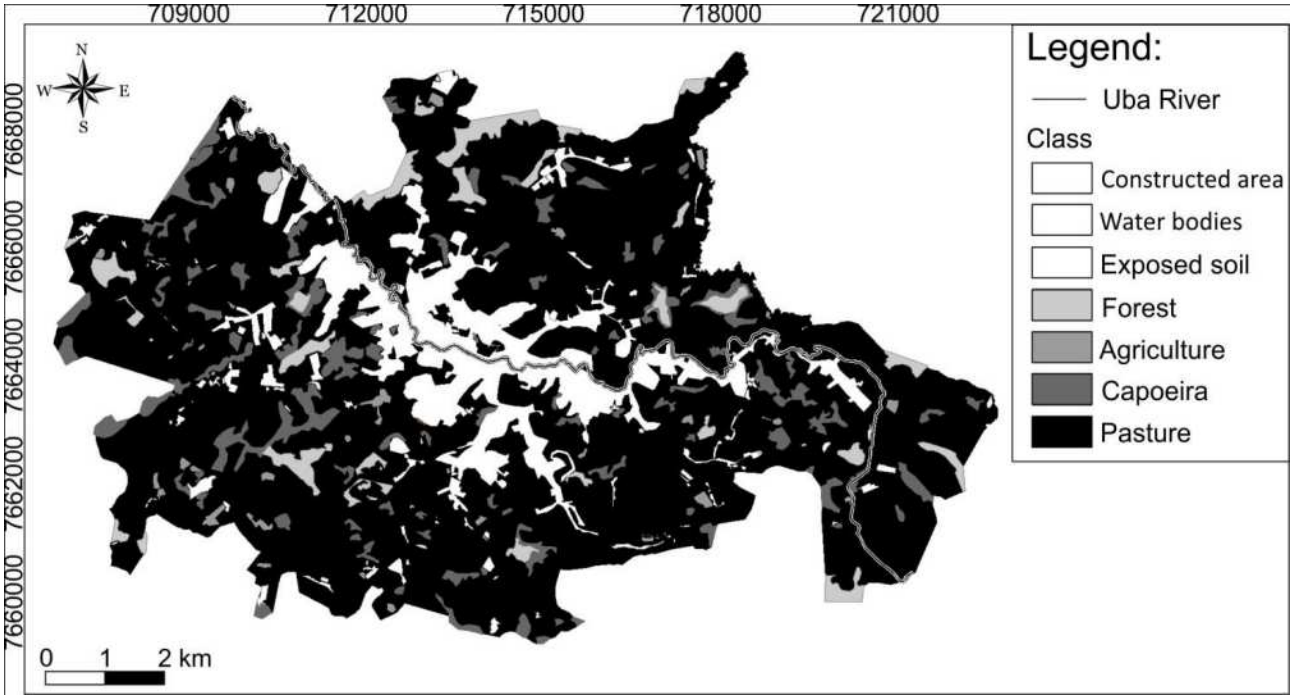

Figure 4. Use and occupation of urban perimeter Uba - MG

Table 1. Table notes the statement of the Fire Risk

Use and occupation		Exposition of the Sun		Slope	
Class	Weight	Class	Weight	Class	Weight
Forest	3	North	10	0º a 10º	2
Capoeira	7	West	8	10º a 20º	4
Agriculture	5	East	6	20º a 30º	6
Constructed area	0	South	4	30º a 40º	8
Exposed soil	0			>40º	10
Water bodies	0				
Pasture	10				

The notations used in Table 1 were based on Torres *et al*. (2008) and Torres *et al*. (2010a) who studied the profile of vegetation fires in the cities of Juiz de Fora and Ubá, both located in the Zona da Mata Mineira, Minas Gerais State, Brazil. The data of reclassified maps were overlaid, according to the tree of Figure 5 decision.

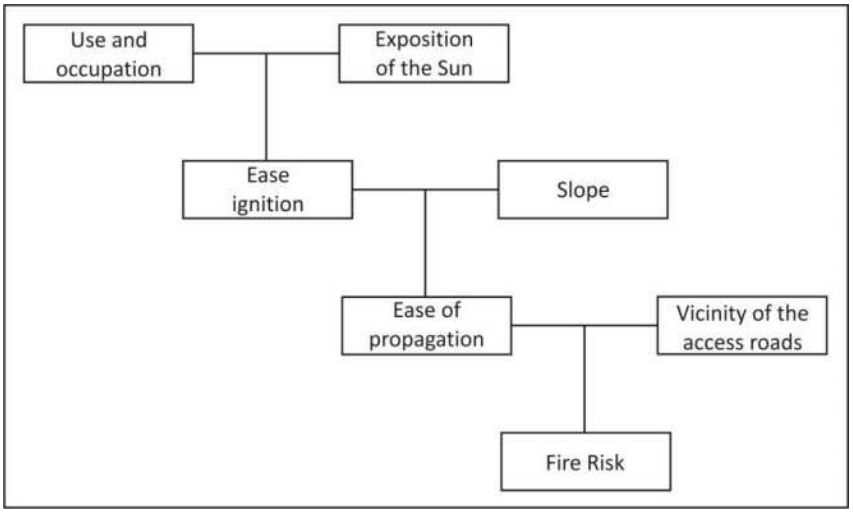

Figure 5. Decision tree for fire risk

The Use and Occupation cartogram was crossed with the Aspect cartogram, both with same weight, generating a Ease Ignition cartogram. Both cartogram has a weight of 66% when crossed with the Slope cartogram (weight 34%), generating the Ease of Propagation cartogram.
This cartogram was overlaid to the proximity of roads and urban areas, creating a 15-meter buffer around them. This was based on Torres *et al*. (2008) that describe the risks of fires in road borders and urban areas peripheries. The final product of these crossings was the cartogram of Susceptibility of Fires in vegetation within the urban area of the municipality of Uba, Minas Gerais Brazil (Figure 6).

Results and Discussion

The cartogram of susceptibility of fires in vegetation in the urban area vegetation of the municipality of Uba - MG (Figure 6) is supported by hazard classes shown in Table 2.

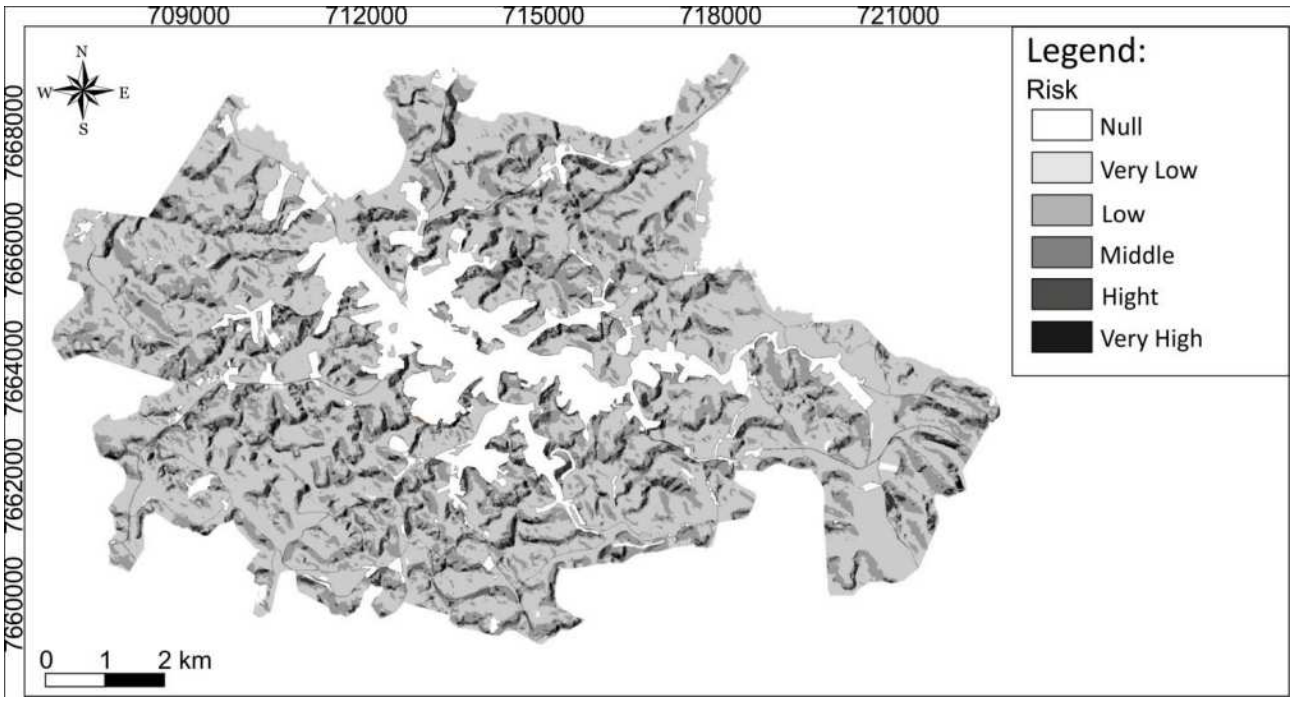

Figure 6. Map of forest fires in the urban perimeter of Uba - MG

Table 2. Areas according to the class of risk

Class	Ha	(%)
Null	1276,1	13.7
Very Low	4636,7	49,8
Low	2480,5	26,5
Middle	289,0	3,1
High	555,8	5,9
Very High	96,0	1,0
Total	**9334,1**	**100%**

It is observed that the risk areas are concentrated near urban areas. This is due to the human presence as the main source of ignition of fires. In studies conducted by Torres *et al*. (2008) and Torres *et al*. (2011), was identified that although the scenario created by the physical environment (slope, aspect, use and occupation of land) without causal agent there is no occurrence of the fire. On other hands, even in an area classified as very high risk area, the fire will occur only if the initial flame, ordinarily, is associated with cleaning burning, smoking and arson. The same occurs in areas classified as very low risk; if there is the ignition, the risk of fire is high in these areas.
To analyze the effectiveness of the cartogram generated, were used the geographical coordinates of all occurrences in the urban area in the period 2006-2012 (Table 3). It was recorded 732 events in the urban perimeter of study area, with 80 % of those located in areas of high and very high risk and 5 % in areas of low and very low risk. These data demonstrate that the generated map portrays well the situation of vegetation fires in the urban area.

Table 3. Percentage of occurrences according to risk class

Risk Class	% of occurrences
Null	0%
Very Low	1%
Low	4%
Middle	15%
High	28%
Very High	52%

The results were similar to those of Coura, Souza and Fernandes (2009) for the city of Rio de Janeiro, Brazil. The authors crossed the maps of geomorphology, aspect and land use and they obtained 79% of occurrences in areas of high risk, 16% on middle and 5% in low susceptibility.

Conclusion

According to the results, it was concluded that:

- The scores and weights used have produced a cartogram that reflects the susceptibility to fires in the urban area of Uba, Minas Gerais, Brazil;
- Areas with Northern aspect, greater slope and near the roads were major points of susceptibilities to occurrences;
- Most of the areas classified as very high risk, as well as incidents recorded by the Fire Department, surrounding the urban area and access roads reflect the high influence of anthropogenic activity;
- the inclusion of changeable factors in the methodology will increase the reliability of the generated cartogram;

- the cartogram generated serves as a tool to aid the development of strategies for fighting fires in the municipality;
- the methodology is simple and shows likely to be used in other areas with the same issue.

Abstract
To aid policy development that reduces fire losses in the wildland-urban interface, we are evaluating changes to risk through time in dissimilar communities that are expanding into fire-prone areas of southern California, USA. Conventional wisdom states that escalating losses are caused, in part, by an expansion of residential development into fire-prone areas. However, various mitigation strategies such as defensible space and improved construction standards have recently been mandated for new developments in California so as to reduce the risk of these losses. Subsequently, older high-risk communities may actually become buffered from wildfires as the WUI expands and subsequently lessens their exposure to flames and embers. Thus, expanding WUI may either increase or decrease risk of residential loss dependent upon the extent of altered fire exposure and the application of mandated mitigation strategies.
To help elucidate this seeming dichotomy, we are utilizing various GIS strategies to spatially analyze changes to development and subsequent risk of structural ignitions through time in three expanding, but demographically dissimilar, residential communities in southern California. Here, we quantify temporal changes in the area exposed to fire hazards in each of the communities over a 26-year period. The amount of area exposed to wildfire increased in each of the communities. The degree and location of newly exposed development, however, differed between communities, which may influence fire risk in an impending assessment we will conduct as part of a larger research project of the area.

Keywords*: Wildland Urban Interface, Land Use, Urban Expansion, Wildfire, Risk, Urban Resiliency, San Diego County*

Introduction

Even with increasing proportions of governmental budgets allocated to fire suppression resources, wildfires annually destroy great numbers of homes and critical infrastructure in the wildland-urban interface (WUI). Indeed, since 2002 in the US, the largest fires in the histories of California, Arizona, Colorado, New Mexico, Utah, Oregon, and Texas have occurred in spite of increased fire agency staffing, equipment, and training (National Interagency Fire Center 2014). In California alone, thirteen fires over 40,500 ha in size have burned since 1990, with 7 of the 10 most destructive wildfires having occurred during this period, resulting in the loss of 53 lives and almost 12,000 structures (California Department of Forestry & Fire Protection 2013). To aid policy development that reduces these losses, we are evaluating how risk changes through time in communities that are expanding into fire-prone areas, but which vary in demographics and socioeconomic status.
The cause of increased fire losses in the WUI is related to a myriad of complex and interacting factors, the influence of each which varies by time and by place. Of especial concern, burgeoning population growth into fire-prone areas has resulted in greater exposure of residential development to wildland fire. Further, with increased population growth into the WUI, there are increased ignitions through accident or arson (Syphard *et al.* 2008).

To better facilitate sustainable communities in the WUI, managers need an accurate and detailed assessment of not only the fire hazard in a given area, but also its risk to assets of value. Many methods of WUI risk assessment involve the use of maps or spatial data (Bar Massada *et al*., 2009; Prestemon *et al*. 2002). Mapping and defining the WUI is critical for wildfire risk management because as the WUI expands, it must be monitored in order for planners to make effective policy decisions to mitigate risk (Stewart *et al.* 2007). Such maps provide powerful visual images and are commonly used as tools to direct policy, which has contributed to their increasing use in the US (Radeloff *et al*. 2005; Theobald and Romme 2007). Many studies of WUI fire risk have used Geographic Information Systems (GIS) to examine changes through time (Greenberg *et al.* 1997; Jain *et al.*, 1996; Nourbakhsh *et al.* 2006), which is an effective approach because fire risk analysis commonly employs both spatial and temporal attributes (Chuvieco *et al.* 2010). A GIS-based model is an especially effective approach for areas in which a large part of the land is being encroached upon by development (Jaiswal *et al*. 2002).

Conventional wisdom is that escalating WUI losses are caused, in part, by an expansion of residential development into fire-prone areas. However, if new construction and landscaping adheres to strict mitigation strategies, then expansion of the WUI (with higher-resistant development) may actually buffer the older, high-risk communities from exposure to flames and embers. Thus, expanding WUI may either increase or decrease risk of residential loss dependent upon the extent of adhering to mandated mitigation strategies.

To help elucidate this seeming dichotomy, we are utilizing various GIS and remote sensing strategies to spatially analyze changes to urban expansion and subsequent potential risk of structural ignitions (including differing wildfire exposure via roofing materials, defensible space, and housing density) through time in growing, fire prone communities in southern California. While these communities are geographically nearby, they are demographically dissimilar, which may influence the ability to mitigate risk. The work presented here is the first stage of a larger, multi-phase project that is investigating changes in fire risk in those communities and the overriding causative agents influencing any changes to risk.

Methods

Study Site

Three residential communities in San Diego County, California, USA were assessed including Rancho Santa Fe, Ramona, and Julian (Figure 1). All of the communities have conditions conducive to high fire hazard, including a Mediterranean climate with extended drought, regular occurrence of high-velocity foehn winds (commonly referred to as Santa Ana winds), steep terrain, and flammable vegetation, all of which have led to several high-intensity, high-loss wildfires there in the past 10 years. The three specific communities represent a range of rates of development, demographics, housing density and geographic area deemed WUI.

Figure 1. Location of study sites and map of 12-year fire history around study sites (Top Left)

Specific demographics of each of the three communities are detailed in Table 1. Rancho Santa Fe has a population of 3,100 with an average household income of over $200,000. The community has taken numerous additional measures above county and state regulations to mitigate fire hazard and lower the likelihood of structural ignitions during wildfires. Some of these measures include mandatory installation of residential fire sprinklers, fire-resistant landscaping, setbacks, and widening of roadways (District 2004). Rancho Santa Fe is regularly viewed as a leader in the US in terms of mitigating fire risks.

While geographically near Rancho Santa Fe, Ramona and Julian differ in demographics, including population size and annual household income. A recent wildfire hazard risk assessment (Botts *et al.* 2013) found that Ramona and Julian had the most residential properties at risk in San Diego County. Both communities have significantly lower mean household incomes and subsequent ability to mitigate against wildfire) than Rancho Santa Fe. Ramona is over six times larger than Rancho Santa Fe. Conversely, Julian has half the population of Rancho Santa Fe.

Table 1. Demographics of the three assessed communities.

Study Site	Population	Average Income (USD)	Average House Value (USD)	WUI type
Rancho Santa Fe	3117	$180,612	$1,139,911	Interface
Ramona	20,292	$60,033	$485,597	Interface
Julian	1,502	$65,781	$510,138	Intermix

Data Analysis

In order to determine land use changes from non-urban to urban through time, we utilized publicly available land use data from the San Diego Regional Data Warehouse (SanGIS 2014). Land use data were available for pre-1986, 1990, 1995, 2000, 2004, 2008 and 2012. The data contained many classes of land use; for the purpose of this study, each year of land use data was classified as either urban or

non-urban. Agricultural and landscaping uses (e.g., vineyards and parks) were considered non-urban. All land uses involving clearing of vegetation and/or paving (e.g., telecommunication right-of-way) were considered urban.
The years of land use were then layered chronologically to show development over time (Figure 2). To quantify the changes in land use over time, the area of the polygons were clipped to a defined study area. In order to be inclusive of all structures within the WUI, a 3.2 km buffer was created around each of the US census-designated place (CDP) boundaries of the study sites, the size of which was chosen because embers regularly travel 1.6 km (i.e., half the buffer size) or more during extreme weather conditions. Also, we included any structures that resided within the 3.2 km buffer from the CDP boundary. Given the nature of urban expansion, it is intuitive to include structures on the outskirts of current boundaries, as the developments of the future are likely to be located here. The land-use data was then clipped to each buffer zone, and the area for each polygon was calculated using GIS. Evaluation included percentage change in urban land use.

Results

Figure 2 shows the results of the land use mapping over time. Rancho Santa Fe has clustered recent development in the eastern portion of the community, which was expected because other existing communities on the western portion limit development there. As can be seen in Figure 1, wildfire events have historically approached Rancho Santa Fe from the east, which is due to the general direction of Santa Ana winds. The newer developments (purple and pink polygons) therefore have the potential to act as a buffer for the town if developed with more fire-resistant construction and landscaping is maintained.

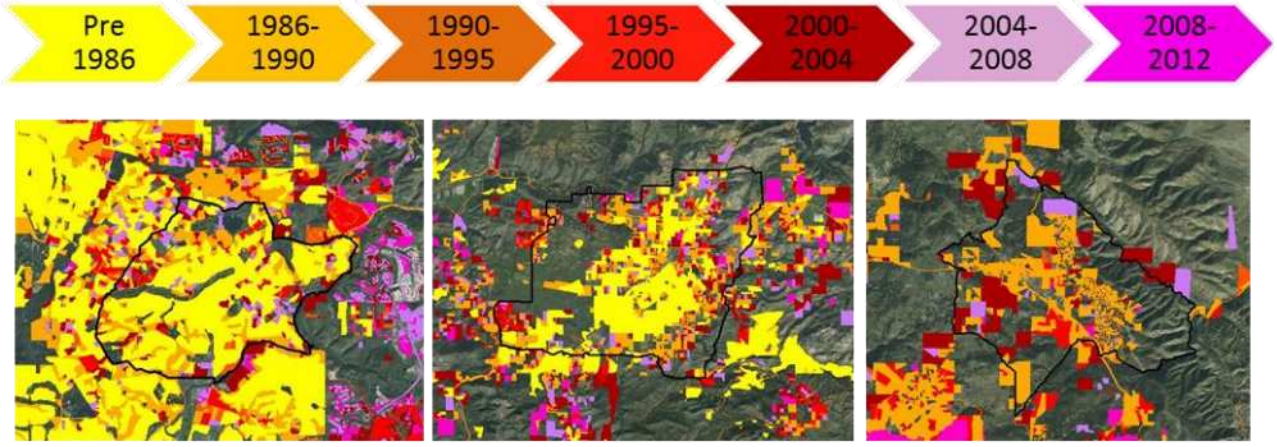

Figure 2. Change in designated land use from "non-urban" to "urban" over time in Rancho Santa Fe (A), Ramona (B), and Julian (C). Data per SanGIS (2014)

Much of the new development in Ramona has taken place on the outskirts of the town to the northeast and southwest, which might be result of the topography of the area limiting new development to those areas. The 2007 Witch Creek burned through the northeast portion of Ramona.

Land use data was not available for Julian pre-1986. The community has experienced little development in the past 8 years. Although the polygons depicting new development in Julian may appear large compared to Rancho Santa Fe and Ramona (Figure 2), many of these polygons only contain 1-3 structures within them. Julian differs from the former two communities that form a classic interface between the built and natural environments. Instead, Julian represents a classic intermix WUI community, where many structures are isolated from each other and have larger areas of vegetative

fuels between them. This is especially the case near the borders of the community. This differs greatly from Rancho Santa Fe, where there is a higher density of structures in both the new and old developments.

Figure 3 illustrates the change in urban land use over time in each of the communities. Each community demonstrated an upward trend over the 26-year period in the percentage of total lands deemed urban development. Results indicate that the majority of urban development in all three of the study sites is taking place as a result of expanding WUI (vs. residential infill into the existing communities). Rancho Santa Fe had the greatest rates of development of the three study sites.

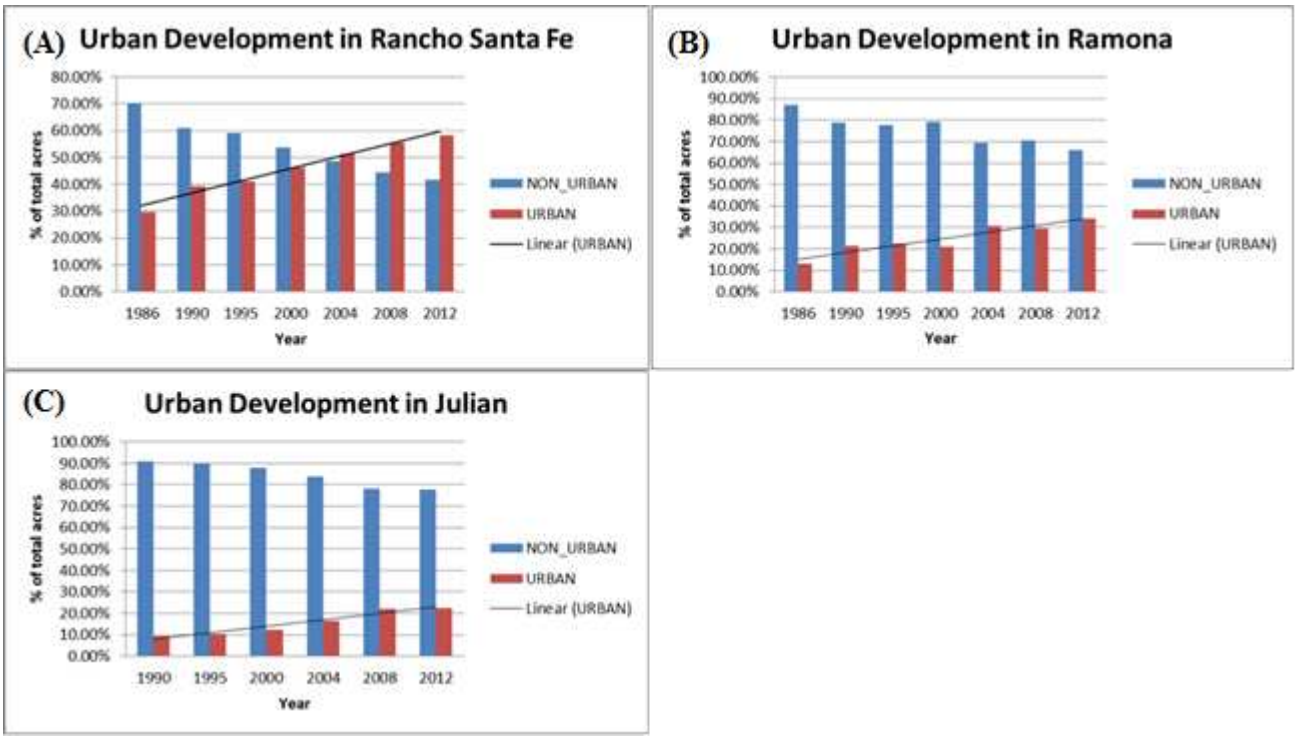

Figure 3. Proportional changes over time of urban and non-urban land uses in Rancho Santa Fe (A), Ramona (B), and Julian (C), including 3.2 km buffer outside of CDP boundaries). (SanGIS 2014)

Discussion

The results confirm that all three communities experienced expansion of the WUI over the past 26 years. Despite major wildfires in San Diego County in 2003 and 2007, which destroyed thousands of buildings, structures continue to be built in fire-prone areas, both to replace existing homes destroyed during wildfires and because of increasing populations in these communities. As previously noted, however, this new development could either exacerbate an already tenuous situation or could provide a means to reduce fire risk to older building interior to the new development, dependent on the nature and degree of fire mitigations that are employed.

Figure 4 illustrates how newer communities could potentially buffer the older communities if appropriate mitigation measures are employed in the new developments. In Rancho Santa (Figure 4A), the parcels east of the yellow line were developed 2004-2010 and could potentially provide a buffer to the structures built 1986, which are west of the yellow line. Likewise, in Julian (Figure 4B), the purple polygon contains a parcel developed in the 2004-2008 time frame (represented by the purple line) could buffer the structure built pre-1990 (the parcel of which is represented by the orange line).

(A) **(B)**

Figure 4. Examples of how new developments (with stricter construction and landscaping standards) could buffer older developments in Rancho Santa Fe (A) and in Julian (B).

Fire managers have multiple mitigation strategies to reduce the risk of fire loss in the WUI at their disposal. One mitigation activity is management of vegetative fuels. There is considerable evidence that fire intensity (and subsequent loss) is reduced when a fire advances through vegetation that has recently been treated by prescribed fire or by mechanical means (Martinson and Omi 2003, Skinner *et al*. 2004, Finney *et al*. 2005). Thus, there has been an escalating call by both land management agencies and the public to significantly modify the amount and arrangement of vegetation in wildlands near the communities so as to mitigate the potential negative impacts of high-severity fires (Dombeck *et al.* 2004; Abrams and Lowe 2005; Ostergren *et al.* 2008). Indeed, the 2001 National Fire Plan, the 2003 Healthy Forest Restoration Act, and the 2014 National Cohesive Wildland Fire Management Strategy all prioritized fuel treatments into national fire policy in the US.

That said, many argue that treating vegetation outside the area immediately surrounding a structure (commonly referred to in the US as the "Home Ignition Zone") is largely futile because of its minimal impact on the factors that impact structural ignition (Cohen 2000). Creation of a defensible space immediately surrounding a building would reduce structural ignitions via direct flame impingement or radiant heat transfer (Cohen and Butler 1998). To that end, the California Public Resources Code Section 4291 has required 9.15 m of defensible space around structures since 1991, which was increased to 30.48 m in 2006.

Even if current regulations are enforced, it must be noted that defensible space would not impact structural ignition from lofted embers, which is a more critical factor in residential losses than flame impingement or radiant heat (Cohen 2000). To mitigate potential residential losses, in 2008 California enacted building standards for new construction in areas in which the state has primary fire protection responsibility. California Code of Regulations Title 24, Part 2, Section 701.A now requires standards for some portions of dwellings that are most prone to ignition, including roofs, siding, attic ventilation, windows, decks, and others. While the new standards will likely reduce fire losses in future development, they obviously cannot impact vulnerability of existing structures.

Additionally, there has been a greater call to limit new construction into areas in which topography, such as steep slopes, naturally facilitates active fire spread (Syphard *et al.* 2008). Indeed, some areas in California now require a minimum setback of structures away from slopes so as to limit their exposure to convective heat transfer from burning vegetation. Of interest, some high-value communities (e.g., Rancho Santa Fe in this study) have taken novel approaches to meet setback regulations such as constructing enormous retaining walls (costing in excess of $400,000 USD) on the

sides of slopes in order to artificially meet the setback standards there (Mike Scott, Rancho Santa Fe Fire District, personal communication).

Unfortunately, W U I residents seem to frequently resist the very regulations that were developed to protect them and their property. For example, residents of one fire-prone area in California did not adhere to defensible space standards because of privacy concerns and a desire to be immersed in "natural" conditions (Delfino and Dicus 2007). Further, fire agencies commonly do not enforce the state-mandated defensible space regulations due to reasons such as lack of budget and personnel or unwillingness to play a perceived adversarial role with the public that they serve. Thus, adherence to sound mitigation standards varies by place and depends in part on the fiscal ability of residents to implement these strategies and the willingness of fire agencies to enforce existing regulations.

The buffer zones identified in this portion of the study, which demonstrate changes to urban expansion through time, will be used for future analysis to assess changing fire risk over time to these communities. In addition to the more traditional parameters of housing density, vegetation, and fire probability, there is a great need to develop a WUI risk assessment that more fully considers aspects of individual structure ignition (Calkin *et al*. 2014; Chuvieco *et al.* 2010; Menakis *et al*. 2003). For example, the inclusion of near-structure vegetation and defensible space in a remote sensing analysis would provide a better means of quantifying fire risk in WUI communities (Calkin *et al*. 2014; Menakis *et al.* 2003). Further, knowledge of a structure's location and arrangement relative to other structures or flammable materials is critical in effective risk analysis (Cohen, 2000; Murnane, 2006). Unfortunately, many risk analysis studies have not considered the fine-scale characteristics of vegetation immediately surrounding a home or have assumed that all structures are equally flammable (Bar Massada *et al.* 2009; Menakis *et al.* 2003; Prestemon *et al.* 2002).

Risk analysis has also traditionally emphasized the ignition and propagation potential of a wildfire, rather than it potential damages (Chuvieco *et al.* 2010). The idea of vulnerability is an important new addition to fire risk assessment models (Calkin *et al.* 2010; Chuvieco *et al.* 2012), which is a result of multiple high-loss wildfire events in the US in recent years (Calkin *et al.* 2014).

Sound risk analysis must therefore include elements of both fire hazard and the susceptibility of assets of value (Calkin *et al.* 2010). Thus, in subsequent phases of this on-going work, we will employ a WUI risk assessment protocol that more fully considers aspects of individual structural ignition as well as surrounding fire hazard and community variables such as housing density and proximity to fuels (Menakis *et al.* 2003; Chuvieco *et al.* 2010; Calkin *et al.* 2014). In order to have an accurate assessment of risk, we will consider roofing materials, vegetation proximity, structure density, eaves, windows, decking and siding materials. We will also measure compliance with defensible space legislation and general homeowner maintenance within the home ignition zone (Figure 5). All of these factors are critical in measuring structural vulnerability as defensible space may not impact structural ignition from lofted embers, which is a more critical factor in residential losses than flame impingement or radiant heat (Cohen 2000; Quarles *et al.* 2010).

Figure 5. Management of the home ignition zone must include implementation of defensible space at multiple scales, the most important of which is the 30 m immediately surrounding a structure.

Conclusions

As new buildings and infrastructure are developed into fire-prone WUI areas, measures must be taken to prevent losses from wildfire. Strategic placement of new developments to buffer vulnerable communities could provide multiple benefits the community. It is significantly more cost-efficient to build a community in a fire resistant manner at the onset than it is to retrofit an existing community. Our on-going research, of which this manuscript details the initial stages, will investigate if and how fire risk is being changed through time in these communities, which while geographically close vary significantly in community demographics and in socioeconomic status. We expect that there will be differences between the three communities in the implementation of mitigation strategies (and subsequent risk of loss) based upon the disparate abilities of residents to pay for modifications and jurisdictional differences in enforcement of the existing regulations.

To sustainably manage the WUI, stakeholders from diverse disciplines and worldviews must collaborate to reduce fire risk in a manner that is environmentally sound (Dicus and Scott 2006). Our ongoing research will provide land managers and policymakers with a means to facilitate that endeavor, creating a process that fosters meaningful dialogue between individuals and groups that sometimes have conflicting objectives. Indeed, while our research is regional in nature, it is hoped that the process that we develop will be able to be utilized by scientists, land managers, and policymakers on an international scale.

Abstract
Facilities in wildland-urban interface were main causes of forest fire ignition or protection objects from forest fire. In Korea, many facilities-for example, ancient temples and pensions-lied in wildland-urban interface and suffered from forest fire extremely. For preventing forest fire damage to these facilities, Korea national government designated the wildland-urban interface, which was located within 30m from forest.
In this study, we established some manuals which were resulted from analysis of damaged facilities records in Korea and referred other management tool-FIREWISE and FIRESMART for estimation of the forest fire danger rating around these facilities and a protection of the life and the property. The manual was consisted by two parts. One was related by environment factors (forest species, forest density, slope, a distance from forest and etc.) and another by artificial factors (a condition of road, distance from forest fire attack agency, distance from water source and etc). Theme maps were made by this factor which was graded by this manual and analyzed using ARCGis 9.3. The map was made on three districts (Kyeongjoo-Si, Uljin-Gun and Bongwha-Gun) in Keongsangbuk-Do and the resolution was 10m. In mapping and analyzing, we graded these factors and classified according to this grade rule using G.I.S tool.
In results, the forest fire danger rate in Uljin-Gun and Bonghwa-Gun was much higher than Kyungjoo-Si. Because of Coniferous forest, the forest fire danger rate in Uljin-Gun and Bonghwa-Gun was much higher than Kyungjoo-Si. And forest fire danger rates related with artificial condition in Uljin-Gun and Bonghwa-Gun much higher than that in Kyungjoo-Si.

Introduction

In Korea, many facilities-for example, ancient temples and pensions, houses, hospitals, gas stations, powerline, etc. - lied in wildland-urban interface and were exposed by high danger rate from forest fire extremely. The large forest fire in Korea, for example, East region forest fire in 2000, YangYang Forest fire in 2005 and other large forest fire, destroyed many houses and building in wildland-urban interface. Especially, Naksan temple, ancient bell and other Buddhism structure, important cultural properties, were destroyed by Yangyang forest fire in 2005. And many houses in highly urbanized area with urban forest on Pohang-Si were damaged and destroyed in 2012. So , in Korea, central and local government were interested in how to protect structures in wildland-urban interface and to lessen damages from forest fire. Therefore, for preventing possibilities of forest fire damage for these facilities, first of all, Korea national government classified the facilities in forest and wildland-urban interface and designated the wildland-urban interface zone, which was located within 30m from forest.
In U.S.A., Willam E. Mell *et al* (2010) reviewed whole method for reducing structure losses. They focused on fuel treatment, risk assessment strategies and test for fire-resistant designs and metarials. In our country, as packaged measure for forest fire would be needed, we would plan to analyze characters of damaged structures and facilities according to forest factors and others for first steps and would make forest fire danger map for risk assessment in wildland-urban interface for next step.
In many countries, many mapping method for forest fire danger map in wildland-urban interface were developed. In Spain, Roul R. Calcerrada *et al* (2008) focused on socio-economic factors and analyzed

the ignition risk characteristics in Mediterranean regions. In U.S., Robert E. Keans *et al* (2008) made fire hazard and fire risk using FIREHARM. FIRE HARM calculate risks of forest fire from fuel moisture and other fire variables. James K. Lein and Nicole I. Stump (2009) assessed wildfire potentials in wildland-urban interface using GIS based models. The vegetation, a intensity of solar radiation, topographic wetness, population densities and near roadway were using for models from forest fire records

In this study, we analyzed damaged facilities records in wildland-urabn interface in Korea and referred to other management tool for facilities in wildland-urban interface-FIREWISE and FIRESMART. Using these results, we established a manual for estimation of the forest fire danger rating of facilities in wildland-urban interface. This manual must be needed for a protection of the life and the property

Methods

The manual was consisted by two parts. One was related by environment factors (forest species, forest density, slope, a distance from forest and etc.) and another by artificial factors (a condition of road, distance from forest fire attack agency, distance from water source and etc).

The survey of environment and natural and artificial factors

Field surveys from forest fire records about damaged structure were carried out in Korea from 2010 to 2012. The main damaged structures were house and storage. Especially in Korea, many farmers houses were located in mountainous topology and near to forest. So, we focused on which natural and artificial factor make to ignite structure. For proving these questions, we analyzed the relationship with facility damages and road condition, vegetation, topographical condition, factors for forest fire attack and other relation factors. These factors which were surveyed factors for estimating forest danger rating were referred to FIREWISE in U.S. and other country mapping results. After surveying, we analyzed the relationship and selecting the factor having high relationships.

The selection of environment and artificial factor

After analyzing whole data about damaged facilities and their natural and artificial environment, we selected a few factor for damaging facilities from forest fire. These were main facfor - the number, width, degree and condition of road to access, road sign, space for attack engine, main species of forests, tree height of trees, D.B.H. of forests, tree density of forests, a fuel condition of shrub, a condition of ladder fuel, a fuel condition of surface, a condition of crown, a distance from forest, a gradient of neighboring ground, a existence of water in near and the distance from forest fire attack facilities.

After selecting factors, we found a relationship with damage rating of facilities per factor. And we designated a weight between factors which was referred to NIST reports about estimating house danger rating from forest in wildland-urban interface.

Using these factors, we made theme maps from D.E.M. and digital forest floor map from K.F.R.I.. We used ARCGis 9.3 for making theme maps. And we wrapped these theme maps using ARCGis 9.3 for making a forest fire danger rating map for facilities in wildland-urban interface.

Results

In results, the forest fire danger rate in Uljin-Gun and Bonghwa-Gun was much higher than Kyungjoo-Si. Because of Coniferous forest, the forest fire danger rate in Uljin-Gun and Bonghwa-Gun was much higher than Kyungjoo-Si. The forest fire danger rate according to the distance from forest in Uljin-Gun and Bonghwa-Gun was much higher than Kyungjoo-Si. Absolutely safety area (distance was above 300m from forest) was 78.6% in Kyungjoo-Si, 52.5% in Uljin-Gun and 48.6% in Bonghwa-Gun. The danger area according to slope was 15.5% in Kyungjoo-Si, 42.1% in Uljin-Gun and 53.7%

in Bonghwa-Gun. And forest fire danger rates related with artificial condition in Uljin-Gun and Bonghwa-Gun much higher than that in Kyungjoo-Si.

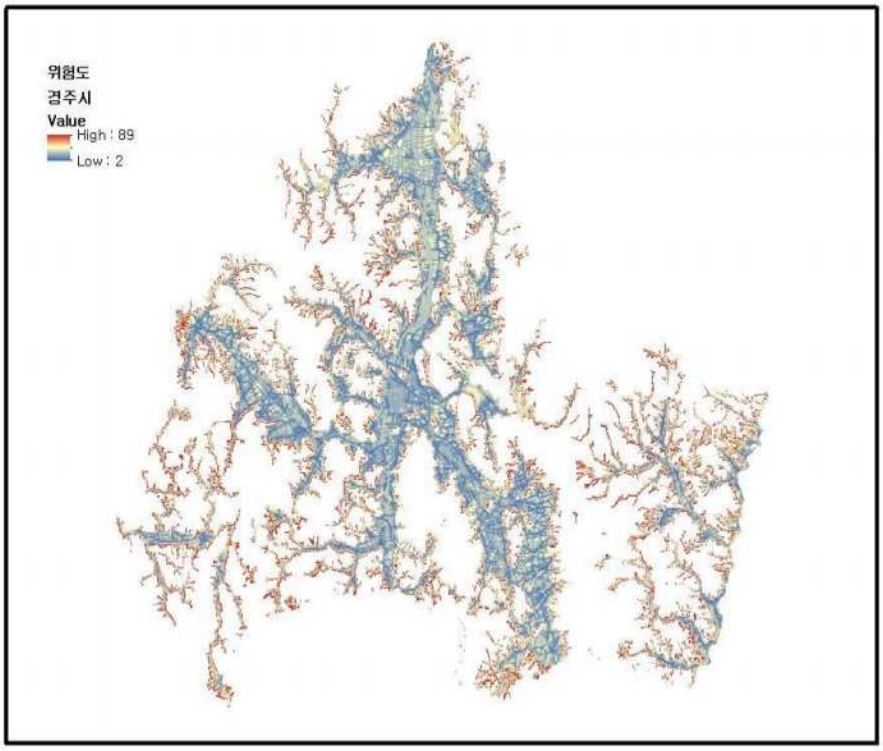

Figure 1. The results of danger rating for forest fire in Wildland-urban interface in Kyeongjoo-SI

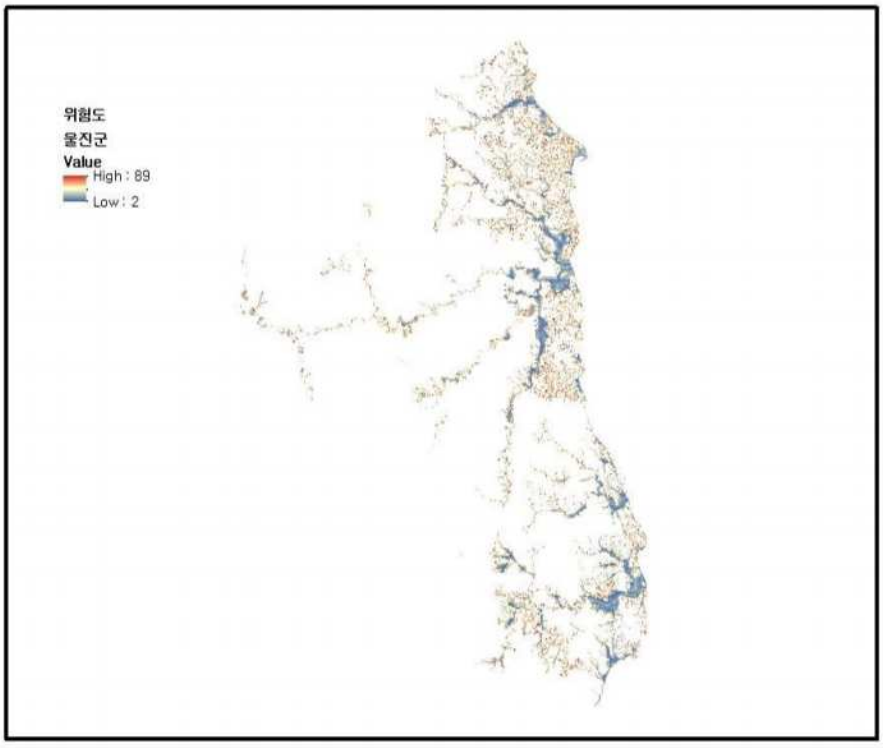

Figure 2. The results of danger rating for forest fire in Wildland-urban interface in Uljin-Kun

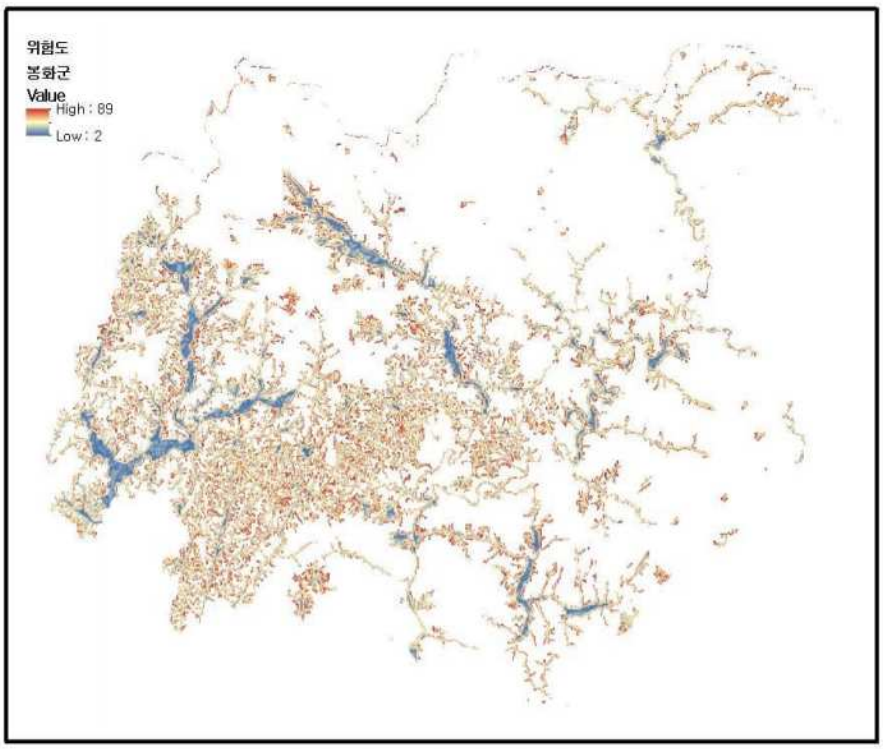

Figure 3. The results of danger rating for forest fire in Wildland-urban interface in Bonghwa-Kun

In results, the proportion of forest danger had a difference between three regions in 5% significant level. For verifying this algorithm, we applied this algorithm to facilities in other region. We tested 11 damaged facilities in wildland-urban interface on Seomi-Ri and Jungmyeong-Ri in Kyeongsangbuk-Do. These facilities damaged from forest fire which occurred in 2011. The mean in a radius of 30m of damaged facilities was 46.98 in 89 scales. the maximum was 70.61. That is over 'danger rate(37/89)' which was referred to home ignition manuals of 'FIREWise'

Using these algorithms, we calculated and estimated the danger rating of main facilities in three regions. In results, Bongwha-Kun was most danger region. An average Danger rating was 44/89. The danger rating according to facilities categories was analyzed. In results, cultural assets were most danger facility category(39.3/89).

The forest management like a fuel management or deploying of forest fire attack resources would be needed for this region and cultural assetsext…

Abstract
The Wildland Fire Decision Support System (WFDSS) was unveiled to the United States (U.S.) fire community in 2009 to facilitate a flexible, agile and scalable risk-informed decision-making process on complex wildland fires. Composed of a collection of spatial and non-spatial data, economic, fire behaviour, smoke, and weather tools, the WFDSS was designed to guide a decision-maker through a deliberative and thoughtful decision. After five years of operational use on federal wildland fires, user trends suggest greater involvement with the decision-making process and an increase in the number of documented decisions made on wildland fires. Despite these trends, increased wildland fire costs and continued fire-fighter fatalities each year reinforces the need to improve fire management decision-making to achieve better performance. After reviewing the intent, implementation, components and usage statistics of the WFDSS, we discuss the strengths, weaknesses, and further opportunities to support the U.S. fire management community with making risk informed decisions. International audiences who are developing similar wildland fire decision-making systems may find value in evaluating the strengths, opportunities, and lessons learned from a national decision support system like the WFDSS.

Keywords*: fire management, United States, risk, decision-making, Wildland Fire Management Research Development and Application (WFMRDA)*

Introduction

The Wildland Fire Decision Support System (WFDSS - Noonan-Wright et.al 2011) was officially unveiled to the U.S. fire community in 2009 to facilitate continued implementation of the 1995 U.S. federal fire policy which acknowledged fire as a critical process that will be planned for in land and resource management planning documents (USDI-USDA 2001, 2009). The revised implementation of this policy in 2009 specified "a new wildfire analysis and decision process, the Wildland Fire Decision Support System (WFDSS), to improve decision documentation, risk assessment, decision support, and operational implementation" (NWCG 2009). The integration of the best available science and tools in the WFDSS was intended to increase decision makers' ability to acquire and synthesize information in order to more make timely and applicable risk informed decisions on wildland fires (Zimmerman 2011).

Two decision processes had been in place for federal agency administrators and fire managers to use in making decisions on wildfires. One very simple process, the Wildland Fire Situation Analysis (WFSA) was used for fires necessitating an aggressive suppression response. The WFSA was a PC-based desktop application with decision tree analysis using expert opinions. Another more complicated process, the Wildland Fire Implementation Plan (WFIP) was required for fires that were deemed to be beneficial to natural and cultural resources and might be allowed to achieve land management plan objectives. After several severe wildfire years affecting almost all portions of the United States, federal agency administrators and fire managers from U.S. land management agencies [including the United States Department of Agriculture, National Forest System (USDA FS); the United States Department

of Interior Bureau of Land Management (USDOI BLM); National Park Service (USDOI – NPS); Bureau of Indian Affairs (USDOI – BIA); and the Fish and Wildlife Service (USDOI – FWS)], agreed that a single process for all wildland fires would be more effective. It was further agreed that the single process would be a deliberative, risk-based process which would provide decision support and also serve as an archive of decisions for organizational learning. Initial research and development of the conceptual design of the WFDSS began in 2005 and was tested during the 2007 and 2008 fire seasons through a new web based fire behaviour model, Fire Spread Probability (FSPro). A decision framework process was quickly added to assist fire and land managers with rapidly evaluating the emerging fire situation and producing a quality strategic decision. The WFDSS was being utilized by all 5 of the largest federal land management agencies in the U.S. by 2010. The primary users of the WFDSS have been Agency Administrators, who have the ultimate responsibility and approval authority for how wildland fire is managed on their home unit. Though the focus of the WFDSS is on strategic decision-making, over time, it has incorporated more tools and data that additionally assist incident command teams and other firefighting resources with gaining situational awareness and developing short-term tactics from the broader strategic direction. Emerging science and technologies are continually integrated, such as the Near-Term and Short-Term fire behaviour models, to further support risk informed decisions that are integral to the WFDSS (Zimmerman 2011).
Despite increased use of a deliberative, risk-based decision process, even the partial costs for suppressing federal fires often exceeds 1 billion dollars a year (Calkin *et al*. 2005, NIFC 2013). The U.S. Forest Service continues to experience annual wildfire costs of approximately 3 billion dollars a year, when both preparedness and suppression costs are included in the estimate (Lichtenstein, 2014). Costs incurred by other federal, state, and local governments push the total costs of wildland fire in the United States far higher. In addition, there are episodic tragedies of loss of firefighter and civilian lives. Consequently, there is a compelling need to enhance the WFDSS as well as improve user understanding and use of this application.

Risk Assessment Process in the WFDSS

The WFDSS is a system for wildfire decision support and analysis based on a deliberative decision process (Figure 1). A risk informed decision process in the WFDSS begins with gathering, analysing and synthesizing new and existing information. Land managers are, by definition, geographically oriented decision makers; therefore, much of the WFDSS information is displayed as spatial data over a variety of different map base layers. The location of the fire start, its size, and the responsible agency is populated and available to a decision maker. Maps with reference data layers showing highly valued resources and assets are evaluated with hazard and fire potential to develop a preliminary risk assessment. Management Requirements and Strategic Objectives from land management planning documents are automatically displayed for the fire area. Users develop incident specific requirement and objectives tiered to the Strategic Objectives, informed by the Management Requirements and tailored to the specific spatial and temporal attributes of the fire. A course of action defining operational actions to meet incident specific objectives is drafted, reviewed, and validated. Collectively, the Agency Administrator, local staff and fire specialists develop a decision, which the Agency Administrator has the option of approving or rejecting. If it is approved, the Agency Administrators document the decision with the rationale behind it and provide it to the incident management team that has been assigned to the fire. After approval, a periodic assessment allows a decision maker to revisit their decision and evaluate its relevance to the current fire situation. All parts of a decision require iterative steps to re-evaluate when conditions change and new information is provided. All components of a risk-informed are available in the WFDSS.

Figure 1. There are seven linear steps to develop and document a wildland fire decision in the WFDSS.

Five Years of Operational Use

After 5 years of implementation, the need to review how the WFDSS is supporting the field to facilitate and document decisions is necessary. Given the capacity of the WFDSS to store analyses and other components of a risk-informed decision, the ability to query the database has enabled retrospective evaluation of the system, which, in part, is described below.

General User Statistics

User statistics in the WFDSS were summarized to evaluate the over-all use and application of the system. Data were normalized by the total number of federal fires per year and scaled by 1000 in order to compare yearly trends (NWCG 2013).

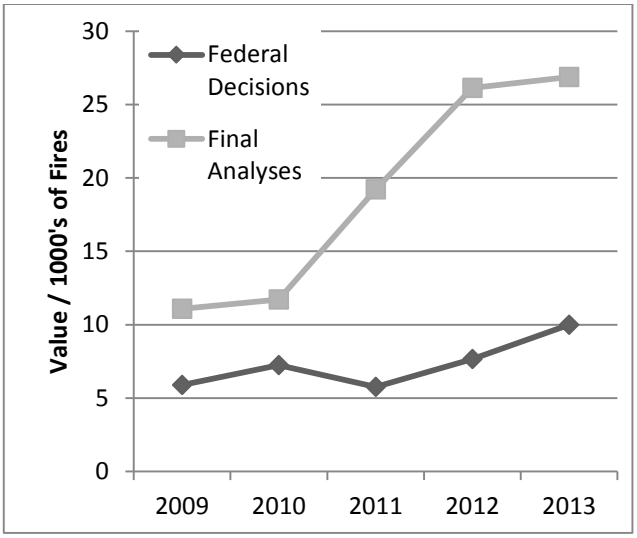

Figure 2. Analyses and Decisions in the WFDSS

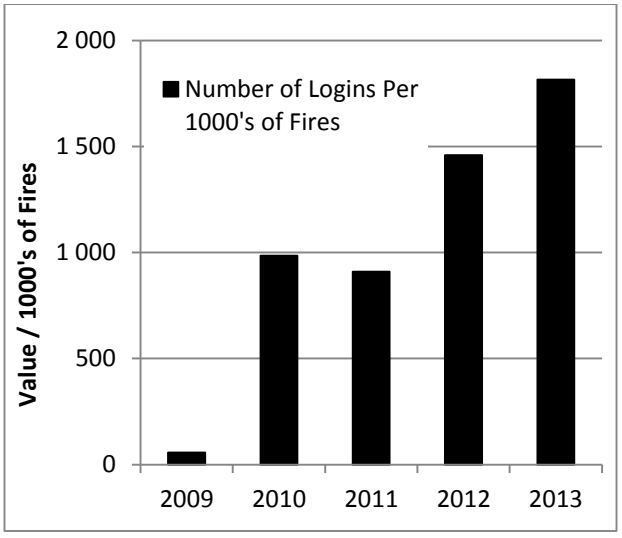

Figure 3. WFDSS Use Since 2009

In Figure 2, it is not surprising that there are more analyses than decisions because multiple analyses would provide part of the information to develop a decision. “Final analyses” are defined as all fire behaviour modelling analyses (Basic, STFB, NTFB, and FSPro) used on wildland fires and formally published in the WFDSS by the fire behaviour specialist. “Federal Decisions” are published documents excluding local, county and state fires that follow a risk assessment process in the WFDSS to document how a wildland fire will be managed. Trends suggest that fire modelling use has been increasing over time with the greatest increase between 2010 and 2012, possibly reflecting the expanded utilization of fire behaviour specialists to support short-term tactics and long-term strategy on wildland fires. There has been a moderate increase in the number of decisions since 2011. The dip in the number of federal decisions in 2011, however, does not correspond with a fewer number of federal fires. In fact, 2011 had more fires than any other year since 2009. Figure 3 shows the number of logins into the WFDSS since 2009 normalized by the total number of federal fires. For example, in 2013, on average, for every thousand federal wildland fires in the U.S. there were 1,800

logins into the WFDSS (or 1.8 logins per fire), which was a slight increase compared to previous years and suggests greater involvement in the decision support tools in the WFDSS.

3.2. Fire Behaviour Analysis to Support Decision-making

Enabling users to gain access to national geo-spatial data layers such as surface and canopy fuels and topography (Rollins 2006) resulted in increased use of fire behaviour modelling systems dependent upon these data sources. The WFDSS contains four primary fire behaviour modelling systems: Basic, Short-term (STFB), Near-term (NTFB) and the Fire Spread Probability (FSPro) Simulator for longer term analyses.

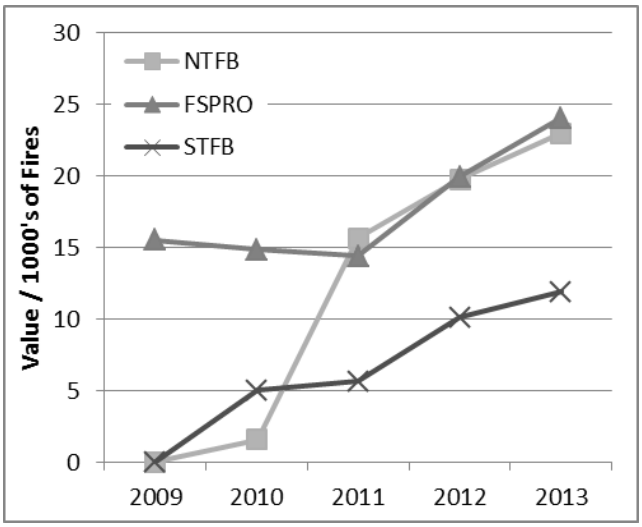

Figure 4. Usage statistics per every thousand federal fires for fire behaviour modeling systems, such as Near-term Fire Behaviour (NTFB), Fire Spread Probability (FSPro) Simulator, and Short-term Fire Behaviour (STFB) in the WFDSS from 2009 to 2013.

The first fire behaviour modelling system in the WFDSS, FSPro, was initially tested in 2007 to support long-term fire behaviour projections. As hardware and software capacity increased, STFB and NTFB modeling systems were added to support short (1-3 days) to mid term (1-7 days) spatial analyses. Usage of FSPro was initially greater than other modeling systems, but an increase in NTFB usage from 2010 to 2011 resulted in almost equal usage to FSPro by 2011. Small fires that were suppressed in the first 24 hours would likely not use fire behaviour modelling systems to gain situational awareness; however, by 2013 for every 1000 fires, there were approximately 11 short-term and over 20 mid to long term fire behaviour analyses simulated for all federal fires. Since 2011, usage for all fire behaviour modelling systems has increased, in addition to the number of federal decisions and logins, suggesting greater usage of the system over time (Figure 4).

Opportunities and Challenges of Risk Informed Decision-making

4.1. Social Science and Fire Management

Developing tools and processes to facilitate smart information sharing, communication, and decision-making was an objective of the WFDSS and continues to be a main challenge for wildland fire management (Zimmerman 2011). Identifying and understanding the institutional practices of the people who will use a process or collection of tools is crucial for implementing a decision support process like the WFDSS. Early adopters within the user community were recruited to assist with training others on the WFDSS and this contributed greatly to its acceptance as a process and a useful tool for fire management. Regional leaders, called Geographic Area Editors, were given authority for managing their user community by assigning user roles and access to the WFDSS based on skill level and need. They were relied upon to provide direction and training on how the WFDSS was

implemented in their region. This collaborative relationship with the user community gave users a sense of ownership and created a feedback loop between them and the developers so that changes and enhancements could be made in a responsive and agile fashion.

The use of the WFDSS to make risk-informed decisions continues to evolve for numerous reasons. The decision makers and their support personnel, including the host unit and incident management team, may vary in their understanding and application of decision science and risk management. This can result in failing to utilize the WFDSS to its full potential by not adequately considering all of the alternatives in developing a course of action or, simply, by using the system to document decisions that were made external to the process

There can be a tendency to reject low probability, large fire growth events when drafting a planning area; a user defined spatial extent that incorporates all of the land the fire may burn during the period that the decision is relevant. Since 2010, 16% of incidents with a decision had two or more planning areas, suggesting that some decision makers draw too small a planning area to manage their fire incident and eventually need to redraw a bigger area as the fire encroaches upon the planning area boundary (Figure 5). When these events occur, decision makers are often forced to rapidly respond to emergency situations and can neglect the careful and deliberative process utilized by the WFDSS. Using a fire behaviour modelling tool such as FSPro could help delineate a planning area that would serve the entire length of the decision. This example illustrates that the process to apply the various tools and information to optimize risk-informed decision-making is still evolving.

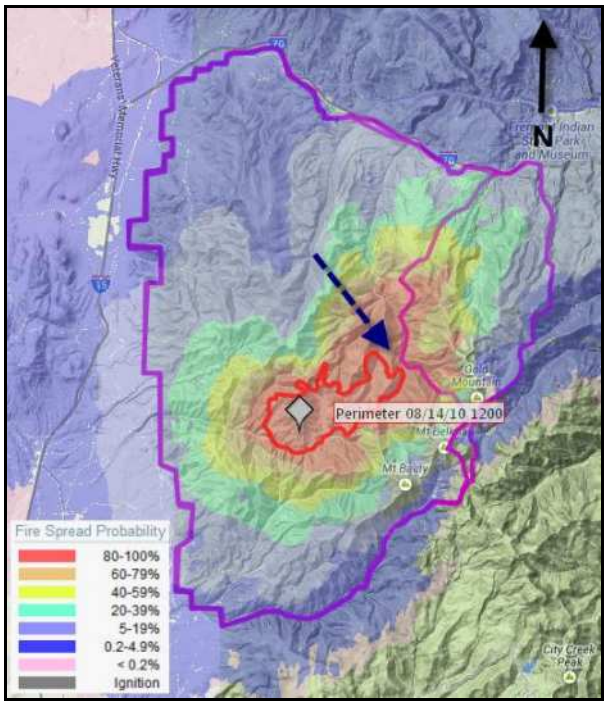

Figure 5. The 8/14 fire perimeter (red line) encroached with 0.2 miles of the first of two planning areas (purple lines) on the east side: the first drawn on 8/14 and the second 8/18 – see black arrow. FSPro is displayed in the background and can be helpful to evaluate fire potential (and the probability) that certain areas will be impacted by the fire over a designated time period, in addition to delineating where the planning area could be located.

4.2. User-friendly, Best Available Science

A current effort amongst land management agencies is to take historically text and paper based fire planning documents (referred to as the land and resource management plans and fire management plans) and convert them into digital and spatially explicit formats. As an alternative to providing lengthy text describing where and how a fire will be managed on the landscape, a location can now be

drawn on a map, and only the pertinent objectives and requirements will be presented for evaluation. Spatial Fire Planning (SFP) is an optional planning process available in the WFDSS that can spatially describe how fire will be managed according to planning documents. The visual depiction of these data allow for greater data control because data managers can upload, manage, and associate spatial polygons, lines or points to represent the planning direction, and make changes as needed throughout the year. The WFDSS initially provided lengthy planning documents in electronic text-based format and made them available to decision makers when they were developing their strategy. While a notable first step, spatial fire planning is the evolution of a process to make information from planning documents more easily consumable during the formulation of wildland fire management strategy and decisions.

Emphasis on pre-fire planning is facilitated by recent advances in quantitative risk assessment (Finney 2005, Calkin *et al*. 2010, Ager *et al*. 2011, Scott *et al*. 2012,) where values on the landscape that are most important are identified and evaluated for their hazard and susceptibility for experiencing harm or benefit from wildland fire. The integration of spatial fire planning and quantitative risk assessment, could result in less exposure to wildland fire fighters, and optimize the strategic wildfire response, i.e. resources are allocated where the probability of containment is highest and values are likely to interact with fire in a negative manner.

4.3. Information Sharing Via the Risk and Complexity Analysis

Gathering and communicating timely information on an emerging wildland fire is challenging for an incident commander. The process to determine wildland fire complexity and what level of an incident management organization is needed on a wildland fire was recently merged into one process called a Risk and Complexity Analysis (NWCG 2013). Historically, a separate risk assessment was done by an incident commander (in the field) and a land manager (in the WFDSS). With this change, intelligence gained in the field can be more readily shared with remotely located Agency Administrators who are ultimately responsible for making wildland fire decisions.

The Risk and Complexity Analysis provides users with the ability to make notes and document mitigations for elements identified as moderate or high complexity on wildland fires. Users evaluate components of risk including values (infrastructure, natural and cultural concerns; the proximity and threat of the fire to values; and social and economic concerns), hazard (fuel conditions and fire behaviour) and probability (the likelihood of a long duration event; barriers to fire spread; and the seasonal severity). The Risk and Complexity Analysis is designed to be completed on paper, and the information easily transferred into the WFDSS. Reinforcing a similar risk assessment process across all vested parties is central to the ideology of the WFDSS.

Conclusion

There are number of decision support systems (DSS) for fire management available internationally (Martell 2011, Mavsar 2013) both for management of fire ignitions and fuels planning. Implemented operationally on a national-scale in 2009, the WFDSS may be considered unique because of its application to a range of different ecosystem types and agencies across the United States. After five years of use, the WFDSS showed a general increase of system application to wildland fires and fire behaviour modelling tools. Challenges remain regarding the optimization of the system to evaluate all facets of ecosystem management, mitigate fire fighter exposure, and utilize fire-fighting resources to manage fire where values are most likely to have a negative impact from wildland fire. As new research methods and products are created, the WFDSS is designed to support and implement new practices to address many of these challenges. Research focused on fire management and decision science (Maguire *et al*. 2005, Thompson *et al*. 2013) is especially relevant. Continued investment in technology transfer to the decision makers and support staff is necessary for continued use and elevated application of the WFDSS as wildland fires become larger (Dennison 2014).

Acknowledgements

Funding for the WFDSS was provided primarily by the USDA Forest Service Fire and Aviation Management, State and Private Forestry, and the Department of Interior Office of Wildland Fire Coordination. Contributing staff and associated work accomplishments by the Department of Interior Bureau of Indian Affairs, National Park Service, and Office of Wildland Fire Coordination also contributed to the implementation of the WFDSS.

The flammability of ornamental species with potential for use in highways and wildland urban interface (WUI) in southern Brazil

Daniela Biondi, Antonio Carlos Batista, Angeline Martini

[a] *Universidade Federal do Paraná, Av. Lothário Meisnner, 900 Curitiba-Brasil, dbiondi@ufpr.br, batistaufpr@ufpr.br, martini.angeline@gmail.com*

Abstract

The areas of wildland urban interface (WUI) are sites that have mixed characteristics, from the influence of rural and urban areas. With the increase in urban population in national and global level, the areas are losing this characteristic transition with diversity of functions. One of the most common problems due to this rural/urban proximity are forest fires that cause damage to many homes in urban areas. The highway is a transportation infrastructure located in the area of the wildland urban interface that can serve as a barrier or mitigation of forest fires that threaten urban areas, through its landscaping. For the highway integrate with the local landscape is necessary that this landscaping provide conservation or ecological, cultural and aesthetic function. The objective of this study was to evaluate the flammability of native ornamental species with potential for use in the prevention of forest fires in the vicinity of highways. The selected species are native from southern Brazil due the presence of interesting aesthetic features. They are: *Aspilia montevidensis* (Spreng.) Kuntze - the family Asteraceae species with ornamental potential both by the beauty of the flowers of bright yellow color, like the long flowering period that occurs almost all year round and can be used in landscaping as ground cover, is indicated for public areas by not requiring maintenance and also for treatment of degraded areas; *Peltodon rugosus* Tolm. - herbaceous species of the family Lamiaceae, native to southern Brazil, on "Estepe Gramíneo-lenhosa" presents both its ornamental inflorescence globose form and by its leaves with visible vein, can be used in degraded areas due to its hardiness; and *Verbena rigida* Spreng - the Verbenaceae family, is a little branched herbaceous perennial, rhizomatous, erect, popularly known as "grass-wire", native of the fields of the plateau in southern Brazil, can reach 20-30 cm in height with decorative flowering, stiff and rough leaves, inflorescences with small flowers blue-purple color formed in spring-summer. For each species were performed 50 burnings in epiradiator of 1 g of material freshly harvested. During the experiments burning in the epiradiator, the following variables were collected: Frequency of ignition (FI), time to ignition (TI), duration of combustion (DC), flame height (AC) and combustion index (IC). Statistical analysis was done by SNK test at 95 % probability. The results of the species flammability show that *Aspilia montevidensis* and *Peltodon rugosus* differ statistically of the *Verbena rigida* for FI and TI, indicating to be less flammable, although all species show low flammability. Given the results, it is concluded that the analyzed species exhibit excellent characteristics for landscape composition on highways both due its aesthetic appearance and functional, and can also serve as a barrier against forest fires in areas of wildland urban interface in southern Brazil.

Keywords*: in forest fuels, epiradiator, native ornamental species.*

Introduction

The Wildland Urban Interface areas, otherwise known as WUI, are places that have mixed features, with influence of rural and urban areas (BIONDI, 2013). Are multifunctional spaces where there are fragmented presence of land use and the absence of urban structure, with deep economic, social and physical transformations and that still feature a dynamic closely linked to the presence of a nucleus around (MIRANDA, 2009).

Radeloff *et al*. (2005) complements the concept of WUI stating that this area is a zone of conflict between humans and the environment, where there is destruction of houses by forest fires, fragmentation of natural habitats, introduction of exotic species and the loss of biodiversity.

According to Biondi (2013), with the increase of urban population, these areas are losing that characteristic of transition and acquiring a rural or urban physiognomy, moreover, to be removed shall

become the boundary between urban and rural zone. With that, one of the most common problems that occur are the forest fires that eventually reach the homes of the urban areas. Thus, since the highway is a transportation infrastructure in urban and rural transition area, could serve as a barrier and mitigation or forest fires that threaten urban areas

The assessment of forest fires risk on the landscape planning of roads should be an essential element to reduce the damage caused by the fire in the wildland urban interface areas of Paraná-Brazil (BIONDI *et al*., 2013). According to the same authors, from the characterization of the degree of risk of fire it is possible to perform the selection and planning of less flammable species composition in order to impede the spread of fire.

The knowledge of how the species differ in their flammability characteristics it is necessary to develop more reliable lists of plants recommended for residential landscaping in wildland - urban interface (WHITE and ZIPPERER, 2010).

According Ganteaume *et al*. (2013) currently, there is no research on the evaluation of flammability of ornamental species.

Flammability can be defined as how easy it is for a material to catch fire, both spontaneously and through exposure to certain conditions (ZHANG *et al*., 2011). According to Anderson (1970) flammability initially was defined based on three components: the potential of ignition, which is the time needed for the fuel reaches the ignition after being exposed to a source of heat; sustainability, refers to the ability to maintain combustion after ignition; and combustibility, which is the rate of burn after ignition.

The plant species that provide the fuel for the fires have specific flammabilities (CURT *et al*, 2011), which varies according to the species and with moisture content (VÉLEZ, 2000). In addition, the volatile organic compounds, such as monoterpenes, constitute other possible factors contributing to the increased flammability vegetation (ALESSIO *et al*., 2008).

The aim of this study was to evaluate the flammability of native ornamental species with potential for use in the prevention of forest fires in the surrounding highways.

Methods

The experiment was conducted in the laboratory of forest fires at the Campus III of the "Universidade Federal Paraná" (UFPR), in Curitiba, Brazil. The original vegetation of the city, before the anthropic action, consisted of "Estepe Gramíneo-Lenhosa" (fields), intermingled of arboreal groupings (with the presence of *Araucaria angustifolia*), next the downloaded and streams (RODERJAN *et al*., 2002)

The climate of Curitiba, according to Köppen classification, is Cfb, humid subtropical, humid, without dry season, with cool summers and winters with frequent frosts and occasional snow precipitation. Has average temperatures of 19.7° C in summer and 13.4° C in winter, with average annual precipitation of 1419.9 mm (IPPUC, 2011).

The species selected for the experiment are native from southern Brazil, on the "Estepe Gramíneo-Lenhosa", and present interesting aesthetic characteristics for use in landscaping. They are: *Aspilia montevidensis* (Spreng.) Kuntze, *Peltodon rugosus* Tolm and *Verbena rígida* Spreng.

Aspilia montevidensis is a species of the Asteraceae family that boasts great potential both for ornamental beauty of flowers of bright yellow color, as for the long flowering period that occurs almost the whole year. In landscaping, can be used as lining plant in flower beds to homogeneous full sun, being indicated for public areas and also in degraded areas, not requiring great care in maintenance.

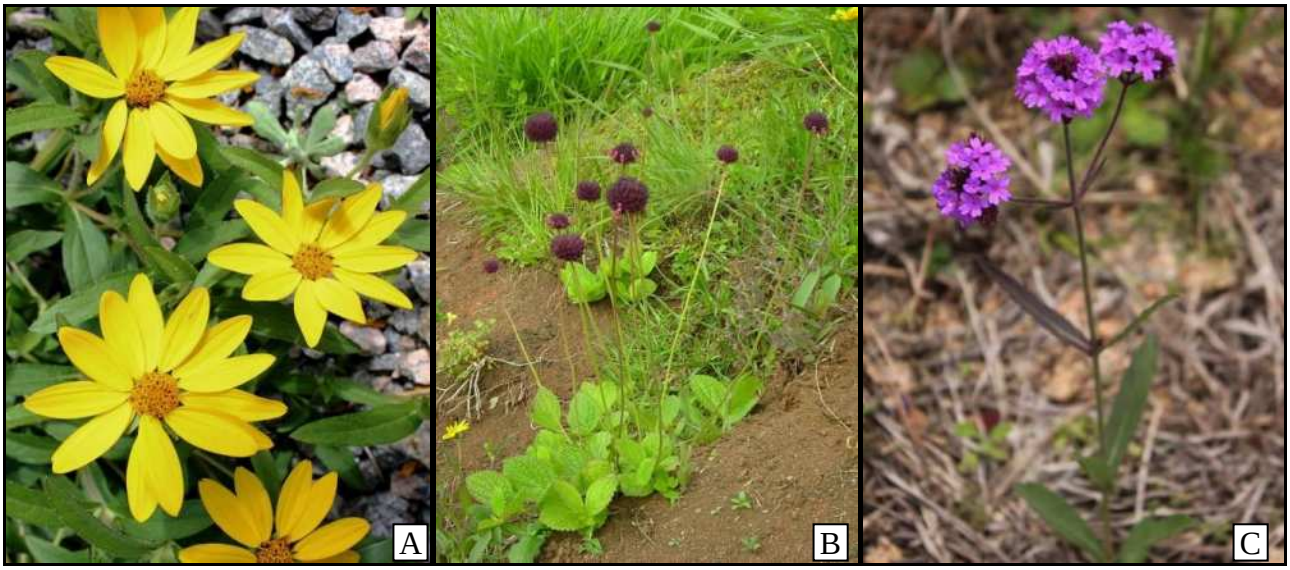

Figure 1. The selected species: A) Aspilia montevidensis; B) Peltodon rugosus, C) Verbena rigida

Peltodon rugosus, of the family Lamiaceae, is a herbaceous plant which features ornamental potential both for its inflorescence shape globe, as by their apparent ribbed leaves. Due to its hardiness can be used in recovery of degraded areas.

Verbena rigida, family Verbenaceae, is a little branched herbaceous perennial, rhizomatous, erect, popularly known as wire weed. Can reach of 20 to 30 cm tall, with decorative flourish, stiff and rough leaves, inflorescences with small flowers-blue color formed in spring-summer.

The concept of flammability can be reduced to distinct aspects of combustion, according to the type of metric used in its assessment (WHITE and ZIPPERER, 2010). Thus, it can be experimentally evaluated by fuel burning in the laboratory, whether in the form of discrete elements (such as a leaf or branch), or as a fuel bed and a heterogeneous set of individual units (FERNANDES and CRUZ, 2012). In this research the flammability was analyzed from the combustion experiments, performed in a chapel (a draught-free location), with an epiradiator of 500 W nominal power constant, kept in a controlled temperature range of 250 °C. The material used in the experiment consists only of leaves of selected species, which were collected in the vicinity of the building of Forestry and Wood of the UFPR, moments before the beginning of the experiment, which was carried out within a maximum of 2 hours after collecting.

Flammability tests were conducted according to the methodology proposed by Petriccione *et al*. (2006) and Petriccione (2006). For each species were performed 50 repetitions, each with 1 g of green fuel material, determined with the aid of a precision balance. The forests fuel was exposed to epiradiator for 60 seconds. In all the steps performed were taken the care required to be no direct contact with the material, so as to avoid interference in their properties.

During the experiment, conducted in the epiradiator, were collected the following variables: ignition frequency (FI), ignition time (TI), duration of combustion (DC) and height of the flame (AC). Flammability values were obtained from the potential of ignition (PI) and the average combustion time (TC) based on table 1 (VALETTE, 1990). This index is calculated based on the values of frequency ignition (FI), which refers to the number of positive ignitions (less than 60 seconds) of a total of 50 repetitions and the combustion time (time that the flame remains visible). Statistical analysis of the data was made by SNK test the 95% probability.

Table 1. Flammability Values (Valette, 1990)

PI TC - s	< 25	25-38	39-48	42-44	45-47	**48-50**
>32,5	0	0	0	1	1	2
27,5 – 32,5	0	0	1	1	2	2
22,5 – 27,5	0	0	1	2	2	2
17,5 – 22,5	1	1	2	2	3	3
12,5 - 17,5	1	1	2	3	3	4
< 12,5	1	2	3	3	4	5

Note:
PI – potential of ignition (positive number of ignitions a total of 50 trials); TC – combustion time in seconds.
0 = very low flammability; 1 = low flammability; 2 = flammable; 3 = moderately flammable; 4 = very flammable; 5 = extremely flammable.

Results

The variables of flammability were analyzed separately, which has shown the difference in behavior between the species studied. The ignition timing in each repetition performed for the species can be observed in Figure 2.

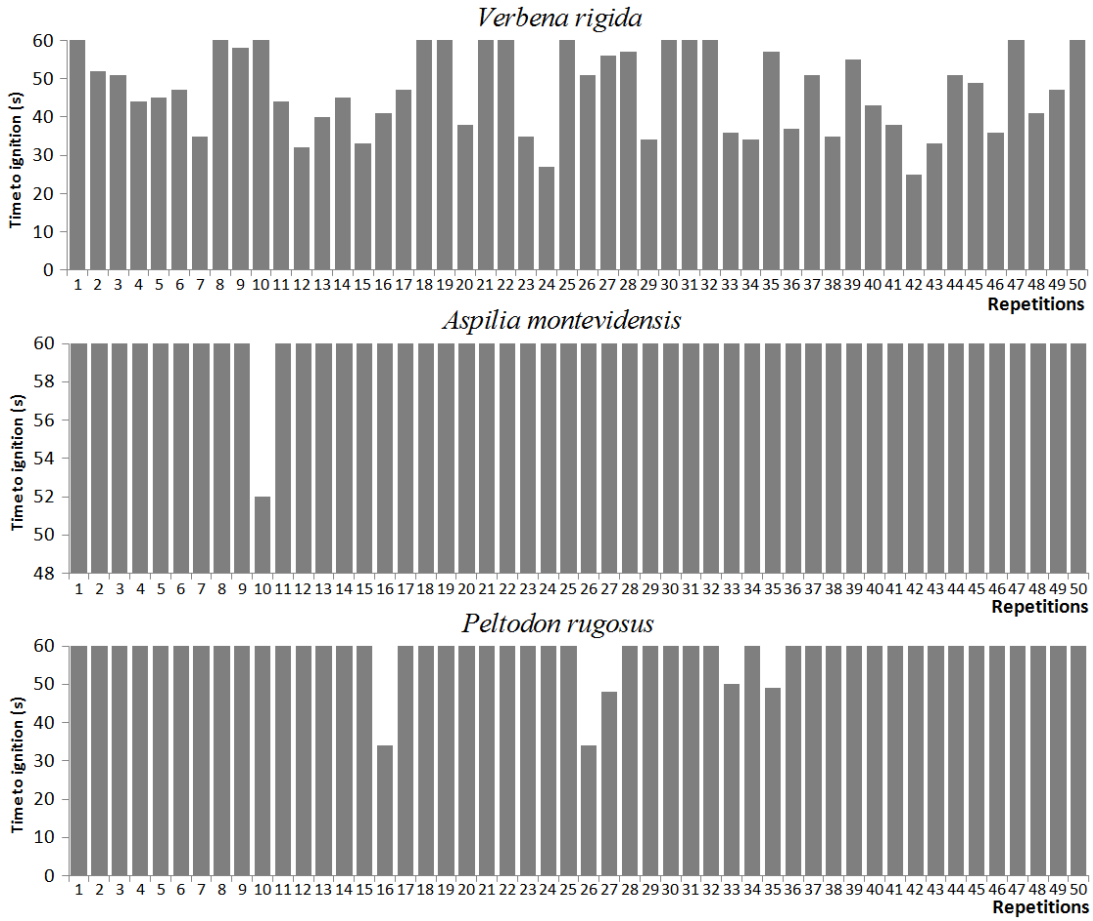

Figure 2. TI of the species in each repetition

It is observed that *Verbena rigida* was the species that presented greater variation in TI, being that most of the repetitions performed less than 60 s, corresponding to positive ignitions.

Aspilia montevidensis presented only one positive ignition, while *Peltodon rugosus* presented five positive ignitions. These results support the use of *Aspilia montevidensis* and *Peltodon rugosus* as barriers to the ignition of the forest fires in the edges of the WUI.
DC and AC variables were only possible to analyze in detail the species *Verbena rigida* (Figure 3 and 4). This is because the other species present in the vast majority of the repetitions, TI greater than 60 seconds, indicating negative ignition, and if "no ignition, no combustion".

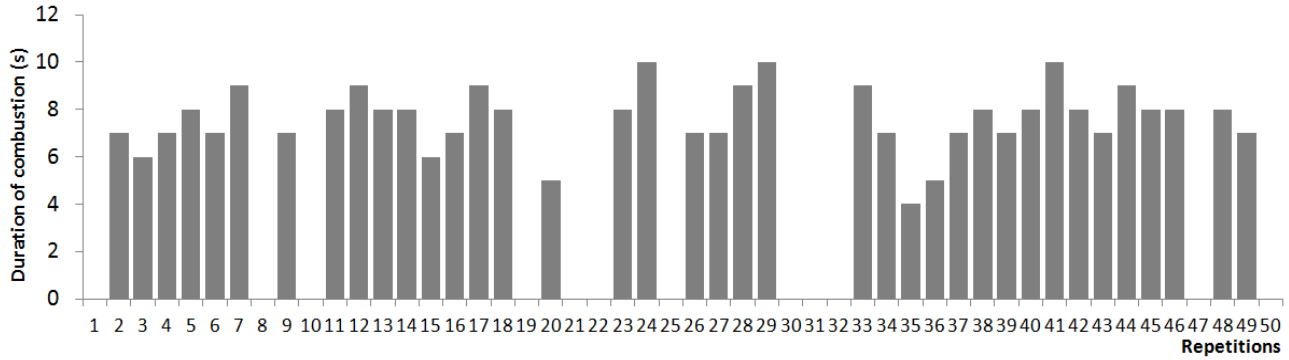

Figure 3. DC of Verbena rigida in each repetition.

It can be observed that there was wide variation in the DC of species in the repetitions performed. The average DC of *Verbena rigida* lasted 7.6 seconds, varying between 4 and 10 seconds.

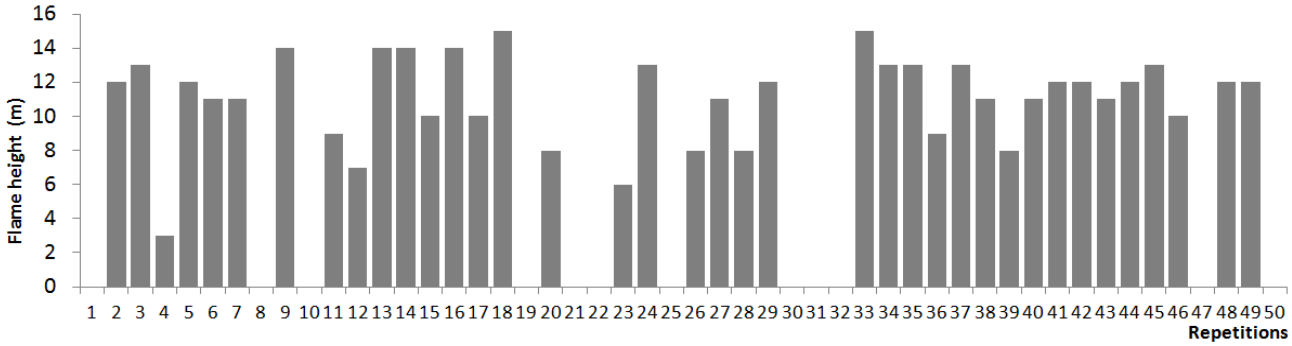

Figure 4. AC of Verbena rigida in each repetition

The flame height of *Verbena rigida* also showed wide variation, with an average of 11.1 cm, ranging from 3.0 to 15.0 cm.
After the analysis of the variables held separately, was assessed the flammability of the species, which allows to obtain a more accurate result regarding its use as a fuelbreak (table 1).

Table 1. Avaliação da inflamabilidade de espécies ornamentais

Species	FI (%)	TI (s)	DC (s)	AC (cm)	Combustion Index (IC)
Aspilia montevidensis	2 (a)	> 60 (a)	13	9	1 - Low flammability
Peltodon rugosus	10 (a)	> 60 (a)	9,2	14	1 - Low flammability
Verbena rigida	76 (b)	43,9 (b)	7,6	11,1	2 - Moderately flammable

Note:
FI -ignition frequency; TI - ignition time; DC duration of combustion; AC - height of the flame.
For FI and TI variables, means followed by the same letter in the column do not differ at 5% significance level by SNK test.

It is observed that *Aspilia montevidensis* and *Peltodon rugosus* differ statistically from *Verbena rigida* for variables FI and TI, indicating they are of low flammability although all species demonstrate weak flammability.

Conclusion

By the results, it is concluded that the analyzed species exhibit excellent characteristic to landscape composition on highways both for its aesthetic aspect as functional, and may also serve as a barrier against forest fires in WUI areas in southern Brazil.
In relative terms of flammability can be concluded that the species analyzed presented the following behavior: *Aspilia montevidensis* < *Peltodon rugosus* < *Verbena rígida.*

Abstract
The year 2013 was particularly negative with regard to forest fires in Portugal. Besides of the large burned area (around 141000 ha until October 15th, according to official data), for a small country, 8 firefighters and a Mayor lost their lives while fighting the fires. In this paper we try to describe the series of events that led to the burning of around 14000 ha in the Northern Region of Portugal, in an unusually short period of time, and in what was the largest fire of the civil year. This fire was to be known as the *Picões* fire. The work described here is based on a report ordered by the Portuguese Minister of Internal Administration, and is part of a larger study involving another large fire (in Serra do *Caramulo*, Central Portugal) and the analysis of the accidents that caused the death of the 9 referred persons.
Countryman's fire environment (1972) and the series of events that potentially led to the unusually large burned area for that region are described in this paper. Fire behaviour is also analysed, with the help of fire behaviour simulations produced for specific periods of the fire.

Keywords*: Large fires; extreme fire behaviour; fire behaviour simulation*

1. Introduction

The forest fire that occurred between July 8th and July 12th in the Northeast of Portugal, the *Picões* fire, burned around 2000 ha of forest stands and 12000 Ha of shrubland, making it the largest one that year. The fire spread across 4 Municipalities: *Alfândega da Fé, Mogadouro, Freixo de Espada-à-Cinta* and *Torre de Moncorvo* (Figure 1).
On July 8th 2013, at 14h44, a fire ignited on the right bank of River *Sabor*. The fire was controlled on that evening, at 20h53 with an estimated burned area of 180 hectares. During the night and the next morning two teams of fire-fighters stayed on watch, monitoring the extinguished fire line. Despite of the vigilance, at 14h00 of July 9th, the fire rekindled and spread, sometimes with extreme violence, until it was dominated very early in the morning of July 12th, leaving an area of approximately 14000 ha burned.
During the afternoon of July 9th the violent fire propagation, with episodes of extreme propagation, burned through 18km in little over 5 hours. Approximately ten of the fourteen thousand hectares burned in less than one day, between 14h00 of July 9th and 10h00 of July 10th.
The reconstruction of a large fire is a slow and meticulous process. For this particular fire all of the major actors involved were interviewed: Civil Protection Authorities, Fire Brigade Commanders, representatives from the municipalities, local inhabitants and others. Also, as a work basis, some important documents were used: the official ANPC (National Civil Protection Authority) Incident Reports and a technical report focusing on the restoration of the burned area, produced by the National Forest Service (ICNF, 2013). MODIS satellite data about the fire progression was obtained from the Joint Research Centre (JRC) of the European Union and the "*MODIS Active Fire and Burned Area Products*" from Maryland University (EUA).

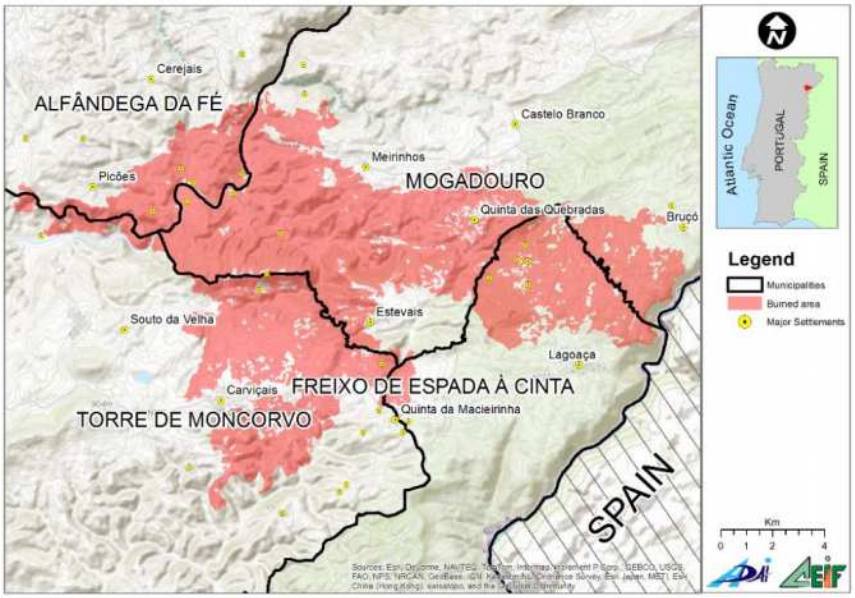

Figure 1. Burned area location, across 4 municipalities of the Northeast of Portugal

It was not possible to visit the area during the fire itself but we did it during October (17^{th}/18^{th}). In this visit we were also able to interview all the above mentioned intervenients.

2. Characterization of affected area

2.1. General characterization

The fire took place in an aged and low populated region, in a mountainous area where most of its inhabitants dedicate their few resources to subsistence agriculture and olive and almond trees. Some *Eucalyptus globulus L*. and *Pinus pinaster Ait*. stands are also present, maintained by the largest Portuguese paper pulp related company.

There are very few settlements in the region, as seen on Figure 1, and of small dimension. Many of them are named "*Quintas*" and consist of only 2 or 3 houses. Considering the fire perimeter and a buffer of 2000 meters outwards we counted 44 small villages and *Quintas.* The largest villages are on the margin of the fire perimeter.

The particularly rainy winter of 2013 had an important impact on the growth of fine fuels all over the country, but particularly in these areas due to 2 important factors. First, the construction of a big dam in the *Sabor* river was being finalized. In order to fill that dam all the vegetation (herbs, shrubs and trees) in the flooding area was being removed in the past months. During 2013 spring, all the basin along these main water tributaries of *Sabor* got covered with rapid growth herbaceous vegetation. Secondly, there is a common practice in the region of superficially ploughing two times the ground of the olive and almond fields, in early spring and in late spring/early summer, basically to remove all herbaceous fuels. The later was not possible, due to the high levels of moisture in the ground. These fields, usually good passive defense areas against fire, ended up with an unusual load of fine fuels. Apart from the described areas, most of the region is covered by shrubs.

2.2. Fire defense related infrastructures

The road network is not very dense, a common pattern found in many mountainous regions of the interior. The main roads (Municipal Roads) usually connect the municipalities' major villages or cities. In the area affected by the fire we found the Forest Road Network to be deficient, not covering most of the area. This aspect is a constraint when managing heavy firefighting vehicles and their positioning, as they have to travel for long distances. With very few exceptions there is one fire brigade per municipality and usually distancing more than 20 km from each other.

The closest brigades from the fire origin were from *Alfândega da Fé* and *Torre de Moncorvo*, approximately 10 km in a straight line.
The first crew to arrive to the fire, composed of 5 men, was transported by helicopter and arrived at the scene 10 minutes after the initial alarm. The ground crews (2 vehicles, 10 men) took 20 minutes.
The water sources or points used by the fighting crews are depicted in Figure 2. There's a main river (4th order) on the East side (*Douro River*) but the orography of the surroundings makes it difficult for the aerial means to use it as a water source. The same for *Rio Sabor* (3rd order), crossing the area from North to West. Besides these two rivers there are only 2 water sources for aerial means identified in the Municipal Defense Plans Against Fires (PMDFCI) obtained from the municipalities. Also, considering a buffer of 2 km from the final perimeter we count 14 terrestrial and 9 mixed water points. We ignore the conservations and usability conditions of these water points.

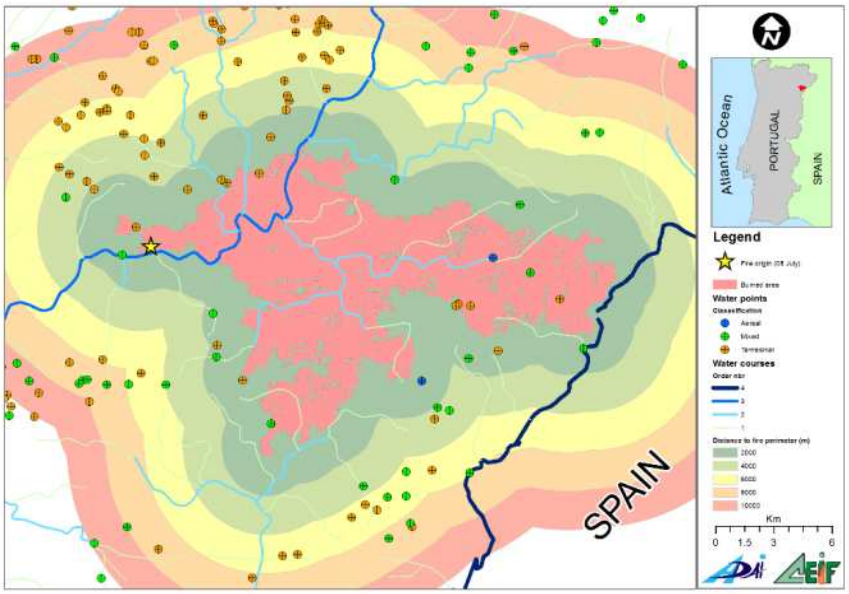

Figure 2. Water points in the area of the fire

Although not inventoried in the Plans, there are also a few dams of different dimensions in the surrounding, which we assume would have good operating conditions for the helicopters.
In such a large fire we consider the water resources to be scarce, even assuming they were all 100% operational. In the fire area itself there are practically no water supplies, and the large concentration of point on the Northwest was progressively being farther away as the fire progressed towards East.

2.3. Fire history

Knowing the fire regime of a particular area is of great importance for forest, fire and land managers.

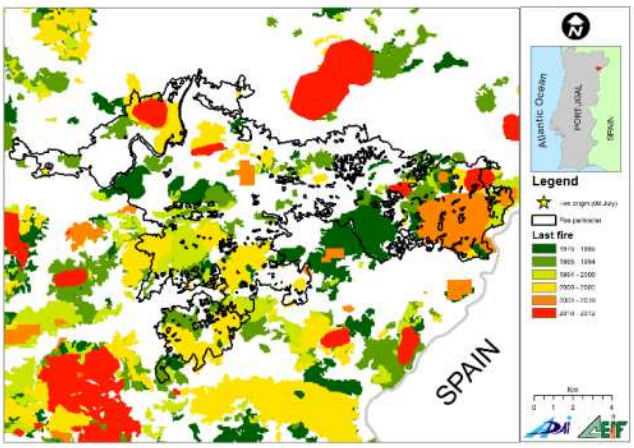

Figure 3. Last recorded fire in the region

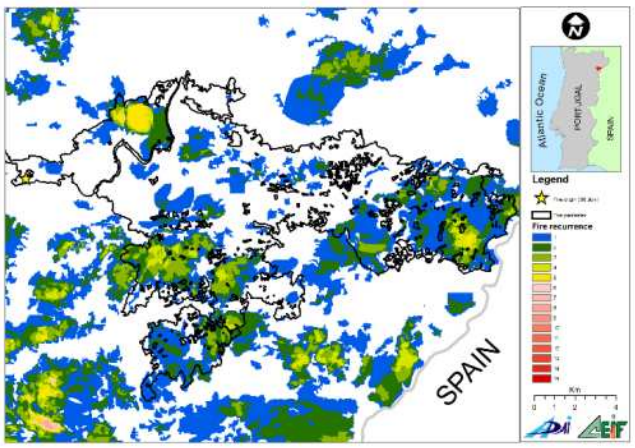

Figure 4. Fire recurrence in the region

In Figures 3 and 4 we can observe that a large portion of the area that burned in this event had not been burned since we have consistent and systematic records of fire perimeters in Portugal (1975).
The Southern part of the 2013 perimeter has burned between 1 and 4 times since 1975 but the last recorded fire was in 2005. The Eastern part has also been frequently affected by fire, some in 2010 and 2011.
The absence of fire in a large part of the region for the last decades, and the progressive abandonment of ancient agricultural practices results in an increasing accumulation of surface fuels, namely herbaceous and shrubs. This is a crucial factor in the increment of the fire potential in the region.

3. Fire environment

The fire environment is a well-known concept (Countryman, 1972) that describes the three main characteristics of the environment that affect the development of a forest fire: topography, fuels and meteorology.

3.1. Topography

The role of topography on fire spread is well known (e.g. Van Wagner, 1977; Pyne *et al*, 1996), namely the slope, by conditioning the rate of spread (ROS), or the orientation, by influencing the solar radiation received by the exposed fuels.
The area affected is mostly a mountainous region, with some open valleys mostly parallel to the wind and fire direction during the most important part of the fire development. The slopes are high in most of the area covered by the fire, in some cases greater than 45%, usually corresponding to the slopes that flank the rivers *Douro* and *Sabor* and their tributaries. A panoramic view of part of the area can be seen on Figure 5.

Figure 5. Panoramic view of part of the burned area

3.2. Fuels

Similarly to most of Portugal interior region, the predominance in this area in terms of land use is agriculture or related activities. However, the area directly affected by fire was mainly composed of shrubs and herbaceous vegetation. The municipal defense plans (PMDFCI) mentioned earlier are obliged to map forest fuels corresponding to a set of fuels derived from the standard American 13 NFFL fuel models (Anderson, 1982). Although there are technical guidelines published by ICNF the identification and mapping of these fuels is still very subjective as it relies on the knowledge and analysis of the different end users (the personnel responsible for the field work and cartography). Figure 7 is a composite of the individual fuel maps obtained from the municipalities. Even visually it is possible to see the lack of uniformity (Figure 6). Not only the resolutions used were different but also there are many cases where the same fuels are mapped with different codes, which denotes different identification criteria.

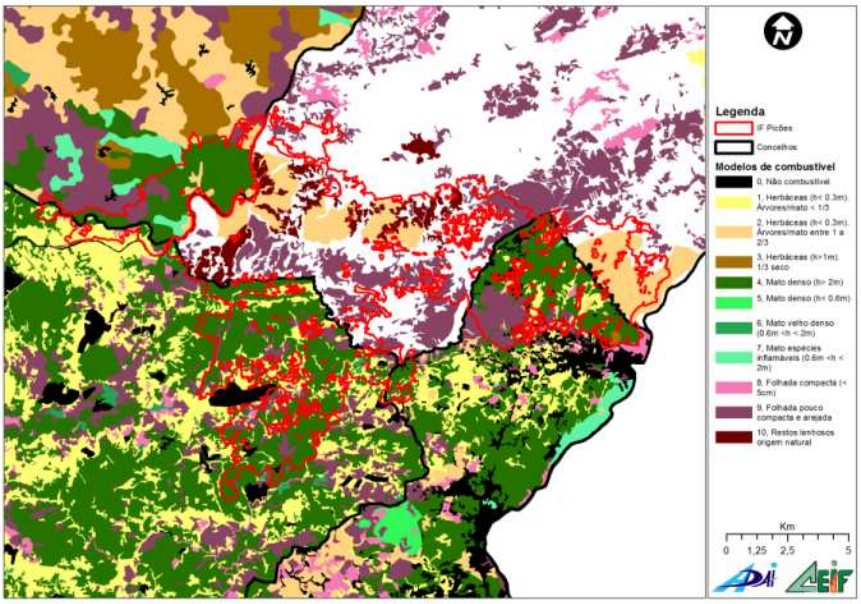

Figure 6. Fuel map of the area affected by the fire

In the surroundings of the ignition zone the prevailing fuels were described as natural herbaceous vegetation and dense shrubland (models 2 and 4). In this type of fuel bed fire spreads very rapidly and the existence of some scattered woody fuels increments its intensity. As the fire progressed to East herbaceous fuels dominate the landscape on the margins of the water courses. Apart from that, the majority of the central region of the fire was dominated by shrubs of different heights and loads (Models 4, 5 and 6). In these models fire propagates rapidly and intensely, even with high moisture contents. There are some forest stands, mainly composed of *Pinus pinaster Ait*. and *Eucalyptus globulus* L..

Very few fuel management activities were identified in all the region affected by the fire and the surroundings. The only management activities carried during the last 3 to 4 years were on the sides of some major roads and along the high and very high tension power lines. It was clearly not enough and not planned in a fire management perspective. Fuel moisture for fine fuels was estimated to be around 7% between 14h00 and 16h00, doubling during the night.

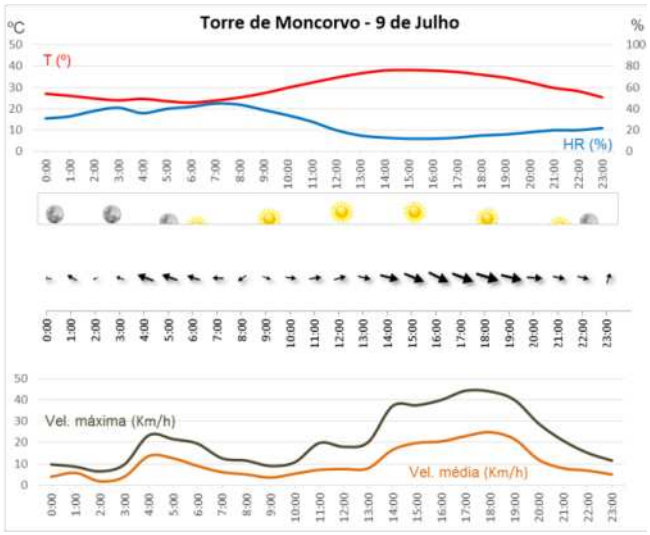
3.3. Meteorology

The year 2013 began with precipitation values above the average (IPMA, 2013a) until the end of May. June and July were below the climatic mean for the period 1971-2000.

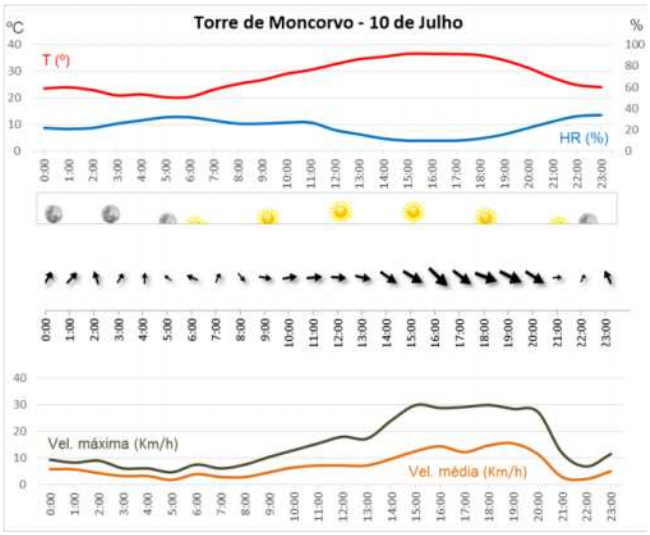
According to the Portuguese Institute for the Sea and Atmosphere (Novo *et al.*, 2013; IPMA, 2013b) on July 3rd a heat wave affected Portugal, staying in the Northeast until July 13th. The precipitation on July was half of the mean value in almost all the country, with the exception of the Northwest.

Between 11th and 18th July some atmospheric instability was present in the North of the Iberian Peninsula, originating periodic episodes of light rain and thunderstorms.

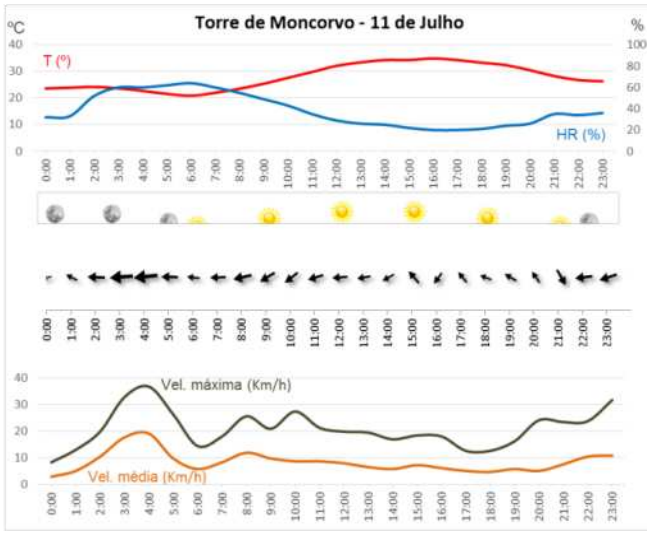
To describe the period from July 8th to 11th, during which the fire spread, we used the meteorological stations owned by IPMA that are located very close to the affected area. One example of the constructed meteograms is shown on Figure 7.



a



b



c

Figure 7. Meteorological data recorded for July 9 (a), 10 (b) and 11 (c)

The recorded values are good reference but may not coincide with the ones registered locally on the different fire sections, mainly due to topographic effects and also to the influence of fire itself.
The values show 3 very hot days with maximum temperatures up to 40ºC and minimum above 20ºC. Relative humidity was also extremely low during the afternoons (around 10%).

3.3.1. July 9th

During the night and morning of July 9th, the wind always presented values of low speed, usually of the order of 5 km/h. During the night the wind was from the East shifting to West during the morning. At night high temperatures between 23 and 27 °C were recorded, together with relative humidity often less than or equal to 40 %.
Between noon and two o'clock the weather worsened. At 14h00 temperature was around 38 °C and humidity of 13%. The wind blew from W-NW with an average speed of 17 km/h and gusts of 37km/h. These values provided a rapidly developing fire after its rekindle. Throughout the afternoon wind speed varied from 17 to 25 km/h with gusts up to 44 km/h. The maximum values were recorded between 17h00 and 19h00, when the village of *Quinta das Quebradas* was hit by the fire.
At the beginning of the night the wind rotated to the South and its intensity decreased to around 5 km/h.

3.3.2. July 10th

During the night of July 10th the wind was from the South. Early in the morning started blowing from West and it increased the speed as the day passed.
At around 14h00 the wind shifted to Northwest and throughout the afternoon the wind remained with velocity varying between 10 and 15 km/h. Starting from 20h00, there has been a pronounced decrease in wind speed to values of around 3 km/h.

3.3.3. July 11th

The night from July 10th to July 11th brought increased wind intensity, unlike the previous two nights that had been very calm. Wind came from the East with gusts up to 40km/h. During the morning speed decreased to 10 km/h, maintaining direction, until it shifted to the Southeast at 15h00.
At the end of July 9th and 10th, in particular to the middle of the afternoon, the wind was weak, rarely exceeding 10 km/h. Under these conditions, in a region of complex topography and with the observed intense insolation, the local effects are dominant. Thus, the extrapolation of the wind behaviour from one location to another is subject to a certain degree of uncertainty.

4. Fire Chronology

4.1. The *Cilhade* fire – July 8th

At 14h44 of July 8th a fire started near a small uninhabited Quinta named *Cilhade*, in the municipality of *Torre de Moncorvo* (*Bragança* District). In less than 10 minutes after the initial alert, the initial attack crew was on the ground fighting a fire that was developing in a highly sloped area.
The fire burned about 180 hectares, according to our reconstitution (Figure 8). This fire was dominated in the early evening (20h53) the same day and the consolidation and mop up were initiated shortly after. During all night and the following morning two crews from the fire brigades involved in the extinction operations remained in the area on surveillance.

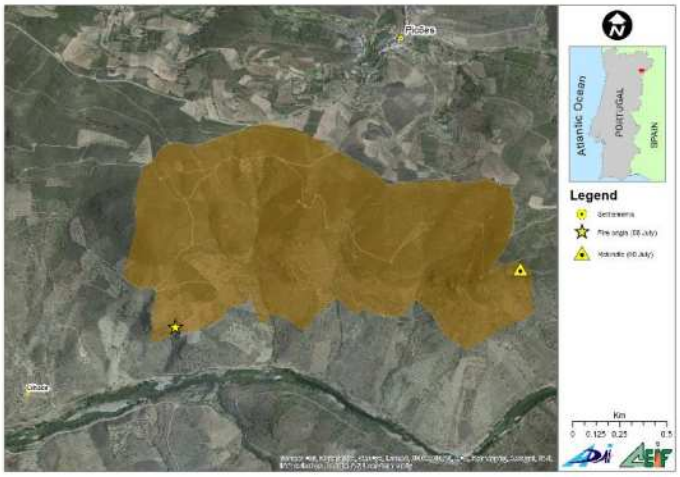


Figure 8. Approximate perimeter of the Cilhade fire on July 8th

4.2. The *Picões* fire – July 9th

Despite the vigilance operations, around 14h00, the *Cilhade* fire rekindled and quickly spread by adjacent sloping areas covered with shrubs. At this time the nearest weather station maintained by IPMA (*Torre de Moncorvo*) recorded temperature values of 38ºC and relative humidity of 13%.
The fire progressed rapidly to the East/Northeast, with the wind blowing from the West at an average speed of about 20 km/h but with gusts reaching 40 km/h. Due to the construction of the *Baixo Sabor* dam almost all the area across the river valley had been cleaned out of vegetation in the last months. The rainy spring of 2013 resulted in the growth, above average, of herbaceous vegetation, especially in these areas, which were relatively clean of trees and shrubs. The orientation of these areas, which would be filled with water when the dam started operating, is a perfect match with the general propagation of the fire in its initial stages.
At approximately 15h30 we estimate that the fire jumped to the left bank of the river *Sabor* (Figure 9).

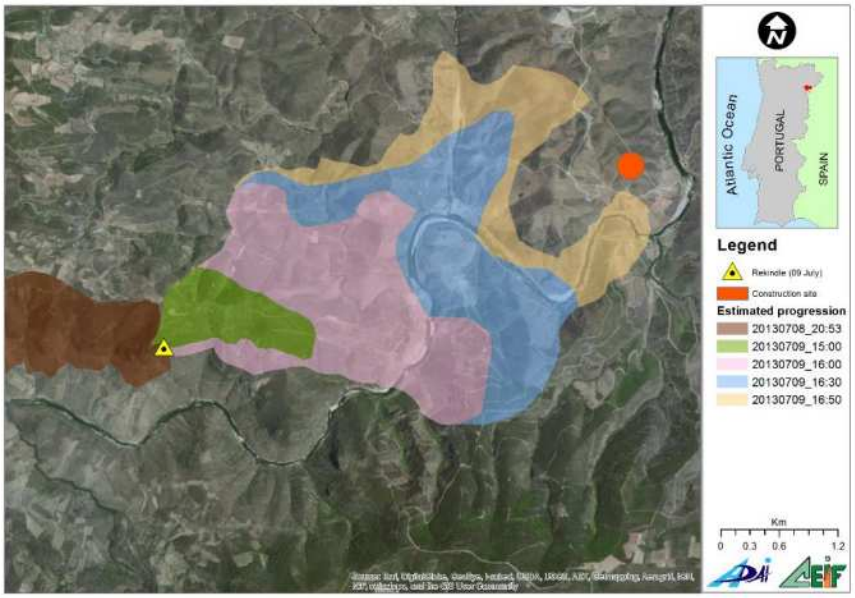

Figure 9. Estimated progression at 16h50 of July 9th

At around 16h50 a request for help was received from the chief of a construction site (marked in orange in Figure 9) who felt was being surrounded by fire, along with 30 workers. This call for help had a direct impact on the firefighting strategy. Although the fire officers had the perfect notion that the construction site was a safe place (that particular mountain had been cleared of vegetation from the middle to its top) they made the decision to displace several crews to evacuate the construction workers.

Between 17h00 and 17h30 the fire entered the long valley of a small water line called *Ribeira do Medal* and spread with a high velocity for about 3.5 km in a Northwest-Southeast orientation. It then split and entered the valleys of 3 other water lines (*Meirinhos*, *Resinal* and *Inferno*), as shown in Figure 10. The orange arrows show the direction of the fire propagation. Eventually the fire also spread North through another smaller water line.

The configuration of the terrain and the waterlines pushed the propagation of the fire towards the existing settlements, mainly *Meirinhos*, *Estevais* and *Quinta das Quebradas*. Also the wind was blowing from the West, which increased the ROS.

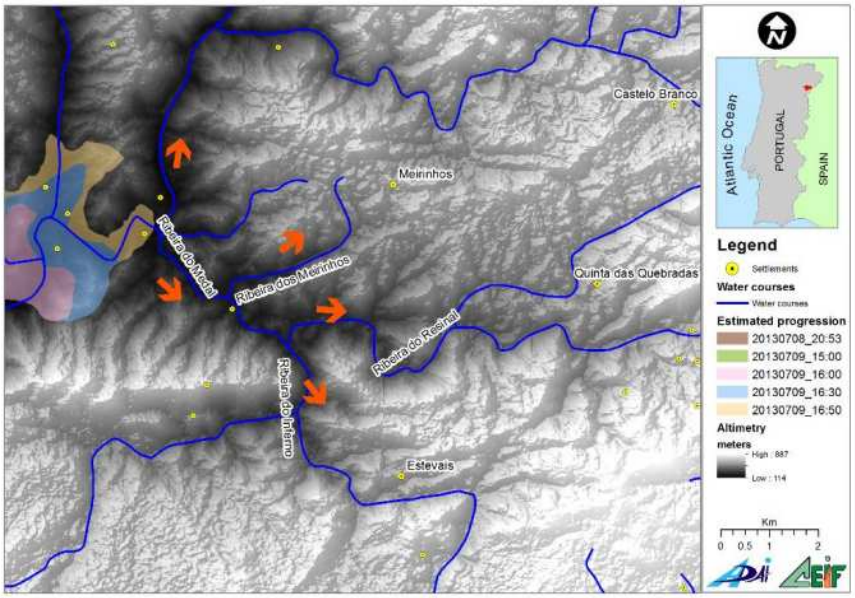

Figure 10. Scheme of the topography, water lines and direction of fire propagation

Around 17h30, with the fire progressing with unusually high rates of spread one of the fire Brigade Commanders identified the small village of *Quinta das Quebradas* as a priority target for defense, as it was located ahead, and on the most likely path, of the fire front. Although the fire front was approximately 6 km away, taking into account the observed ROS and the knowledge about the poor road network, it was decided to allocate some firefighting resources to protect the houses and people still there.
Between 17h00 and 19h00 the wind was blowing with an average of 20 km/h but with gusts up to 40 km/h. The fire was progressing not only by surface but with a considerable amount of flying embers, creating numerous spot fires. One of them was registered flying about 3 km from the main front, originating a spot fire less than 3 km west of *Quinta das Quebradas*. Another one was registered 1 km South/Southwest of the small village around 19h00. Shortly after another one at Southeast. Figure 11 represents the estimated propagation on the afternoon of July 9th. The orange arrows indicate the approximate location of the described spot fires.

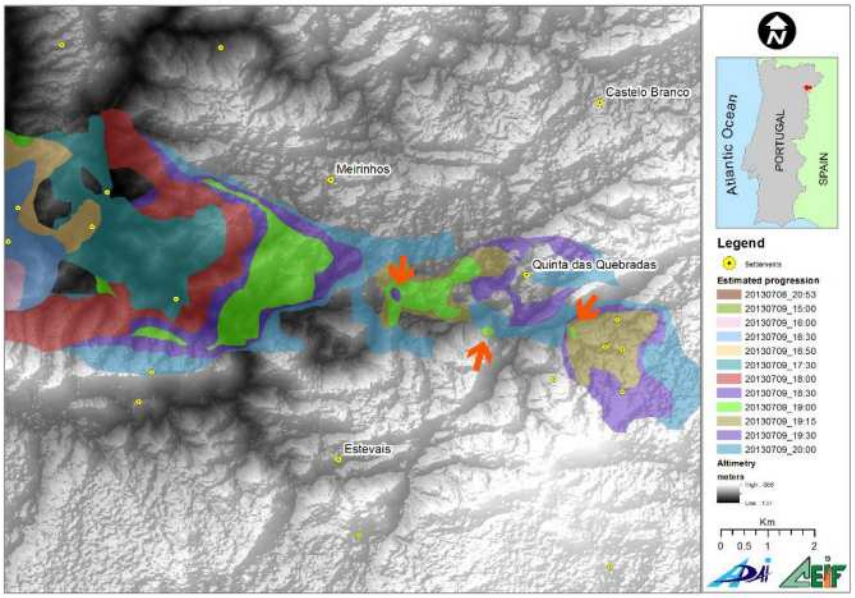

Figure 11. Estimated propagation on the afternoon of July 9th

The protection to *Quinta das Quebradas* was an important milestone of the fire as it coincided to the time of the most violent propagation of the fire, either by the rapid surface propagation and the numerous spot fires. By this time (around 19h00) 30 vehicles and 99 men were protecting the village and the fire was spreading freely. It even spread through the middle of the village.
The time from the decision of going to protect the village and the passing of the fire was of around one and a half hours. The fire spread through 6 km, which represents roughly 4 km/h, quite above the "normal" rate of spread.
The development of the spot fires helped accelerate the spread of the fire at this stage and lengthened it. Shortly after 19h00 traffic was cut on National Road EN221, which connects *Mogadouro* to *Freixo de Espada-à-Cinta*, about 2 km East from *Quinta das Quebradas*. At the end of the day, early evening, the wind calmed. Already in the early morning of the 10th, the front advancing Eastward stopped its progression on extremely steep slopes, often devoid of vegetation, leading down to the *River Douro*. One or two burning embers flew across the river and fell in Spain but were immediately extinguished by the Spanish firefighting crews.

The events that were just described, were the most important on the history of this fire, with a West-East axis of progression, perfectly aligned with the wind direction and most of the valleys and watercourses present in the area.

4.3. The *Picões* fire – July 10th

During the night (July 9th to 10th) the wind swirled South and decreased in intensity, registering speeds varying between 2 and 6 km/h and the fire began to expand laterally, with lower propagation speed.
During the morning of the 10th the fire was progressing very slowly all over the perimeter. The prevailing wind was from the West once again with hourly average below 10 km/h.

Figure 12. View from Google Earth of the fire going downslope into the Ribeira do Inferno

By late morning, a small section of the fire was spotted on the right flank, progressing downslope, and slowly heading to the valley of the *Ribeira do Inferno*. At this time the wind was weak and from the West but the forecast predicted a slight rotation to the Northwest accompanied by a small increase in speed. In low wind conditions and in the presence of a heat source (fire) the local effects induced by the topography in the wind dispersion are more pronounced.
Analysing the topography South of the region where this situation was detected, and knowing that the wind would be aligned with the valley of *Ribeira do Inferno,* it could probably be anticipated an increase in intensity and ROS of the fire as soon it reached the base of the slopes that are seen in Figure 12.
Indeed, around 14h00 on the 10th the wind increased in intensity and suffered a rotation to the Northwest. Virtually the entire left flank (North) and the back of the fire (West) were dominated or in mop up actions. Progression to East was contained in the *Douro* river. This change mainly resulted in the right flank gaining intensity and rapidly propagating South, in the direction of three small villages. By this time a large number firefighting crews and all available aerial means were dislocated to this area to protect the villages and its inhabitants, especially *Carviçais*, South of the fire. Figure 13 shows the estimated area burned at 22h00 of July 10th.

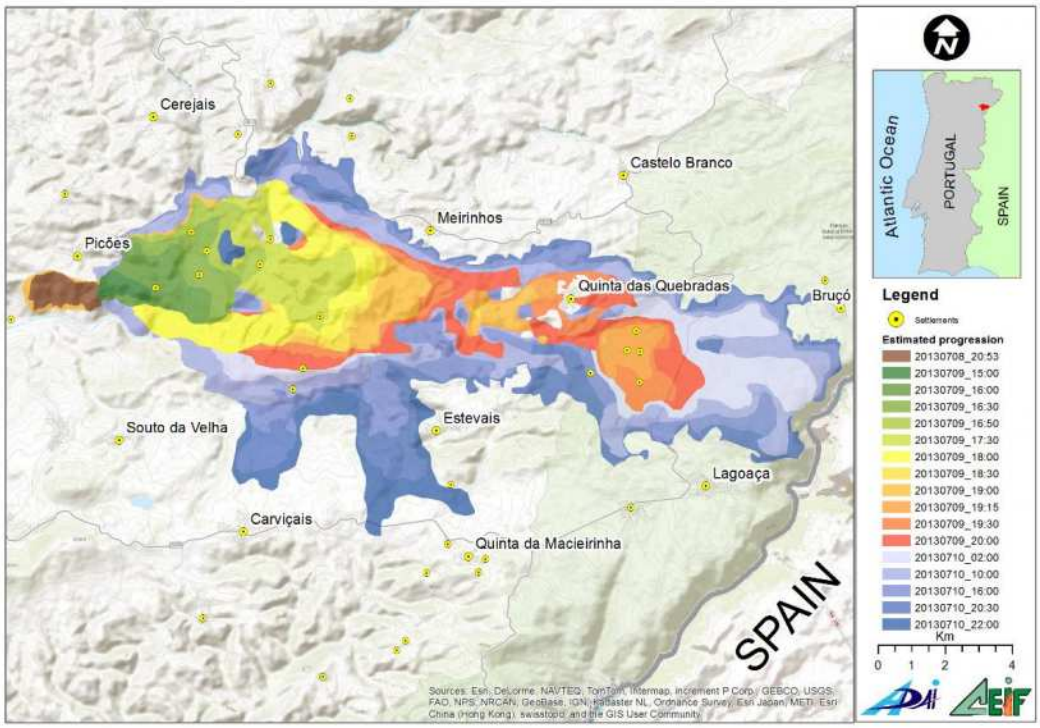

Figure 13. Estimated fire progression at 22h00 of July 10th

4.4. The *Picões* fire – July 11th and 12th

The morning of July 11th was not as favourable in meteorological terms. From 02h00 the wind increased in intensity prevailed from East, favouring the spread of the fire to the West. The average speed became of 15-20 Km/h with gusts of 30 to 40 Km/h.

The North area of *Carviçais* has an intensive and active agricultural occupation, posing as a natural barrier to the fire spread. There is also a major road crossing in an E-W direction, used as a support to the firefighting actions. Still, the fire jumped through in a small area occupied by shrubs. The wind changes that followed brought the fire, more than once, near the mentioned village of *Carviçais*, first in the North and then by South (Figure 14).

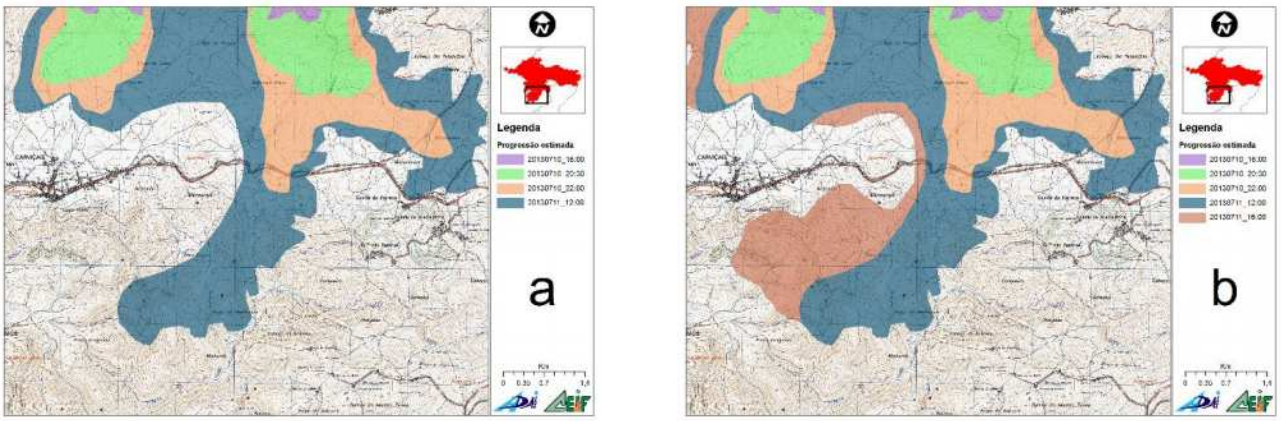

Figure 14. Detail of the estimated fire progression threatening Carviçais: at 12h00 (a) and at 16h00 (b)

During the night of 11th to 12th the prevailing East wind was of the order of 7-8 km/h and the fire did not propagate much more.

According to the Incident Report from ANPC the fire was finally declared extinguished at 09h30 on July 12th. The final burned area by registered ICNF was 13706 hectares, 1983 hectares of forest plantations and 11723 hectares of shrubland. Later on the final perimeter was released showing an area of 14136 hectares burned.

5. Analysis

5.1. Fire behaviour

The described fire evolution and its final burned area, depicted in Figure 16, were strongly affected by 3 major events: i) the rekindle of the original fire, ii) the defense of *Quinta das Quebradas* and iii) the wind shift that turned the right (South) flank into a fire front.

5.1.1. The rekindle of the original fire (beginning of the afternoon, July 9th)

The initial attack on the *Cilhade* fire was quick and effective. Given the location of the fire and the lack of good access road that hinders the arrival of heavy combat trucks, containing the fire in six hours and about 180 hectares can be considered a positive performance. Despite of the vigilance throughout all night and the next morning, at 13h47 the fire rekindled. This was probably the key element on the final outcome of the large *Picões* fire.

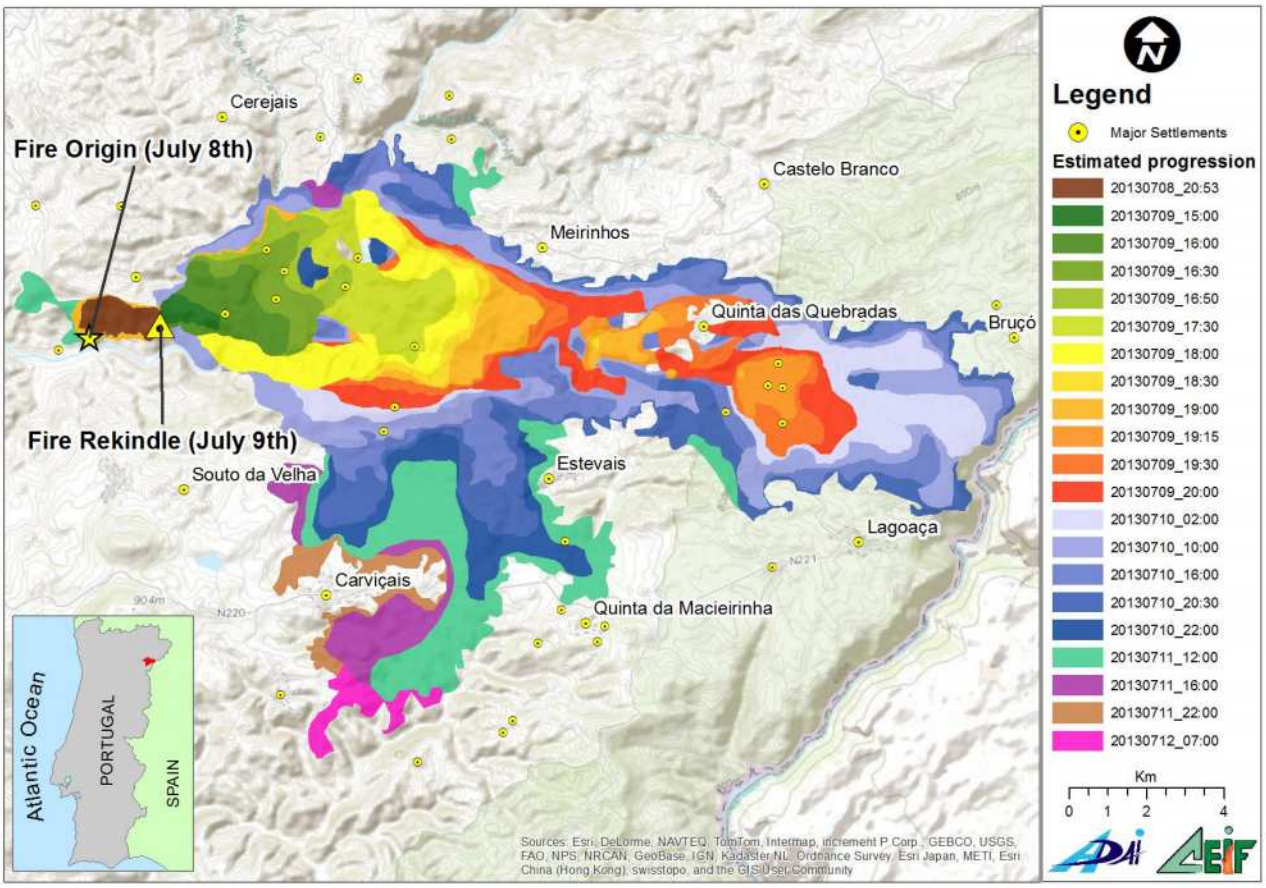

Figure 15. Global estimated fire evolution

Being able to predict changes in the wind field is extremely useful in fire management activities, especially if one is able to predict the influence of topography in its dispersion. IPMA provides atmospheric wind forecasts but using the fire behaviour simulator *Firestation*, developed in ADAI (Lopes *et al* 2002), we can simulate the effect of topography on the distribution of the wind field (Figure 16).

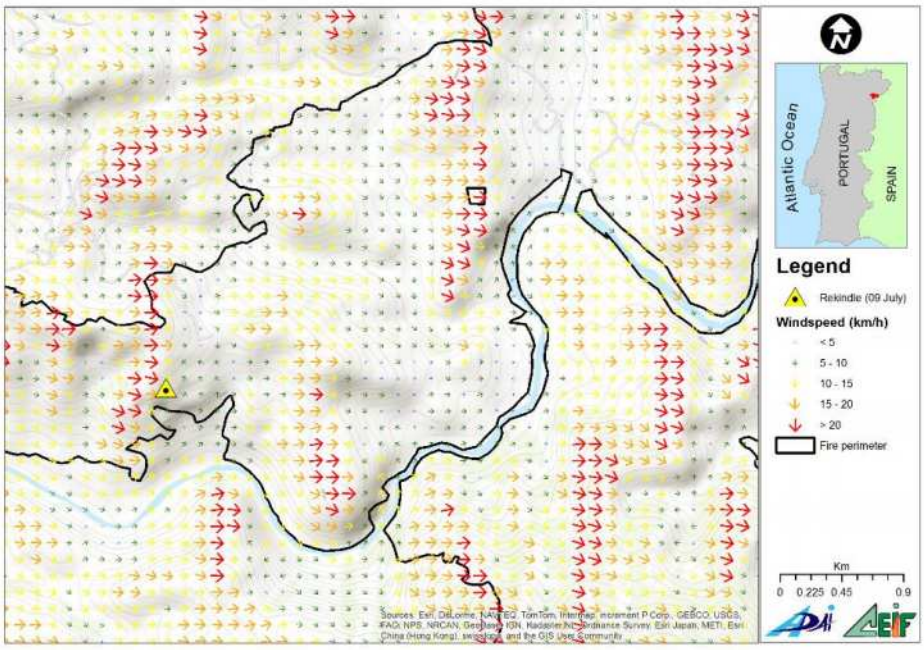

Figure 16. Simulated wind field at the time of the rekindle

At the time of the rekindle the West winds had higher overall speeds when going up the slopes facing West. The lower speed would be registered in the more sheltered valleys, with prevailing downslope East exposure. Jumping over river *Sabor* wouldn't have been hard as the strong winds easily carried burning embers across the valley. As described earlier, the herbaceous fuel load along the banks of the water lines was considerably high, as well as its curing degree. We assume the ROS at this early stage would have been very high. The air temperature was 38ºC and the relative humidity 13%. The surrounding area was still warm and the unburned fuels desiccated from the heat released from the fire of the previous day. When the fire started again it spread very quickly to adjacent fuels.
The alarm was not as swift as it should be and the initial attack on this rekindle was not strong enough to prevent the fire from spreading. In the first 3 hours of propagation the fire ran approximately 5 km in a W-E orientation (in a straight line) which corresponds to a mean rate of spread of 1.67 km/h. Figure 17 shows the vertical profile and the slope variation along the mentioned line of 5 km. Slope has several abrupt changes but sometimes is negative (fire progressing downslope). It is generally between 20 and 40%.

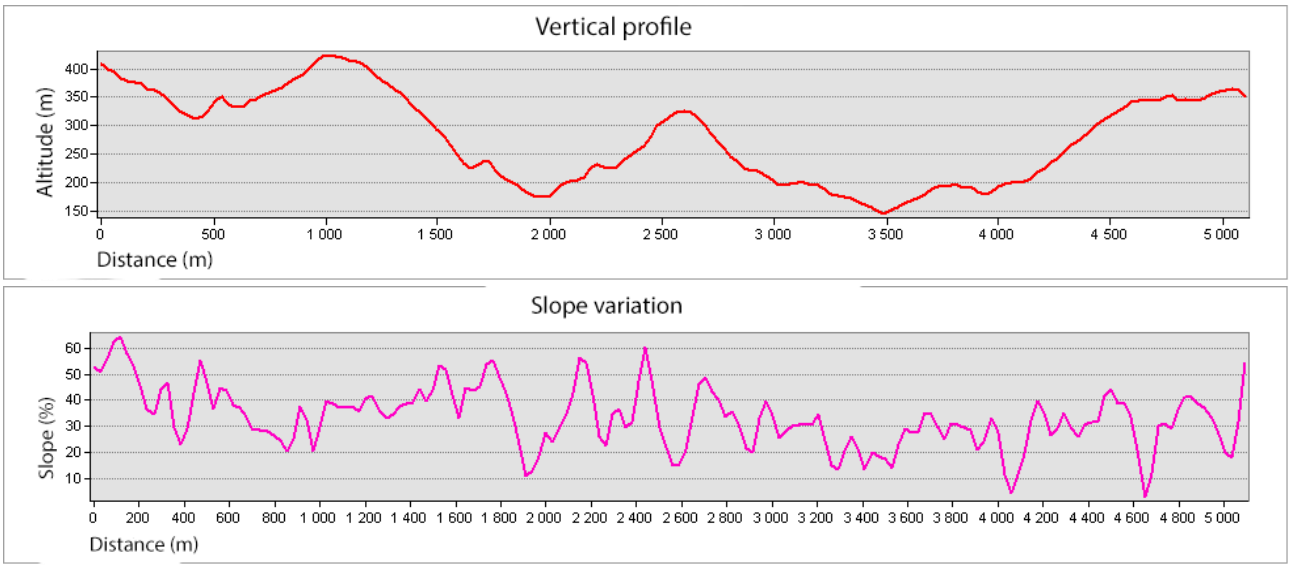

Figure 17. Vertical profile and slope variation in the first 5 km of fire spread (after the rekindle)

Using BehavePlus (Andrews *et al*, 2008) we estimated the fire rate of spread herbs and shrubs, in function of the slope and, assuming the slope is always positive, the predicted ROS was always below the observed (**Erro! A origem da referência não foi encontrada.**1):

Table 1. Predicted ROS according to BehavePlus

Slope	%	20	30	40
Rate of spread (km/h)	Herbaceous	1.25	1.33	1.45
	Shrubs	1.05	1.10	1.19

From the middle of the afternoon the fire progressed with very high speed, not only through the surface but also with numerous spot fires.

5.1.2. The defense of the small Quinta das Quebradas village (late afternoon, July 9th)

During the afternoon of July 9th, and at the time of the most violent fire propagation, this village of around 100 inhabitants was stroke by the main fire front. At this time, in about one and a half hours the fire ran 6 km in a straight line, averaging approximately 4 km/h of ROS. Several spot fires were identified. There were practically no passive defensive structures around the village so, as it usually happens, firefighters stopped fighting the fire and concentrated on defending the structures, livestock

and, most important, the people living there. An important number of means were dislocated to this action: 30 vehicles and 99 men.
As the night progressed the meteorological conditions became more favourable and the fire slowed its W-E progression and eventually stopped on the steep scarps of river *Douro*.
At this stage the fire propagated very slowly on the flanks.

5.1.3. The wind shift that turned the right (South) flank into a fire front (morning, July 10th)

During the morning of July 10th the fire kept burning slowly on the flanks and the National Incident Command Structure in charge of the strategy believed it would soon be controlled. Despite the fact that wind predictions indicated a shift in the wind direction the overall strategy failed to adapt in time to the probable fire behaviour change. At the time the wind changed we estimate that the area burned should be around 8000 ha, far from the final 14000 ha. The fire was being pushed by slow Westerly winds into the East.
In the area identified and described earlier (see Figure 12) the fire was burning slowly and downslope, with the wind blowing sideways, but there weren't any firefighting crews nearby. In any fire, particularly a large fire, constant observation over the entire perimeter is of the utmost importance (either by terrestrial or by aerial means), as is the analysis of weather forecasts and topography and their expected influence on fire behaviour. We believe the reaction to the predictable wind shift was very late. We cannot tell for sure that, had this situation been anticipated, the fire would be contained, but evidence suggests that if the descending fire was attacked during the morning there was a strong possibility that it would be contained at this time.
After the wind has changed to the Northwest the right (South) flank of the fire became an active fire front and propagated to the South endangering some villages, one of them multiple times (*Carviçais* – see Figures 14 and 15).
During July 11th practically all manoeuvres were concentrated near *Carviçais*, where the fire reached from multiple points, as described earlier.

5.2. Fire behaviour simulation

Fire behaviour simulation is nowadays a very important tool in fire management, although a perfect knowledge of its fundaments and limitations is required. ADAI team has been developing a spatial simulation software called *FireStation* (Lopes *et al*, 2002), based on Rothermell's surface fire spread model (1972). The system takes as input static maps of fuels (obtained from the mentioned PMDFCI) and topography (in for of Digital Elevation Map) and point measurements of wind characteristics, that can be updated as needed. *Firestation* uses a wind simulation model called *Canyon* (Lopes *et al*, 1998), which is a model used for complex topography and that takes into account the different thermal and recirculation effects.
We chose 3 instants to simulate, corresponding to the 3 key events described earlier.

5.2.1. Phase 1 – the rekindle

For this first stage we used an ignition on the spot where the rekindle was identified. The area corresponding to the original fire was simulated as already burned, in order to avoid any interaction with the fire and wind simulation. Figure 18 represents the predicted and estimated fire progression for this period. Time since ignition and fire line intensity are shown.

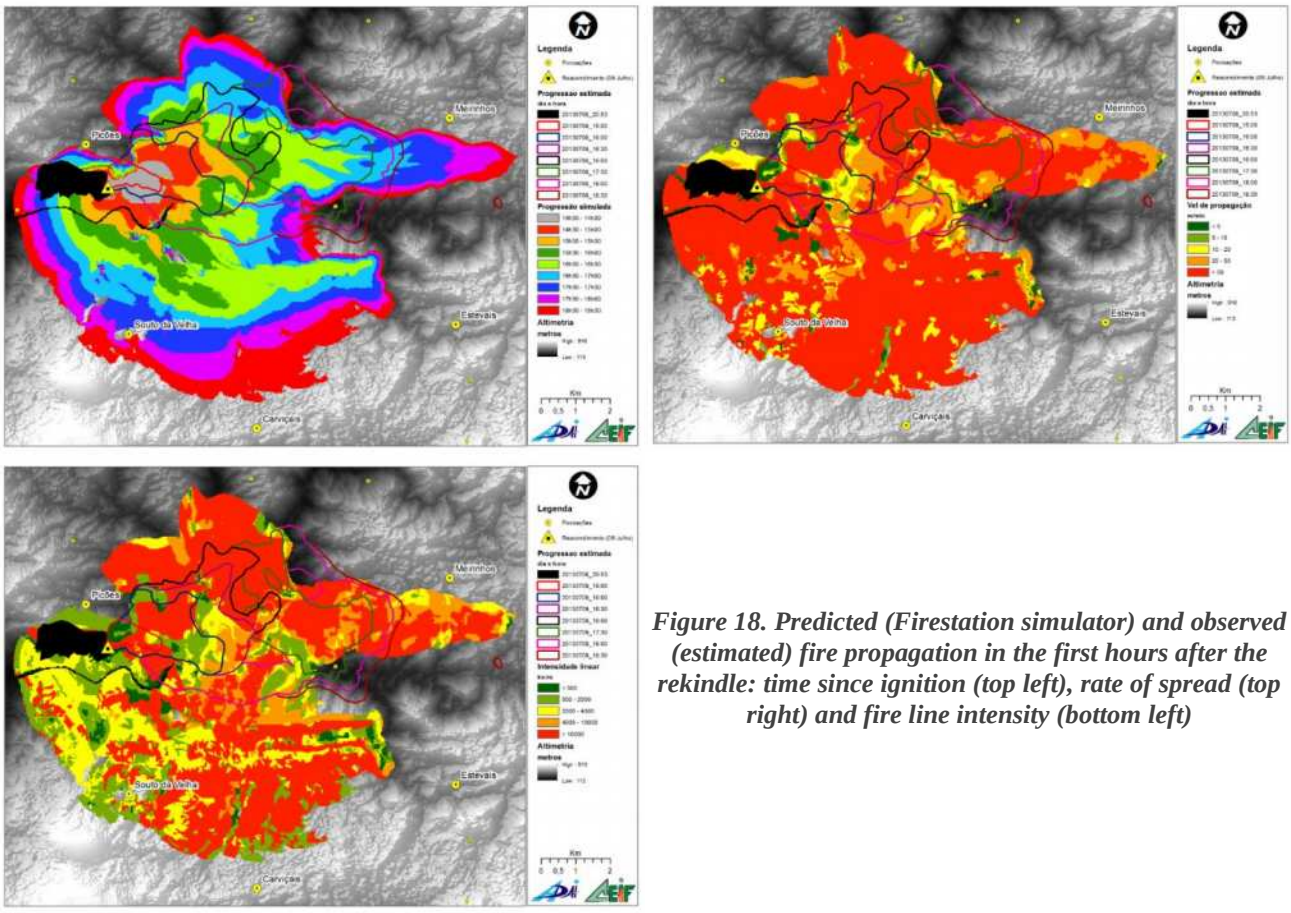

Figure 18. Predicted (Firestation simulator) and observed (estimated) fire propagation in the first hours after the rekindle: time since ignition (top left), rate of spread (top right) and fire line intensity (bottom left)

The coloured areas represent the simulation while the contours represent the observed (estimated) progression.

At a first glance we can see that the final shape of the simulated fire does not correspond to reality. Looking in more detail we observe however important results. The simulated fire has spread extensively to the South because it crossed river *Sabor* immediately after the rekindle and we know that that did not happen. We also know that, on the hill below the rekindle, the fuels were very scarce and the fuel map we used did not reflect that. Also the fuel map doesn't map the river in its whole, making fuels continuous from one bank to the other. This wrongly allows the fire to easily cross the river. If we limit the analysis to the Northern half of the simulation similarities with reality increase.

In the initial zone of fire propagation the simulated ROS exceeds 50 meters per minute (approximately 3 km/h), as seen in Figure 18. Moreover, according to the simulation, and with the exception of the period between the estimated progression of 16h00 and 16h30 (blue and violet lines), the entire area burned with ROS exceeding 50 m/min.

The intensity of a fire at the front can be related to the difficulty of attacking it and the probability of success, as shown in Table 2. Observing again the simulated fire intensity (Figure 19 - bottom left) we see that, during the first moments of the fire, its intensity could have been above 10000 kw/m, were any efforts to contain it would be virtually impossible.

Observing all these data we can assume that, after escaping initial attack, and with the few resources available in the field, the fire spread with a ROS that would make unfruitful any firefighting strategy

Table 2. Difficulty of fire control related to fire line intensity

Danger class	Fire Control	Fire line intensity (kW/m)	Fire suppression interpretations
Low	Relatively easy	I< 500	Direct attack at fire's head or flanks by firefighters with hand tools and back-pack pumps possible. Light aerial means effective.
Moderate	Moderately difficult	500 < I <2000	Firefighting along the flanks and eventually some spots in the fire front. Water is needed to control the fire. Medium to heavy aerial means can be effective
High	Very difficult	2000 < I <4000	Any attempt to contain the fire's head limited to the use of aerial means. Control efforts may fail.
Very High	Extremely difficult	4000 < I <10000	Suppression action restricted to back and flanks of the fire. Direct control of the fire likely to fail. Indirect attack with heavy aerial means. Spot fires expected to appear.
Extreme	Virtually impossible	I > 10000	Extreme fire behavior. Number of spot fires can increase rate of spread. Direct attack ineffective. Ground attack limited to flanks and back. But with low probability of success.

(adapted from Alexander & Lanoville, 1989)

5.2.2. Phase 2 – fire approaching Quinta das Quebradas

The ignition used for the 2nd phase was coincident with the estimated perimeter of the fire at 18h30 of July 9th, including the spot fire. The results are shown in Figure 19.

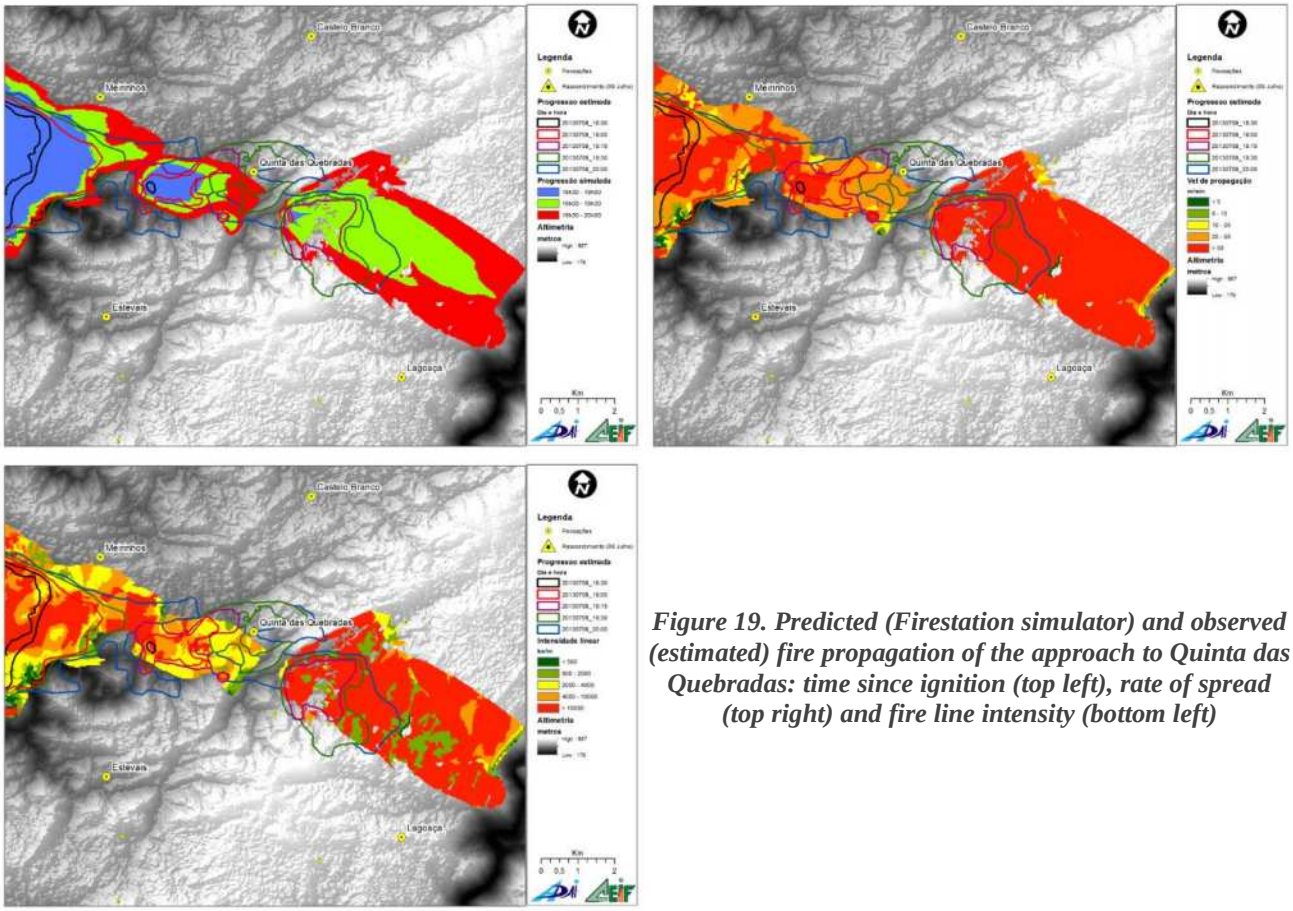

Figure 19. Predicted (Firestation simulator) and observed (estimated) fire propagation of the approach to Quinta das Quebradas: time since ignition (top left), rate of spread (top right) and fire line intensity (bottom left)

Simulation shows a fire intensity between 2000 and 10000 kw/m, with very few possibilities of a direct attack on the fire front. After passing through *Quinta das Quebradas* the fire gained intensity, mainly due to the change in fuels that were then dominated by shrubs.

5.2.3. Phase 3 – fire entering Ribeira do Inferno

The ignition in this phase corresponds to the area identified earlier when fire was progressing downslope (Figure 12) and at the time of the wind change. The simulation doesn't predict two fire "heads" but only one continuous front (Figure 21). Nevertheless the predicted rate of spread is above 20 m/min (1.2 km/h) and in a considerable area above 50 m/min (3 km/h). The higher values of intensity correspond to the fire entering *Ribeira do Inferno* and to the Southwest and Southeast of the simulated burned area.

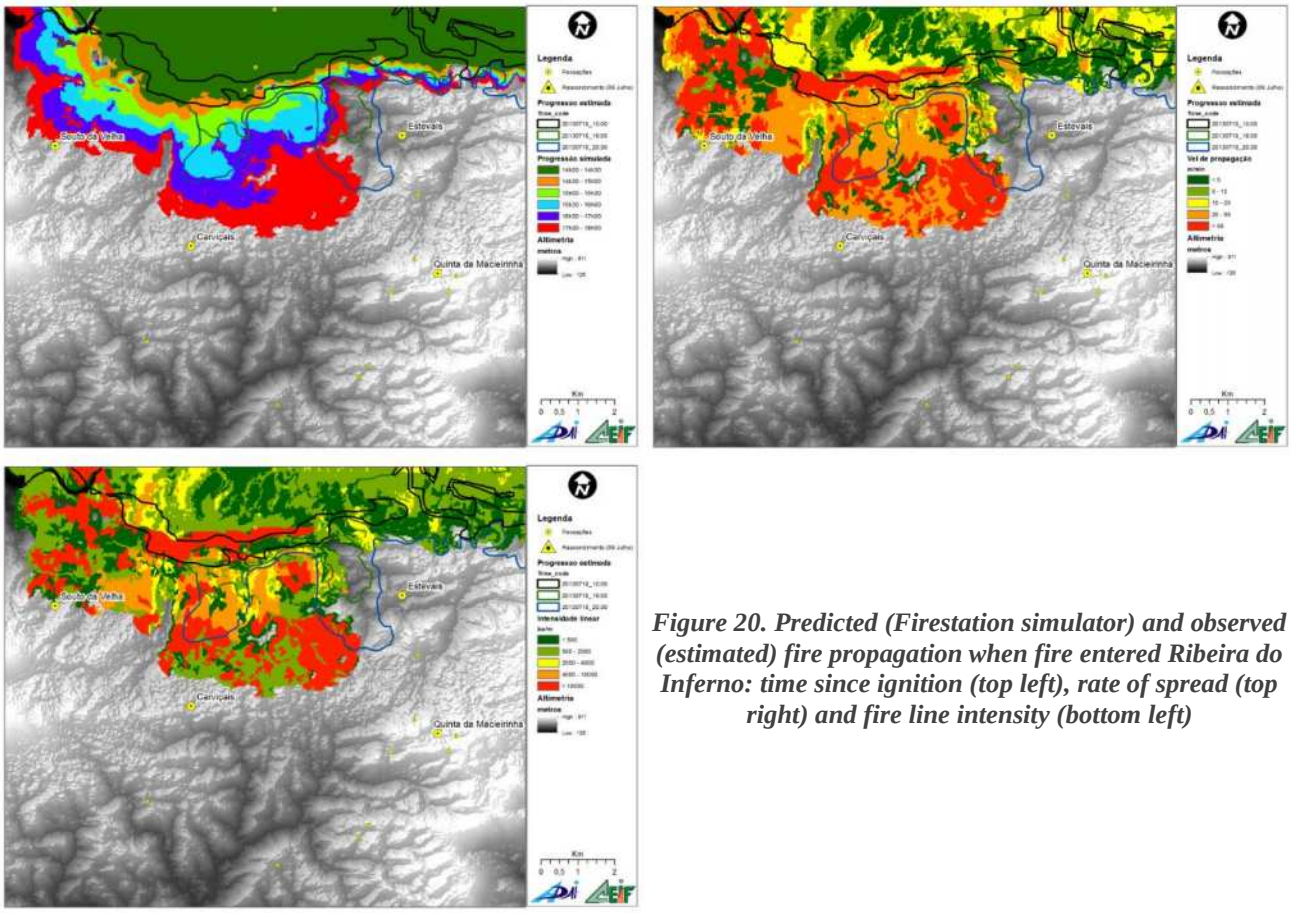

Figure 20. Predicted (Firestation simulator) and observed (estimated) fire propagation when fire entered Ribeira do Inferno: time since ignition (top left), rate of spread (top right) and fire line intensity (bottom left)

6. Conclusions and recommendations

The large fire of *Picões* had some moments in which any efforts from the firefighting crews to control it would not have been enough. There are 3 key moments, 2 of which with direct implications, that can explain the large area burned. The reconstitution we made is the closest possible to the real progress of the fire, although we admit that there may be some discrepancies with the actual progression. However, except for errors of detail, we believe to have recreated all the most important events accurately. The main conclusions we withdrew from this study were:

- The fire that occurred on July 8th in *Cilhade* was dominated and finished with an area of approximately 180 hectares burnt. After the mop up actions, surveillance was assured by teams who had already participated in the firefighting. These teams would perhaps not have the best state of mind and physical conditions to remain overnight and the following morning on surveillance. Vigilance was long because it was understood that, if there were any rekindle this would have to be controlled quickly under the threat of the fire gaining strength again. Probably would be a wiser decision to place new (fresher) crews on the vigilance. Despite of the

vigilance, on July 9th around 13h47 a rekindle of this first fire occurred. This was the first key moment of *Picões* large fire.

- The rekindle took place in a difficult access to ground crews and at a time when weather conditions were particularly adverse. A rekindle usually develops faster than a starting fire even more with these weather conditions. Although we have no data to confirm this, we believe that it was not detected in time. The difficulty in accessing the area allowed the fire to rapidly grow in area and intensity.
- The population of the affected area has a high aging index, on average 2 times higher than the national average but in some regions gets to be 10 times higher. This aging results in some degree of abandonment of agricultural practices and a lower availability to implement self-protection measures near the urban centres. This is particularly noticeable in the small villages, like *Quinta das Quebradas*.
- The villages and *Quintas* are not in large numbers but they are disperse and their access is very difficult. The firefighting crews deployed to protect the buildings had great difficulty, not only in reaching there but also later on in reallocating to actively fight the fire.
- There's an enormous lack of self defense culture among the majority of urban areas, despite of their size, as well as in isolated houses. Not only by managers, or politicians but also by the inhabitants themselves. The major consequence is that in most cases fighting the fire becomes secondary for the crews, as they have to protect houses and people first.
- The construction of the *Baixo Sabor* dam was at a very advanced state of execution, as were the preparatory measures necessary before the filling. Much of the valleys in this region, especially the main water lines had already been cleared of shrubs and trees. A very wet spring of 2013 resulted in a substantial herbaceous production, all over the country but especially in those areas that were devoid of vegetation. The existence of a large amount of dry and cured grass favourably influenced the rapid progression of the fire, especially on day 9th.
- During the afternoon of July 9th the fire reached velocities much higher than what we consider normal fire behaviour. Between 17h30 and 19h00 the fire ran about 6 km towards East, reaching *Quinta das Quebradas* with great violence. The protection of this small village was the second key moment of the fire. A large number of human and material resources were required for the defense of people and their assets, consequently abandoning the combat against the propagating fire.
- Fuels management in the area affected by the fire was incipient. Almost no fuel breaks are present in the area and the ones that exist lack maintenance.
- The water points' network in the area was not adequate, requiring extensive travel for water refuelling.
- Data analysis about terrain and weather forecasting is of great importance in fire behaviour prediction, even without taking into account the fuel. During the morning of July 10th this prediction did not motivate a timely reaction by the Commanding Officers and this was the third key moment of the *Picões* fire.
- Expert fire behaviour prediction is still not being taken into account on normal fire management activities, and we believe this to be a gap in the system that should be filled.

Abstract

Several spectral indices based on measurements in the optical domain have been proposed for the estimation of equivalent water thickness (EWT), which is defined as the mass of liquid water per unit of leaf surface. However, fire models rely on the live fuel moisture content (LFMC) as a measure of vegetation moisture. LFMC is defined as the ratio of the mass of the liquid water in a fresh leaf over the mass of oven dry leaf, and traditional vegetation moisture spectral indices are not as effective in capturing LFMC variability. Recently, the perpendicular moisture index (PMI), based on MODIS, was proposed to overcome this limitation and provide a direct measure of LFMC. The aim of this research was to understand the potential and limitations of the PMI in predicting fire hazard. To this purpose, more than 19000 fire records in Provence-Alpes-Côte d'Azur (31400 km^2), France, Toscana (22994 km^2), Italy and Campania (13595 km^2), Italy, over heterogeneous periods between 2000 and 2012 were compared against PMI derived from MODIS reflectance images. Results show that PMI maps capture both year-to-year variability of vegetation condition and its evolution during the advancement of the dry season. The PMI appears to be correlated with mean rate of spread and mean number of fires.

Keywords*: MODIS; Live Fuel Moisture Content; Perpendicular Moisture Index; Fire hazard.*

Introduction

The remote-sensing community has developed a number of spectral indices based on broadband satellite measurements in the optical domain for the assessment of vegetation water content measured as equivalent water thickness (EWT), which is defined as the mass of liquid water per unit of leaf surface (e.g. Hunt and Rock 1989; Gao 1996; Pinty *et al.* 2002). However, fire models rely on the live fuel moisture content (LFMC) as a measure of vegetation moisture (Yebra *et al.* 2013). LFMC is defined as the ratio of the mass of the liquid water in a fresh leaf over the mass of oven dry leaf, and spectral indices proposed so far are not as effective in capturing LFMC variability as with EWT (Danson and Bowyer 2004; Caccamo *et al.* 2012).

In a recent paper (Maffei and Menenti 2014), the perpendicular moisture index (PMI) was introduced to exploit MODIS spectral characteristics and to overcome some of the limitations of the traditional vegetation moisture spectral indices. The PMI is a direct measure of LFMC, but its potential in the evaluation of fire hazard is unexplored.

The objective of this research was to understand the potential and limitations of the PMI in predicting fire hazard, i.e. in providing relevant information on the characteristics of fires that might occur in a certain area. To this purpose, three large study areas were selected, and MODIS-derived maps of PMI

were evaluated against fire occurrence records. The relationship between the PMI, the average fire propagation speed and the mean number of fires was investigated.

Materials and methods

Study areas

The research was performed on three study areas of the Western Mediterranean basin (Figure 1):

- Provence-Alpes-Côte d'Azur (PACA, 31400 km^2), France;
- Toscana (22994 km^2), Italy;
- Campania (13595 km^2), Italy.

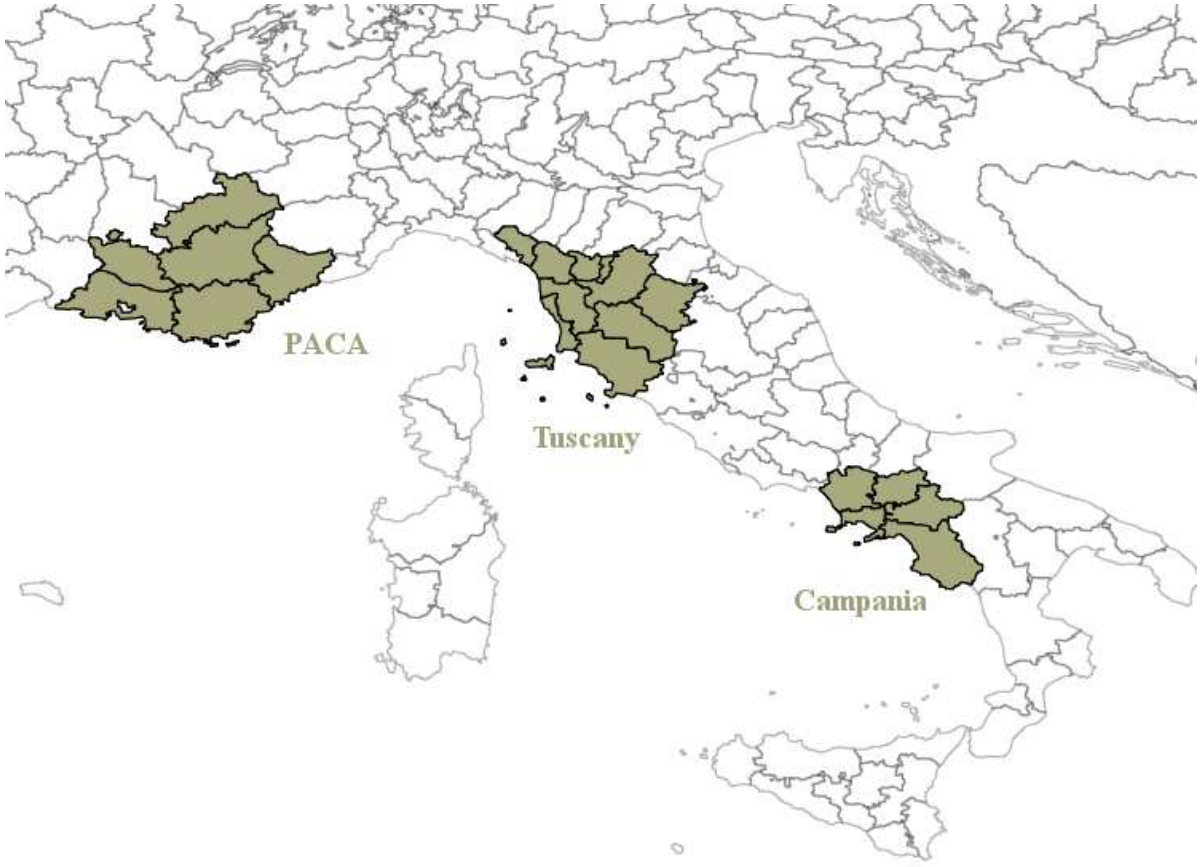

Figure 1. Study areas.

Fire data

Fire records from different sources were used in this research:

- PACA: a collection of more than 9400 fires between 2000 and 2012 extracted from the Prométhée database ("Prométhée: Forest fires database for Mediterranean area in France");
- Toscana: a database of more than 2300 fires records between 2000 and 2007, provided by the Regional Administration of Toscana;
- Campania: a database of more than 7700 fire records covering years between 2000 and 2008, provided by the Italian Forest Corps (*Corpo Forestale dello Stato*, CFS).

2.3. MODIS data

Moderate Resolution Imaging Spectroradiometer (MODIS) sensors mounted on Terra and Aqua satellites from NASA view the entire Earth's surface almost on a daily basis, recording radiance in 36 spectral channels ranging from the optical to the thermal domains. MODIS data are free of charge, and can be downlinked and processed at ground stations for the near-real-time delivery of derived products. For this research, 8-day composites of Terra-MODIS reflectance data (product MOD09A1) were retrieved from the Land Processes Distributed Active Archive Center ("LP DAAC") hosted by the United States Geological Survey (USGS). All composites covering June to September were selected, for the years corresponding to the availability of fire data in each study area.

2.4. The perpendicular moisture index

The perpendicular moisture index (PMI) was developed from the observation that, in the spectral plane spanned by MODIS channels 2 (0.86 μm) and 5 (1.24 μm), points characterised by the same value of LFMC lay on straight parallel lines. This led to the definition of a measure of vegetation moisture as the distance of a reflectance point in this plane from a reference line, according to equation:

$$PMI = -0.73 \cdot (R5 - 0.94 \cdot R2 - 0.028)$$

where R2 and R5 are reflectance measurements in MODIS channels 2 and 5 respectively.

2.5. Indirect validation of the PMI

Maps of PMI were calculated from MODIS data, and masked basing on CORINE Land Cover (CLC) classes. Due to a difference in the way the Italian and French fires databases were constructed, CLC mask for the Italian sites included all forests and natural areas classes, whereas in France it also included agricultural lands.

For each fire in the data sets, the value of the PMI was sampled from the PMI map corresponding to the MODIS 8-day compositing period previous to the date of the event. PMI values at fires' locations were compared to fire rate of spread. This parameter was computed from fire size and duration, and in this sense it does not give any information about the actual rate of spread; however, it provides information on "how fast" the area affected by the fire was burnt.

To understand the relationship between the number of fires and the PMI values, within each intermediate administrative unit (departments in PACA, provinces in Toscana and Campania), the median PMI in an 8-day compositing period was calculated and the fires in the following compositing period counted. This led to the construction of a number of couples of values of PMI and number of fires that were grouped by regular intervals of PMI; in each group, the mean number of fires was calculated and assessed against PMI values.

3. Results

Maps of PMI show clear seasonal trends as well as year-to-year variability. In Figure 2 four maps produced from the MOD09A1 data of the 208th day (composite of days 201-208) of years 2003, 2004, 2005 and 2006 in PACA clearly show how spatial patterns of PMI vary for the same compositing period on a yearly base. Similar considerations can be drawn in Toscana (Figure 3) and Campania (Figure 4).

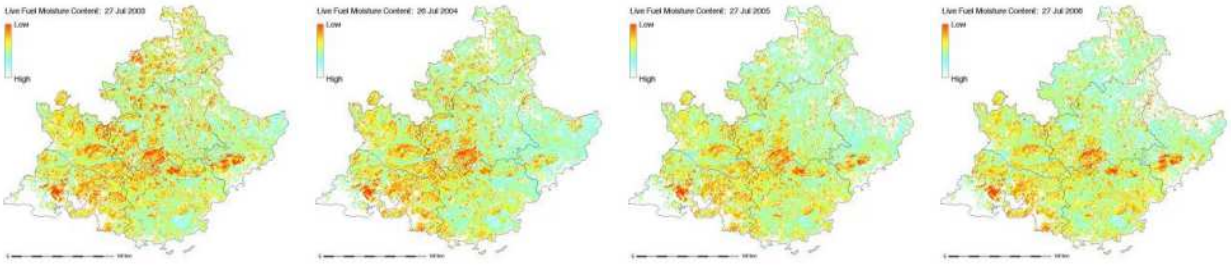

Figure 2. Maps of PMI in the same date of four successive years in the study area of PACA.

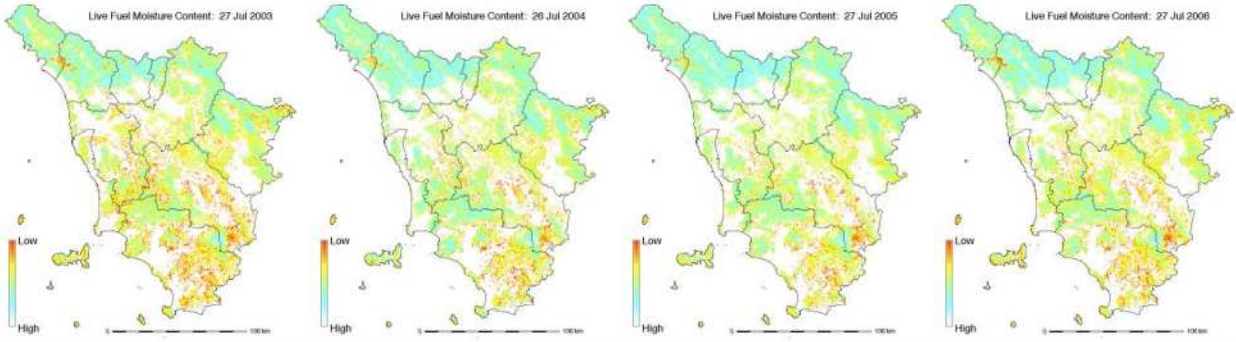

Figure 3. Maps of PMI in the same date of four successive years in the study area of Toscana.

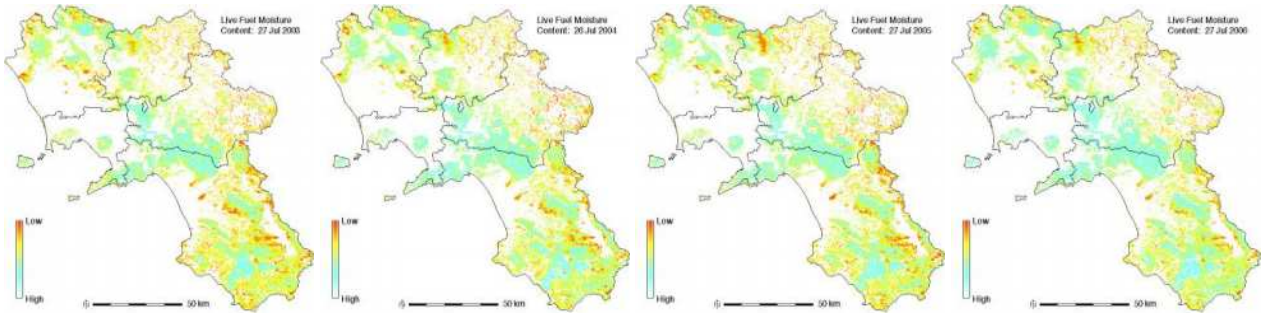

Figure 4. Maps of PMI in the same date of four successive years in the study area of Campania.

Figure 5 shows four successive 8-day maps of PMI of year 2003 in PACA. The PMI appears to capture the evolution of vegetation condition during the summer (dry) season, toward conditions of lower moisture content. Also in this case, similar considerations can be drawn in Toscana (Figure 6) and Campania (Figure 7).

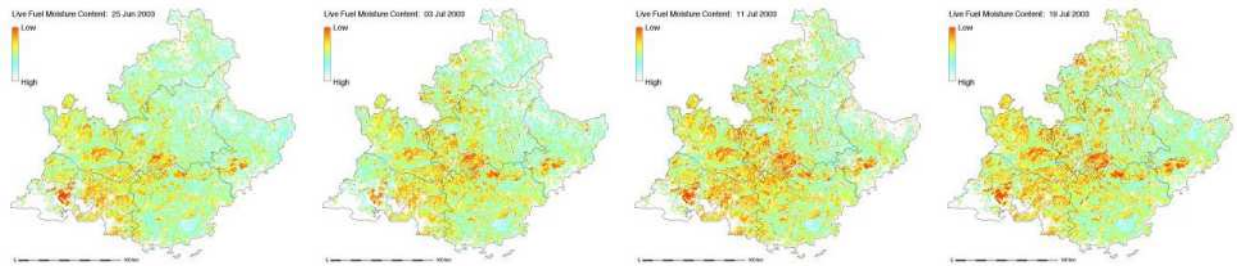

Figure 5. Maps of PMI in four successive compositing periods of the same year in the study area of PACA.

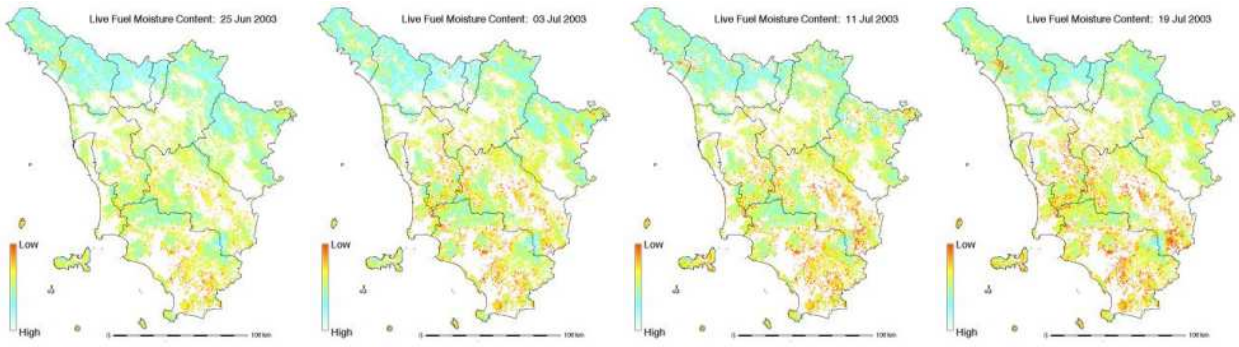

Figure 6. Maps of PMI in four successive compositing periods of the same year in the study area of Toscana.

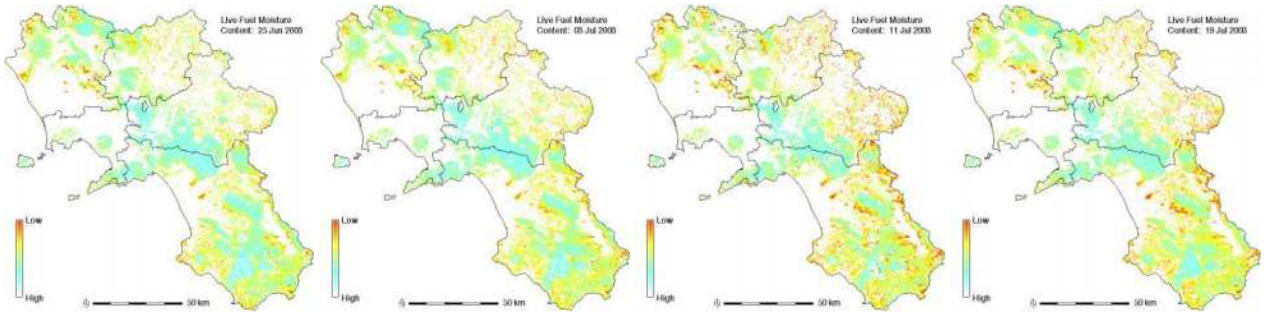

Figure 7. Maps of PMI in four successive compositing periods of the same year in the study area of Campania.

Fire rate of spread is affected by several factors of different nature. To isolate the role of vegetation moisture (as estimated by the PMI) from that of all the other factors, the PMI values associated to all fires in a study area were divided into bins delimited by their 0th, 10th, …, 100th percentiles. Within each bin, the mean value of the rate of spread was associated to the corresponding median value of PMI. This observation was only performed in Toscana and Campania, since the Prométhée database does not contain information on fire duration. Figure 8 shows evidence of the observed relationship between PMI and fire rate of spread. Higher PMI values imply a lower rate of spread, as would be expected in conditions of higher moisture content in leaf tissues. In both study areas the regression is linear; however, the dynamic range of the rate of spread differs.

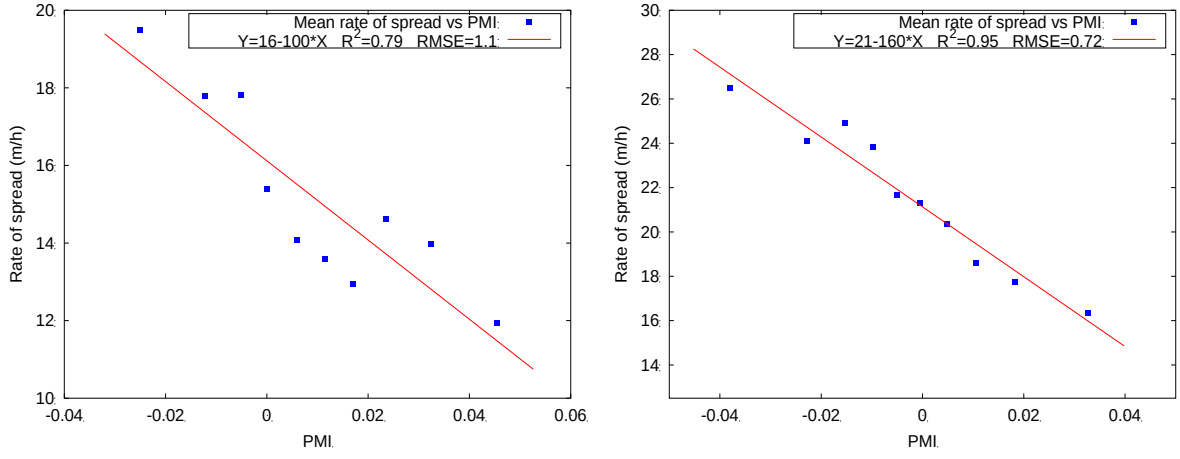

Figure 8. Relationship between PMI and mean rate of spread in Toscana (left) and Campania (right).

The variation of the mean number of fires with the median PMI value recorded in each department of PACA appears to follow a general trend (Table 1): when the vegetation moisture content is higher (the

PMI is higher), a lower number of fires is observed. Similar results were found in Toscana (Table 2) and Campania (Table 3).

Discussion

The recently introduced PMI tries to overcome some of the limitations of the traditional broadband spectral indexes in the quantification of LFMC. Its main limitation is given by its sensitivity to the leaf aria index. It is expected that the PMI underestimates vegetation moisture when vegetation cover is less dense. Its application to fire hazard mapping was here evaluated in three large study areas in France and Italy.

From a qualitative point of view, the PMI appears to capture the seasonal variation of vegetation moisture, exhibiting decreasing values of PMI during the evolution of the dry season (Figures 5, 6, 7). Although not shown here, this pattern was observed in every year under consideration. Similarly, the proposed spectral index shows clear year-to-year variability for any selected compositing period (examples shown in Figures 2, 3, 4).

More quantitative observations lead to the clear identification of a linear relationship between PMI and average fire rate of spread (Figure 8). However, it must be noted that the regression lines are different in Toscana and Campania, suggesting that landscape factors may affect it.
Clear trends are observed between median PMI value calculated at department / province level and the mean number of fires in each 8-day observation period (Tables 1, 2, 3). No assumptions were made on the actual distribution of the number of fires in each observation period, as this is part of further investigations.

Time series of land surface temperature from daily MODIS measurements for the prediction of fire hazard

Carmine Maffei, Silvia Alfieri, Massimo Menenti

[a]*Delft University of Technology, Stevinweg 1, 2628 CN, Delft, Netherlands, c.maffei@tudelft.nl, s.m.alfieri-1@tudelft.nl, m.menenti@tudelft.nl*

Abstract
Prolonged heat and absence of rainfall drive vegetation into water stress conditions that lead to an increase of its temperature. Since stressed vegetation is more prone to fire, it is expected that remote sensing mapping of temperature anomalies might be a viable tool to predict fire hazard. The identification of these anomalies requires the prior definition of a reference temperature against which compare actual recorded temperatures. This can be achieved by using long time series of satellite data and the HANTS (Harmonic ANalysis of Time Series) algorithm. The objective of this research was the characterisation of fire hazard using temporal series of land surface temperature (LST) derived from Terra-MODIS measurements. The investigation was based on a sequence of MODIS LST data from 2000 to 2008 in Campania (13595 km^2), Italy, and on a data set of 7700 fires recorded in the area in the same period. Missing and/or cloudy LST data were reconstructed by means of the HANTS algorithm applied to annual sequences of daily observations. The coefficients of the Fourier analysis were assessed against spatial patterns of fire occurrence. HANTS algorithm was also used to construct daily reference temperature maps against which to evaluate temperature anomalies and cumulated temperature anomalies. Results show that fires tend to occur in areas characterised by specific values of several Fourier coefficients with high significance, and to avoid the other areas. The amplitude of the second harmonic is the only Fourier coefficient dictating mean fire size. The mean fire size and the proportion of large fires correlate with both daily and cumulated thermal anomalies.

Keywords*: Land surface temperature; MODIS; Time series; HANTS; Fire hazard.*

Introduction

Prolonged heat and absence of rainfall drive vegetation into water stress conditions that lead to an increase of its temperature. Since stressed vegetation is more prone to fire, there might be a potential role for Earth observation technologies in mapping fire hazard (Leblon 2005), whereas it is proved that current orbiting instruments are able to detect anomalies in vegetation temperature.
The identification of temperature anomalies requires the prior definition of a reference temperature against which compare actual recorded temperature. By using long time series of satellite data it is possible to identify expected temporal patterns on a pixel-by-pixel basis. The HANTS (Harmonic ANalysis of Time Series) algorithm accomplishes this task by means of a Fourier series (Verhoef *et al.* 1996). HANTS has been reported to successfully provide reference data for both vegetation spectral indexes and land surface temperature (Julien *et al.* 2006).
The objective of this research was to develop and test a methodology for the characterisation of fire hazard from anomalies of daily land surface temperature (LST), as derived from thermal infrared measurements of the Moderate Resolution Imaging Spectrometer (MODIS) on board Terra satellite, evaluated against a reference temperature calculated with HANTS algorithm. Since maps of HANTS coefficients provide a detailed characterisation of the spatial and temporal pattern of surface temperatures, their potential to explain spatial patterns of fire occurrence was also investigated.

Materials and methods

Study area

The research focussed on Campania (13595 km^2), Italy. The Italian Forest Corps (*Corpo Forestale dello Stato*) provided a dataset of more than 7700 fire records covering years between 2000 and 2008. Data included date and time, coordinates, duration and extent of each event.

Figure 1. Study area.

MODIS land surface temperature data

A collection of daily diurnal (approximately 10.30 am local time) Terra-MODIS LST data from 2000 to 2008 was used for this research. These data are publicly available at the Land Processes Distributed Active Archive Center ("LP DAAC") hosted by the United States Geological Survey (USGS).

2.3. Fourier analysis of LST data

Series comprising three harmonics (365, 180 and 120 days) were fit to the data with two different methods, to achieve the diverse purposes of this research:

- HANTS was executed on each yearly sequence of daily LST data separately, to reconstruct missing or cloudy data (Roerink *et al.* 2000). The retrieved yearly images of Fourier coefficients (mean LST, amplitude and phase of the three harmonics) were then compared against spatial patterns of fire occurrence.
- The algorithm was executed on the whole 2000-2008 dataset to construct daily maps of reference temperature (Azzali and Menenti 1999). These served as a basis for the calculation of thermal anomalies.

2.4. Spatial patterns of fire occurrence

Yearly maps of Fourier coefficients were masked on forest and natural areas (as from the CORINE Land Cover 2000 map) and segmented into labelled classes. Masking was performed to ensure

consistency between the characteristics of the database, which includes only fires occurred in forests and other natural areas, and further analyses based on the spatial distribution of fires.
Spatial patterns of fire occurrence were assessed with respect to fire number and mean burnt area in terms of selectivity, i.e. by understanding whether in each class fire incidence is higher (preferred) or lower (avoided) than expected from a random null model (Bajocco and Ricotta 2007).

2.5. Analysis of LST anomalies

Daily maps of thermal anomalies (TA) were computed by subtracting the daily reference temperature from MODIS LST. Forest fires are expected to occur in areas where there has been a prolonged exposure to lack of rainfall and high air temperature. In these circumstances a temperature anomaly is observed over a number of consecutive days. For this reason cumulated anomalies (CTA) were calculated as the sum of all the observed thermal anomalies from the day when the thermal anomaly was first recorded in the pixel up to the current day. Each fire in the database was then associated to the values of TA and CTA observed at fire's location in the day previous to the event.

Results

The mean annual temperature and the amplitudes of the three harmonics used in the analysis have an evident role in determining spatial patterns of fire occurrence (Tables 1 to 4). Among the phase components, fire occurrence shows clear spatial selectivity only against the first (Table 5, other tables not shown). Mean fire size shows unambiguous spatial selectivity solely in the amplitude of the second harmonic (Table 3).
Temperature anomalies and cumulated temperature anomalies were evaluated against fire size by first calculating the conditional mean fire size observed when the TA (CTA) was larger of the considered value, and then plotting the calculated means against the values of anomaly (cumulated anomaly) used in the calculation. In a similar manner, the conditional proportion of large fires (larger than 16 ha, which is the 90th percentile in the study area) was evaluated against anomaly and cumulated anomaly.

Daily thermal anomalies appear to be related to fire size: with increasing values of the thermal anomaly, the expected mean fire size in all areas with thermal anomaly larger of that value increases (Figure 2, left). A similar pattern is observed with the conditional fraction of large fires (Figure 2, right). A wider dynamic range in fire size and fraction of large fires is observed when the same analysis is performed against CTA (Figure 3).

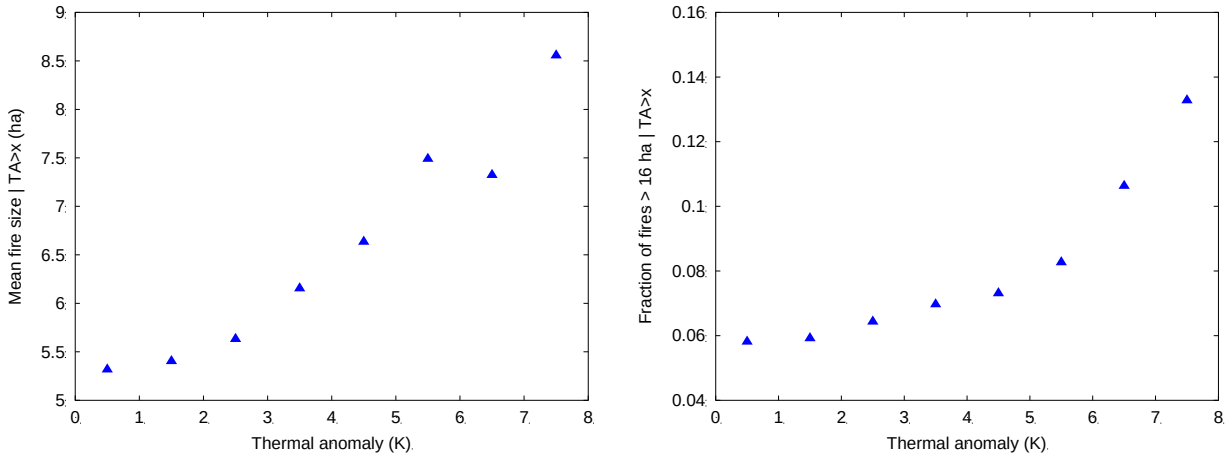

Figure 2. Relationship between conditional mean fire size (left) and conditional fraction of large fires (right) against values of thermal anomaly (TA) observed in the day previous to the event at fires' locations.

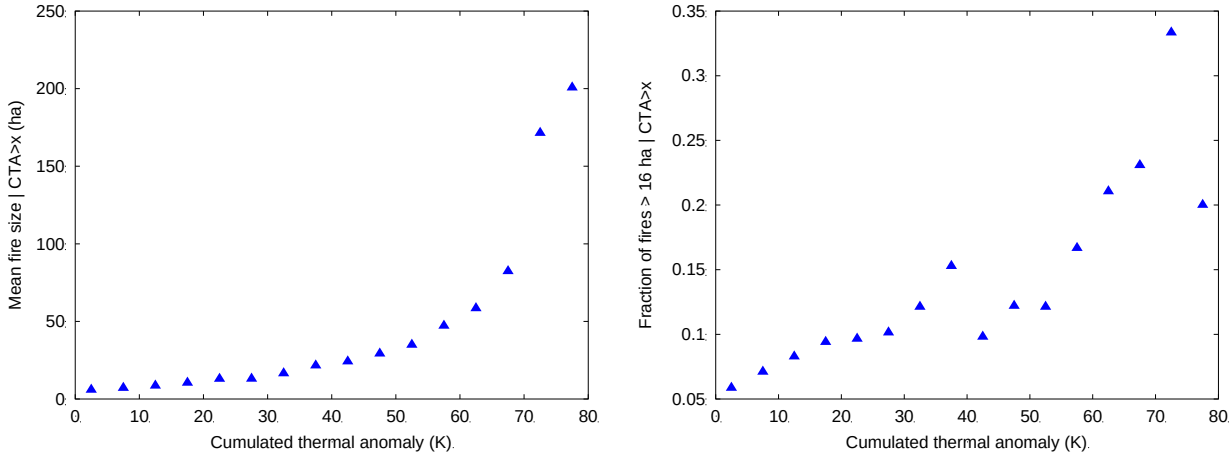

Figure 3. Relationship between conditional mean fire size (left) and conditional fraction of large fires (right) against values of cumulated thermal anomaly (CTA) observed in the day previous to the event at fires' locations.

Discussion

Results show that the HANTS algorithm plays an important role in both characterising spatial patterns of fire occurrence and in predicting mean fire size. Indeed, fires occurrence shows clear selectivity against mean value, amplitude of the three harmonics and phase of the first harmonic of LST computed on a yearly basis. Mean fire size shows selectivity only against the amplitude of the second harmonic. Here, a clear inverse relationship between number of fires and mean fire size is observed, with larger fires significantly preferring areas where the amplitude is larger (Table 3).
The only phase component of the Fourier analysis related to fires incidence is that of the first harmonic; fires significantly prefer areas where this phase is higher. The phase carries information on the timing

of fire events, and indeed a larger number of fires is observed where the phase is higher, i.e. when a prolonged warm season occurs.
A relationship was found between conditional mean fire size and thermal anomalies (Figure 2). With increasing values of the thermal anomaly, the conditional mean fire size increases. A similar trend is observed with the conditional fraction of fires larger than 16 ha. From the point of view of fire size, cumulated thermal anomaly maps carry a stronger informative content. CTA is a measure of heat "accumulated" in a certain area, providing more direct information on the prolonged exposure of vegetation to stress conditions. This is reflected in the prediction of expected mean fire size over two orders of magnitude (Figure 3). Moreover, when the cumulated anomaly is larger that about 60 K, a steep increase in mean fire size is observed, potentially allowing the production of more meaningful fire hazard maps as compared to TA.

Abstract[1]
Rekindles and false alarms are phenomena that have a significant presence in the Portuguese forest fire management system and an important impact on suppression resources in particular and fire management resources in general. As illustration, in 32,357 incidents that the suppression system handled in 2010, 12.3% were false alarms and 13.0% were rekindles, rising to 12.5% and 15% respectively, during the summer, the critical period.
In this work, we propose a discrete-event simulation model of a forest fire suppression system designed to analyze the joint impact of primary fires (ignitions), and non-value-added fire suppression activities such as rekindles (defects, inappropriate processing) and false alarms (motion) on the performance of the system. The work contributes to address a research gap concerning that impact, and features a novel application of simulation to suppression systems, as a screening tool to support more holistic analyses.
The model was implemented in ®ARENA and is applied to a case study of the district of Porto, Portugal, for the critical period of the forest fire season, between July and September 2010.
We study the behavior of the system's point of collapse, comparing the real base scenario with a benchmark scenario built with reference values for rekindles and false alarms, and also as a function of the number of fire incidents, considering historical variations.
The results of the analysis are useful for operational decision-making and provide relevant information on the trade-off between prevention and suppression efforts. In particular, we have found that reducing false alarms and rekindles to benchmark values would significantly reduce pressure on firefighting teams, enabling more effective suppression operations.

Keywords*: wildland fire suppression, rekindles, false alarms, hoax calls, discrete event simulation, wildfire*

Introduction

We propose in this work a discrete-event simulation model of a forest fire suppression system, designed to analyse the joint impact of ignitions and non-value-added fire suppression activities such as rekindles (defects, inappropriate processing) and false alarms (motion) on the performance of the system. The application of the model is illustrated with a case study of the district of Porto, in Portugal, for the critical period of the forest fire season, between July and September 2010. Our motivation for this work comes from the perception that rekindles (RK) and false alarms (FA) – malicious or good intent calls – have unusually high values in the Portuguese forest fire management system, and thus

[1] In this work we extend, with additional cost and optimization analysis, the recently published paper: Pacheco, A. P., J. Claro, and T. Oliveira. 2014. "Simulation analysis of the impact of ignitions, rekindles, and false alarms on forest fire suppression." Canadian Journal of Forest Research no. 44 (1):45-55. doi: 10.1139/cjfr-2013-0257.

represent an also unusually high burden on the suppression resources in particular, and fire management resources in general.
Since fire departments cannot presume that a call is an FA and must respond as they would to a fire (Ahrens 2003), the deployment of crews to non-existing fires, cause them to be unavailable for real fires, deprived of time to rest and recover, or hastily redeployed from other incidents, prematurely abandoning mop-up efforts and possibly creating conditions for fires to rekindle. In the little research available about FA performance measures (Flynn 2009), we have found values for the U.S. - 4.4% of all calls in 2009 and 4.1% in 2010 (Karter 2011); New Zealand - between 4.6% and 5.4% (Tu 2002); and the U.K. - 5.0% in Derbyshire (Yang *et al.* 2003) and 6.2% in South Wales (Corcoran *et al.* 2007), accounting for all emergency calls. These numbers suggest that there is still room for improvements regarding FA in Portugal.
The proportion of RK is also extremely high, still very much above the target defined in the "Technical Proposal for a National Plan of Defence of the Forest against Fires", PTPNDFCI (ISA 2005), or the values of other countries, such as the US, for which, in a report on the factors that contribute to new ignitions, Ahrens (2010) mention rekindles as responsible for 3% to 6% of the local fire department responses, between 2004 and 2008. The figures for FA and RK reveal futile suppression efforts that contribute to an overload of the suppression system.
Fire occurrence rates vary over both time and space (Martell 2001) and an increased response time is considered intrinsically linked to a decreased probability of containment of new fires (Quince 2009) and a larger intensity-weighted burned area (Mercer *et al.* 2008). Hence, it is reasonable to use response time as a performance measure to evaluate an initial attack (IA) and for operational decision-making. Minimizing fire response time is crucial to minimize the number of fires that escape IA (Islam *et al.* 2009). Therefore, the use of response time as a proxy of suppression effort is meaningful because it is related to available suppression resources (Butry 2007) and most strategic fire management planning models use this simple performance measure to reflect suppression cost effectiveness (Martell 2007; Quince 2009). For any fixed quantity of mobile suppression resources, such as IA crews, as the occurrence rate increases, so do response times, and thus, daily IA effectiveness will saturate at some rate, beyond which the proportion of fire escapes will increase (Cumming 2005). This limit where the system starts to fail is what we call "point of collapse", which we define as an average waiting time above ten minutes, based on conducted field interviews.

Materials and Methods

The model that we present was designed based on a literature review, field trips, informal meetings, formal recorded interviews, and data analysis of a database of fire suppression interventions. It was implemented in ®Arena, and used for a case study of the district of Porto in the critical period, between July and September 2010 (Pacheco *et al.* 2012b, 2012a).
There are four key motives for the choice of the district of Porto as a case study: the district is particularly interesting as it has a high number of fire occurrences and available data about deployed resources; the proportion of rekindles and false alarms is slightly below, but still in line with national figures; 84% of the ignitions, corresponding to 96% of the burnt area, occur in the three-month period considered; and 2010 is the first year to have appropriate data on false alarms available. The database was used, jointly with non-parametric statistical analysis, to parameterize and validate the model, which was subsequently used with sensitivity and optimization analyses to understand the impact of ignitions, rekindles and false alarms on the performance of the suppression system, particularly on the "point of collapse", the system dimension below which the mean time between the alarm and the IA starts to grow exponentially (Pacheco *et al.* 2014).

Results

Our data analysis of forest fire incidents in the district of Porto, between July and September 2010, highlights the importance of addressing the phenomena of rekindles and false alarms. Jointly, rekindles and false alarms represent almost 20% of the incidents, with daily peaks that are exactly coincident with the peaks of requests of suppression resources for real new forest fires. Although on average false alarms use resources for a time interval lower than an IA, there is a very high opportunity cost to that time. In the case of rekindles, this is worsened by the fact that rekindle suppression operations are much harder, as made clear from the fact that initial and extended attack durations are higher for rekindles.

The extra pressure that these additional classes of incidents put on the suppression system raises difficult challenges to its management. We believe that deviations from operational standards found in our analysis, such as the number of crews dispatched to an IA, or its duration, are evidence of this pressure. In a fire prone country with an extensive wildland urban interface (WUI), where the average number of fires in the last decade corresponds to over 50% of the whole EU Mediterranean region (San-Miguel-Ayanz *et al.* 2013), increasing suppression effectiveness is particularly important to avoid that small fires become mega-fires in days of critical fire danger (Tedim *et al.* 2013).

Using our simulation analysis, we found that bringing RK and FA down to benchmark levels, would lead to a reduction in the point of collapse of approximately 9.8%. This means that managing FAs, for instance, will lead to a lower number of events in the system, which reduces pressure and releases resources that become available for real fires and to invest more time in mop-up, thus reducing the number of rekindles, contributing again to reduce the number of events, and so on, in a positive feedback loop. This highlights as well the risk of not managing FAs (Pacheco 2011).

Another very important challenge for the suppression system is the huge inter-annual variability of the number of ignitions. We sought to characterize the impact of overall ignitions on the point of collapse and, for the range of values observed between 2001 and 2010, we found a linear relationship between the number of ignitions and the point of collapse, with a decrease of 1.00% in the daily rates of ignitions leading to between 0.85% and 0.96% reduction in the number of required suppression teams, in the range that we studied. Since 98% of ignitions are of human origin (arson, negligence or accidental) this indicator provides a relevant threshold for the investment in prevention: a reduction of 1% in ignitions allows for a reduction of the point of collapse of one firefighting team, inverting the vicious circle more fire, more teams.

A final analysis that we performed aimed at comparing the point of collapse criterion with a cost criterion. Two simulation optimization analyses, with each of the criteria, led to the same result in the minimum number of crews, supporting the relevance of the point of collapse as a useful indicator in capacity decisions for a suppression system. Arriving early increases the probability of containing the fire in its initial stage and, additionally, if the resources are insufficient, the pressure to attack starting fires increases the premature abandonment of mop-up operations of already controlled fires, leading later to more rekindles and thus even more fires.

Abstract
The problem of forest fires in the wildland-urban interface raises the issue of security of wood-framed constructions. The ability of external wooden walls to resist against fire exposure constitutes the framework of the present study. The flammability of the samples of wooden planks from framing lumber of *Pinus sylvestris, Apuleia leiocarpa* and *Pinus pinaster* used in a house construction in Portugal was assessed. The influence of the wood density on time to ignition, position and time of combustion phases (drying, pyrolysis and char combustion), mass loss decay, heat release rate and total heat released was evaluated.

Keywords*: wildland urban interface, flammability, wood-framed construction*

Introduction

In the United States of America, Canada, Australia and some countries in Northern Europe, wood-framed houses with up to two floors are the most common type of residential buildings, particularly in rural areas. According to Gustavsson *et al.* (2006), the market share of wood in construction of single-family houses constitutes 90-94% in North America, and 76-85% in Canada. It varies largely in Europe. In Scandinavian countries and Scotland, the share of timber-framed housing is 60-90% (Tykkae *et al.* 2010), while in Central Europe it ranges between 10 and 50% (Richter, 2012). Lowest values (<5%) were registered for Mediterranean countries (Gustavsson *et al.* 2006, Richter 2012). Regarding multi-family (multi-story) residential houses, the use of wood as the main structural material is much lower, with a market share of 2-10% in European countries and 4% in North America (Tykkae *et al.* 2010, Richter 2012).
Low construction costs, durability, thermal comfort, attractive facade, and limitless architectural possibilities of wooden houses encourage the use of wood in construction. The problem of GHG emissions and efficient ways of carbon storage enhances the usefulness of wooden buildings and the benefits of wood as a sustainable building material within the concept of green buildings (Naturally: wood 2011). Satisfactory performance of wood-framed buildings in earthquakes is another positive factor for use of wood in construction (Rainer and Karacabeyli 2000, Ceccotti 2008).
The efforts of industry, research activities, policies and governmental initiatives create the basis for wood-based construction systems, and statistics confirm the increased use of wood in residential and commercial buildings, especially in European countries. Portugal follows this trend, and the construction of wood-framed houses in rural areas is growing. Since 2006, an increase of the number of small enterprises working in wood-building construction sector was verified (Morgado *et al.*, 2011).
The problem of forest fires in the wildland-urban interface (WUI), which is critical in USA, Canada, Australia, Mediterranean countries and Portugal, raises the issue of security of wood-framed constructions, which constitutes the framework of the present study.
Many different types of soft and hard wood with a wide variety of characteristics are available for building construction. Soft and hardwoods are considerably different in flammability properties and combustion (Janssens 1991, Drysdale 2011, Cholin 1997, White and Dietenberger 1999, Van Loo and

Koppejan 2008). Wood type and species influence the combustion process through physical/chemical characteristics such as chemical composition, volatile content, density and porosity. The chemical composition is related with the gross calorific value, emissions and ash-content. Together with the volatile content, it also influences the thermal behaviour of wood. The density, varying within each tree and also significantly between hardwoods and softwoods, is related with the burning time and the total energy released. The porosity influences the burning rate.
Ignitability and heat release rate are determining parameters in the evaluation of fire hazards and combustibility of a material, and are essential for fire safety engineering towards a building design. The objective of the present work was to study the flammability of *Pinus sylvestris*, *Apuleia leiocarpa* and *Pinus pinaster* woods, used in wood-framed construction in Portugal. The influences of the wood density on the time to ignition, the time and duration of the combustion phases (drying, pyrolysis and char combustion), the mass loss decay, the heat release rate and the total heat released were evaluated.

Materials and methods

Wooden material

The samples of wooden planks from framing lumber used in a house construction were provided by the company Exotic House - Casas de Madeira, Lda (http://www.exotic-house.pt/Index.html). In the house under construction where the samples were collected (Figure 1), *A. leiocarpa* wood, imported from Brazil, was used for external walls, and *P. sylvestris* wood, imported from Northern Europe, for internal walls. The response of these wood species to heat flux exposure was compared with that of *P. pinaster* wood, the native species with a great potential for the construction industry.

Figure 1. Wood-framed house under construction

The density of wood at 12% moisture content for collected wooden planks was 870 kg/m^3 for *A. leiocarpa*, 472 kg/m^3 for *P. sylvestris*, and 582 kg/m^3 for *P. pinaster*.
To protect wood from insect and fungal attack, wooden planks were submitted to chemical treatment. Used for internal walls, low dense *P. sylvestris* wooden planks were treated by substances against insect and fungal attack and impregnation and thixotropic varnishes. Used for external walls, denser *A. leiocarpa* wooden planks were treated only by impregnation and thixotropic varnishes. Flammability of wooden samples with and without chemical treatment was studied.

Samples preparation

Samples of 60×60×35 mm and 60×60×20 mm were cut from wooden planks (Figure 2). To measure the variation of the temperature inside the wood sample, holes were drilled at 5, 15 and 25 mm from sample surface to fix thermocouples (Figure 3).

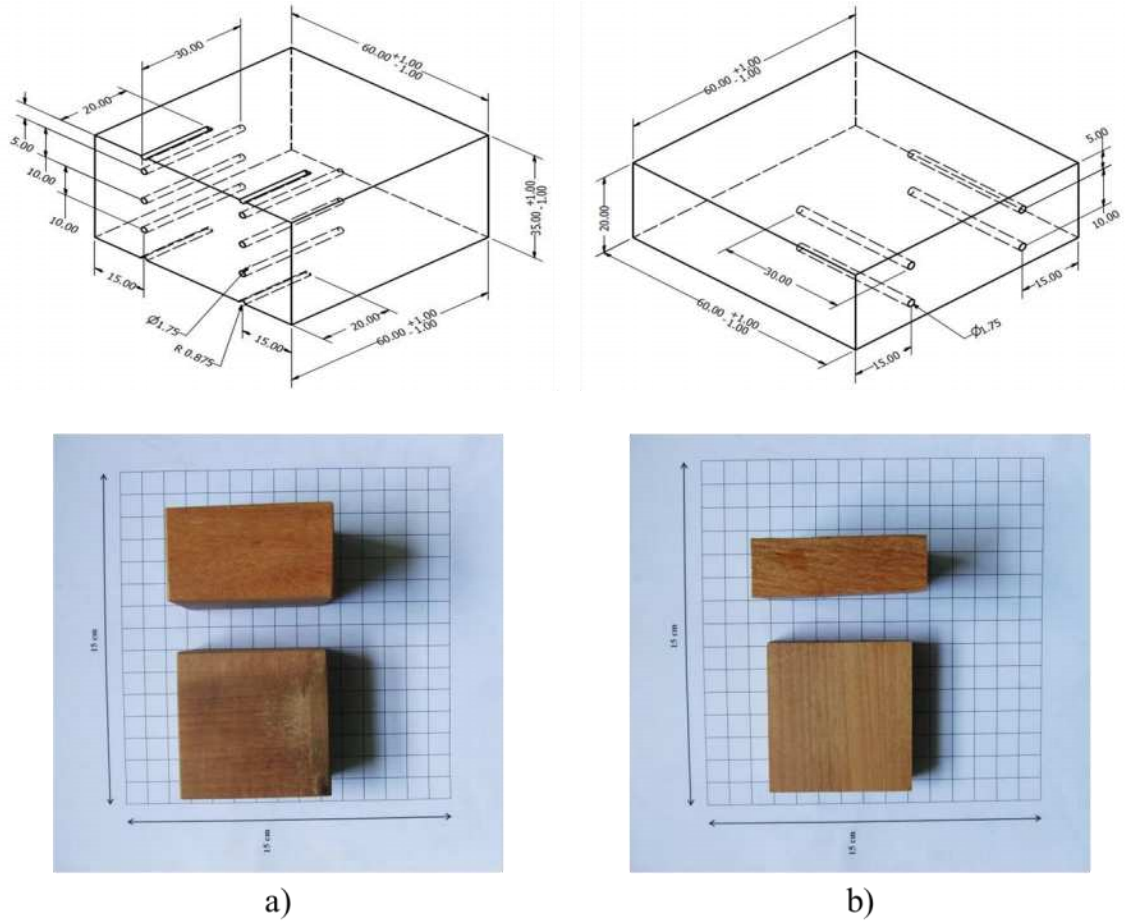

Figure 2. Two types of studied samples: a) 60×60×35 mm; b) 60×60×20 mm. In this figure, samples of Apuleia leiocarpa wood are presented.

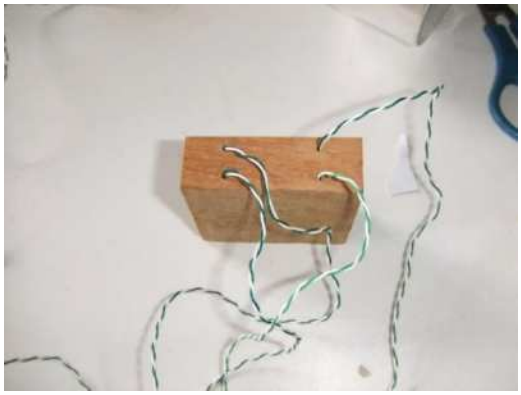

Figure 3. Apuleia leiocarpa wood sample with thermocouples fixed inside

2.3. Flammability test

Flammability tests were performed in a cone calorimeter (Figure 4) at a constant heat flux of 16kW/m^2. At least three replicates of each sample types were made. Samples were laterally wrapped in a single layer of aluminium foil and placed in horizontal orientation on calcium silicate support. A fuel sample was permanently radiated and an ignition source (pilot flame) provided. During the test, the sample mass was continuously measured using an AND FXi3000 electronic balance and the time variation of the temperature inside the wood samples was measured and registered using thermocouples, fixed inside and on the sample surface and connected to a PICO TC-08 data logger. Mean values of the studied parameters are reported.

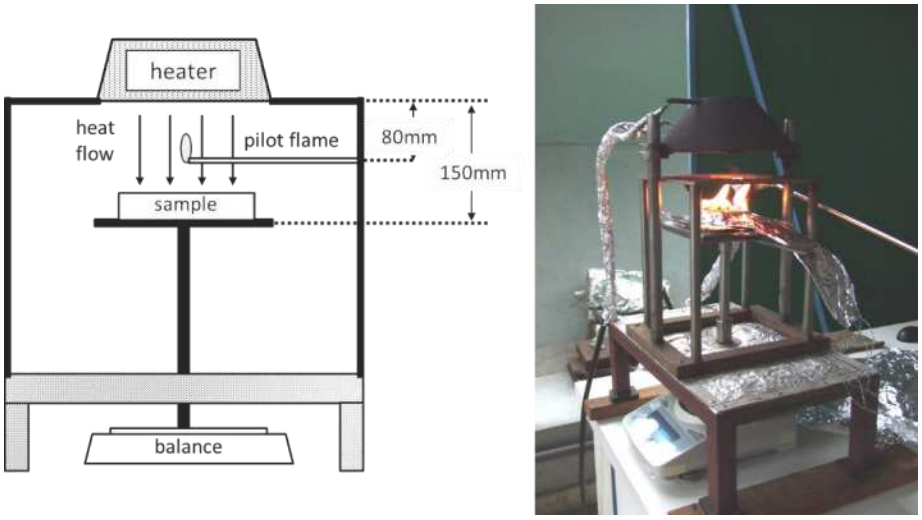

Figure 4. Sketch of cone calorimeter and experimental set-up for the flammability test

The heat release rate (HHR) was evaluated using the equation:

$$HRR = \dot{m} \times NCV$$

where $\dot{m} = -dm/dt$ is the mass loss rate and *NCV* is a net (or low) calorific value. Values of the *NCV* referred by Telmo and Lousada (2011) were assumed. For *P. pinaster*, the *NCV* was of 16.936 MJ/kg. For *P. sylvestris* and *A. leiocarpa*, mean values for softwoods (16.423 MJ/kg) and hardwoods (16.030 MJ/kg) were taken as a reference.

The total energy released was evaluated by:

$$q = \int_0^{t_f} \dot{q}\, dt = (m_i - m_f) \cdot NCV$$

where t_f is the time when the test was complete (flameout); $\dot{q}$ is the heat release rate; and m_i and m_f are the initial and final masses of the sample, respectively.

Results and discussion

3.1. Time to ignition

Figure 5 shows the results of time to ignition (t_i) measurements for *A. leiocarpa*, *P. sylvestris*, and *P. pinaster* wood samples, with and without chemical treatment. Characterized by highest density (870 kg/m^3), *A. leiocarpa* wood has longest time to ignition (t_i = 66 s) as compared with *P. pinaster* (582 kg/m^3, t_i = 28 s) and *P. sylvestris* (472 kg/m^3, t_i = 24 s) woods. Despite the small difference in density,

denser *P. pinaster* wood took a longer time to ignition than less dense *P. sylvestris* wood. Chemical treatment reduced time to ignition by 23% for *P. sylvestris* wood (24 s for non-treated and 18 s for treated wood) and 27% for *A. leiocarpa* (66 s for non-treated and 48 s for treated wood).

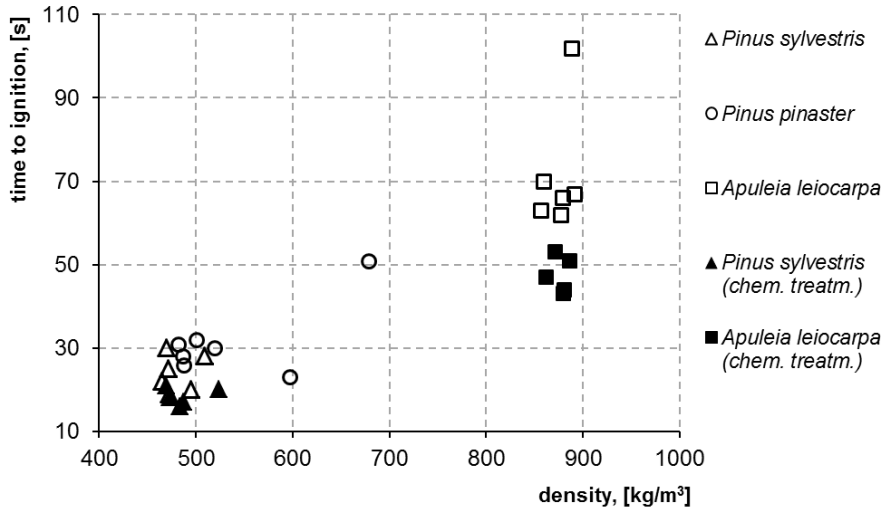

Figure 5 –Influences of density of wood and of chemical treatment on the time to ignition

Temperature variation

Figure 6 shows time-temperature curves for the surface and interior parts of the samples (at 5, 15 and 25 mm from the surface) for *P. sylvestris* and *A. leiocarpa* wood samples. The effect of wood density on the temperature variation, where higher density corresponds to lower temperature for all depth levels, was observed. The difference in the registered temperatures is greater on the sample surface and at a 5 mm depth, which may be explained by time to ignition, which is shorter for less dense *P. sylvestris* wood. Smaller and similar differences of temperature for *P. sylvestris* and *A. leiocarpa* wood were observed at 15 and 25 mm depths.

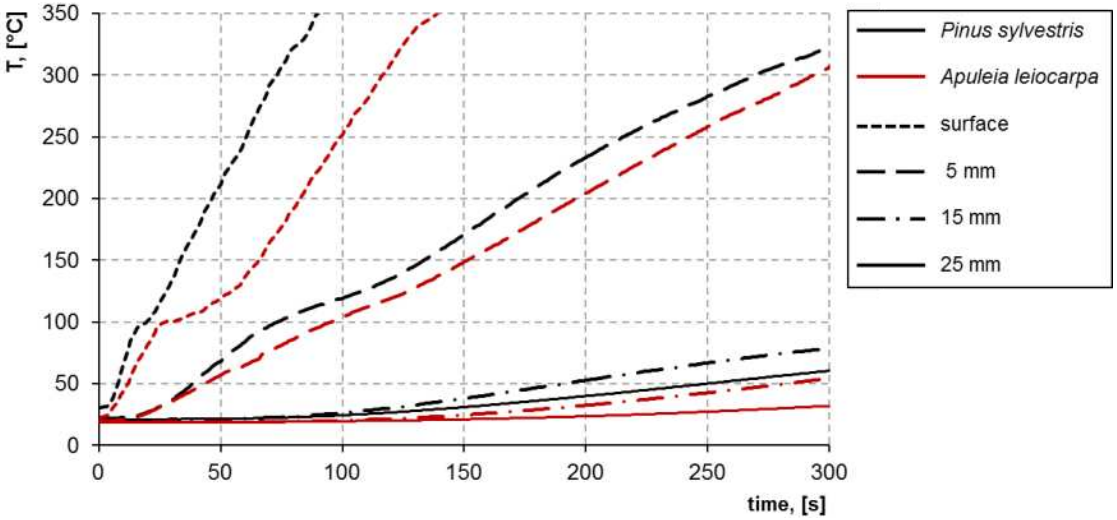

Figure 6. Temperature variation on the surface and inside the sample for Pinus sylvestris and Apuleia leiocarpa woods

The effect of chemical treatment on the temperature variation on the surface of the sample is more notable for *P. sylvestris* wood (Figure 7**)**. The difference between surface time-temperature curves for non-treated and treated *P. sylvestris* wood is higher as compared with *A. leiocarpa* wood, which may be related to the more complex chemical treatment applied to *P. sylvestris* wooden planks.

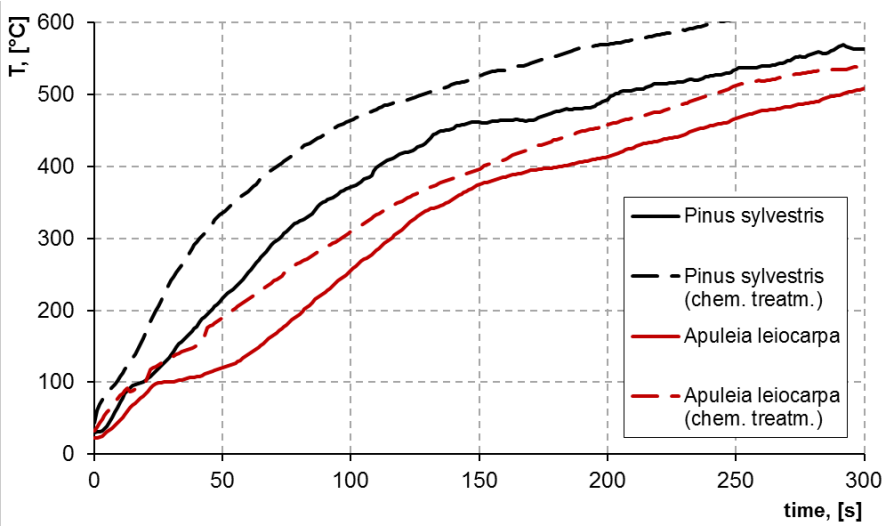

Figure 7. Temperature variation on the surface of the sample for Pinus sylvestris and Apuleia leiocarpa woods, with and without chemical treatment

3.3. Mass loss rate, heat release rate and total energy released

The mass loss ($\Delta m = m_f - m_i$), the heat release rate, HRR, and the total energy released (q) increase with increasing density of the wood. **Erro! A origem da referência não foi encontrada.** shows the mass loss rate and HRR curves for the studied wood species. Due to the greater time to ignition, the mass loss rate for *A. leiocarpa* wood starts growing later than for *P. sylvestris* and *P. pinaster* woods (Figure 8a). The highest maximum value of mass loss rate (0.051 g/s) was obtained for *A. leiocarpa* wood. Similar and lower values were found for *P. sylvestris* and *P. pinaster* wood (0.047 and 0.045 g/s, respectively). As the gross and net calorific values are lower for hardwoods than for softwoods, the difference in positioning of HRR curves as compared mass loss rate curves will decrease. Figure 8b shows that the HRR curve obtained for *A. leiocarpa* wood is less distant from HHR curves for *P. sylvestris* and *P. pinaster* wood. The maximum values of HRR are 214 kW/m^2 for *P. sylvestris*, 213 kW/m^2 for *P. pinaster* and 228 kW/m^2 for *A. leiocarpa* woods. The values of mass loss Δm and of the total energy released are 28.37 g and 10.53 MJ/kg for *P. sylvestris*, 32.28 g and 10.79 MJ/kg for *P. pinaster*, and 54.26 g and 12.12 MJ/kg for *A. leiocarpa*, respectively.

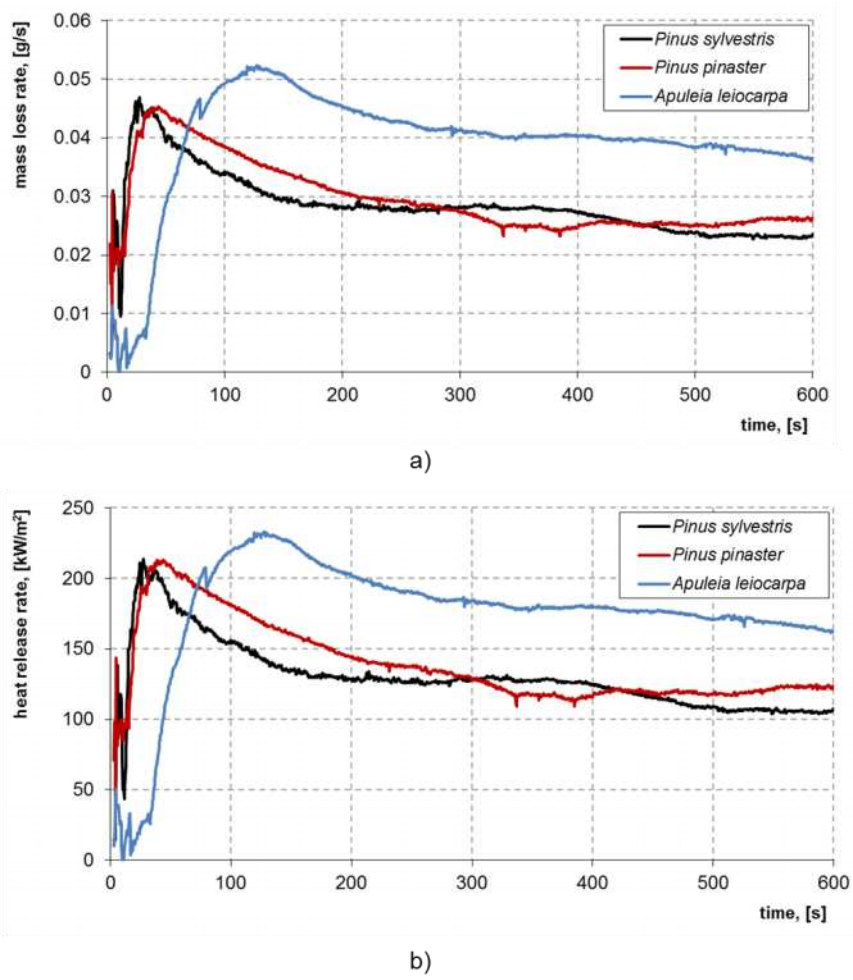

Figure 8. Mass loss rate (a) and heat release rate (b) for Pinus sylvestris, Pinus pinaster and Apuleia leiocarpa woods

Conclusions

Most hardwoods have a higher density than softwoods and, consequently, are more resistant to fire than softwoods. The use of hardwood for external walls in wood-framed buildings increases the resistance of these constructions to fire exposure. Flammability parameters such as time to ignition, mass loss, heat release rate, temperature of ignition and variation of temperature inside the wooden samples of one hardwood (*Apuleia leiocarpa*) and two softwood species (*Pinus sylvestris* and *Pinus pinaster*) used in construction of wood-framed buildings in Portugal were studied. Under a constant heat flux of 16kW/m^2, the time to ignition of *A. leiocarpa* wood (hardwood) was more than twice longer as compared with two softwood species (*P. sylvestris* and *P. pinaster*) and, consequently, a slower temperature rise on the wooden sample surface was verified. However, *A. leiocarpa* wood showed higher peak values of the mass loss and heat release rates, i.e. higher fire intensity, when ignition occurs. Higher mass loss rate also results on higher quantity of toxic gases resulting from combustion. The use of chemical treatments shortens the time to ignition, an effect that was more pronounced in the case of *A. leiocarpa* wood than with *P. sylvestris* wood. On the other hand, resistance of denser hardwood to insect and fungal attack allows moderate chemical treatment usage, which positively leads to lower temperatures on the surface of the wooden samples after ignition. Inside the wood samples, the temperature tends to present similar variations in softwoods and in hardwoods as the depth increases. Thus, for any wood type, the thickness of the wooden planks used in the building envelope construction may be an important parameter to control the temperature rise at the inner

surface of the external walls, in case of intense heat fluxes in the outside, and thus prevent ignition of flammable materials inside the construction.

Acknowledgments

Authors are thankful to Eng. José Neves of the company Exotic House - Casas de Madeira, Lda. for supplying wooden planks from framing lumber, and to Armindo G. Teixeira (UTAD) and António Cardoso (ADAI) for the technical support in preparing the samples.

Fire Risk Assessment and Climate Change

A new calibration for Fire Weather Index in Spain (AEMET)

Romero, R., Mestre, A., Botey, R.

Agencia Estatal de Meteorología (Aemet), Spain, rromerof@aemet.es, amestreb@aemet.es, mboteyf@aemet.es

Abstract
The Fire Weather Index (FWI) is an index based on meteorology. The system consists of six components and it depends on weather variables taken each day at 12 UTC (or forecasted for 12 UTC): temperature, relative humidity, wind speed and rain during the previous 24 hours. FWI is an accumulative index, that is, subindexes values for a day D are used for the calculation of the final index the following day D+1. The procedures for the calculation for Iberian Peninsula and Balearic Islands were initialized by AEMET in 2008 March, being executed daily without interruption since then. Canarias Islands procedures are being executed since 2013 May. Procedures include analysis for day D and forecasts for day D+1, D+2 and D+3 in a 0.5ºx0.5º horizontal resolution grid cells with data provided by the HIRLAM numerical weather prediction model.
FWI values calculated for a determinate localization have no meaning for themselves. It's necessary to make a correspondence between the danger classes and those FWI values in order to calibrate it. For this, five danger classes split has been calculated only from a climatological point of view. Each class or risk level corresponds with a range of values of FWI between different percentiles. Thus, fire low risk corresponds with FWI values below its percentile 40; moderate risk with FWI values between percentile 40 and 65; high risk between percentile 65 and 85; very high risk between percentile 85 and 95 and extreme fire risk above its percentile 95. In the calculation of the different percentiles, a data period from May 2008 until December 2013 has been used. This period will be updated with most recent values according to the month pass.

***Keywords**: FWI, fire risk, danger classes, calibration, validation*

Introduction

The purpose of the Fire Weather Index (FWI) system, based on the Canadian system, is to account for the effects of weather on forest fuels and forest fires. The system consists of six components: three primary subindexes representing fuel moisture and following daily changes in the moisture contents of three classes of forest fuel with different drying rates, two intermediate subindexes representing rate of spread and fuel consumption, and a final index representing fire intensity as energy output rate per unit length of fire front.
The three primary subindexes are, according to *Van Wagner, C.E., (1987)* :

- Fine Fuel Moisture Code (FFMC), which represents the moisture content of litter and other cured fine fuels in a forest stand, in a layer of dry weight about 0.25 kg/m^2.
- Duff Moisture Code (DMC), which represents the moisture content of loosely compacted, decomposing organic matter weighing about 5 kg/m^2 when dry.
- Drought Code (DC), which represents a deep layer of compact organic matter weighing perhaps 25 kg/m^2 when dry.

Those three primary subindexes plus wind are combined in pair to produce the two intermediate subindexes, ISI and BUI. Final index, FWI, is formed by a combination of the two intermediate subindexes. According to *Van Wagner, C.E., (1987)* :

- Initial Spread Index (ISI), a combination of wind and the FFMC that represents rate of spread alone without the influence of variable quantities of fuel.
- Buildup Index (BUI), a combination of the DMC and the DC that represents the total fuel available to the spreading fire.

- Fire Weather Index (FWI), a combination of the ISI and the BUI that represents the intensity of the spreading fire as energy output rate per unit length of fire front.

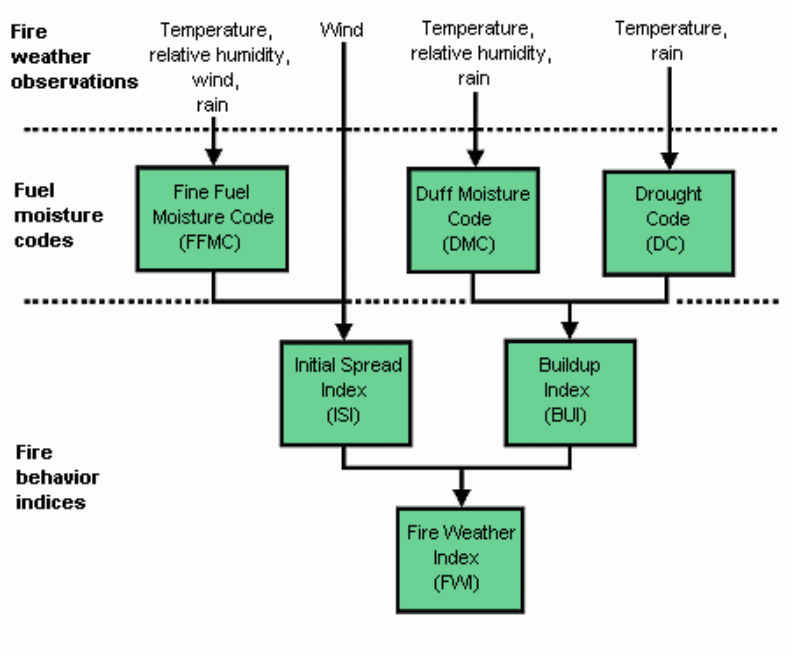

Figure 1. FWI system components.

The system depends on weather variables taken each day at noon Universal Time Coordinated UTC (or forecasted for 12 UTC): temperature, relative humidity, wind speed and 24 hours-precipitation values. FWI is an accumulative index, that is, subindexes values for a day D are used for the calculation of the final index the following day D+1. Moreover, in order to guarantee the estimations stability, calculations must be initialized in a high rain period, when fine fuel moisture content is maximum.
Two different procedures are used in AEMET in order to calculate the FWI system components: *Iberian Peninsula and Balearic Islands* on the one hand and *Canary Islands* on the other hand.
Procedures for the calculation for *Iberian Peninsula and Balearic Islands* were initialized by AEMET in 2008 March, being executed daily without interruption since then. Procedures include analysis for day D and forecasts for day D+1(H+24), D+2(H+48) and D+3(H+72) in a 0.05ºx0.05º horizontal resolution grid cells for D+1 and 0.16ºx0.16º horizontal resolution grid cells for D+2 and D+3. Meteorological data are provided by the HIRLAM numerical weather prediction model. *Canary Islands* procedures are being executed since 2013 May. Procedures include analysis for day D and forecasts for day D(H+12), D+1(H+36) and D+2(H+60) in a 0.05ºx0.05º horizontal resolution grid cells for D and D+1 and 0.16ºx0.16º horizontal resolution grid cells for D+2. Meteorological data are provided by the HIRLAM numerical weather prediction model.

Methods

FWI values calculated for a determinate localization have no meaning for themselves. It's necessary to make a correspondence between the danger classes and those FWI values. Furthermore, non meteorological factors such as type, quantity and fuel distribution must be taken in account when assigning danger classes in the different areas. In order to represent a range of climatological conditions, FWI values are calculated using daily weather data provided by the numerical weather prediction model HIRLAM during several years. Cutoff values for the different danger classes are calculated from the value at different percentiles.

Old calibration Peninsula and Balearic Islands.

Five danger classes have been established in AEMET: low, moderate, high, very high and extreme fire risk level. Until 2013, according to that division, FWI had been calibrated for the location of a set of observatories and automatic meteorological stations by setting four threshold values for delimitating those five danger classes. From those four threshold values, by interpolating, a file with the four threshold values in every grid point was generated. Fire risk level is calculated by comparing, in every grid point, FWI daily value with the corresponding four threshold values for that grid cell. That calibration has been carried out by starting off FWI values at meteorological stations and historical records of burned area of fires surrounding those stations. A 10 years period (1997-2006) only with months between June and October was considered.

New calibration Peninsula and Balearic Islands.

However, as we have considered that the fire risk level provided should only take into account meteorological and climatological factors, it's necessary to try another different calibration according to the above requirements. For this, five danger classes division has been calculated only from a climatological point of view. Each class or risk level corresponds with a range of values of FWI between different percentiles. Thus, fire low risk corresponds with FWI values below its percentile 40; moderate risk with FWI values between percentile 40 and 65; high risk between percentile 65 and 85; very high risk between percentile 85 and 95 and extreme fire risk above its percentile 95. In the calculation of the different percentiles, a daily data period from May 2008 until December 2013 has been used by using weather data provided by the numerical weather prediction model HIRLAM. This period will be updated with most recent values according to the month pass.

FWI values have been separated in two different periods; from May to October, and from November to April. Thresholds obtained for May-October period have been generated from FWI series values ranging from April to November during 2008-2013, thus, 8 months. In the other hand, thresholds generated for November-April period have been calculated from the whole FWI values series(2008-2013).

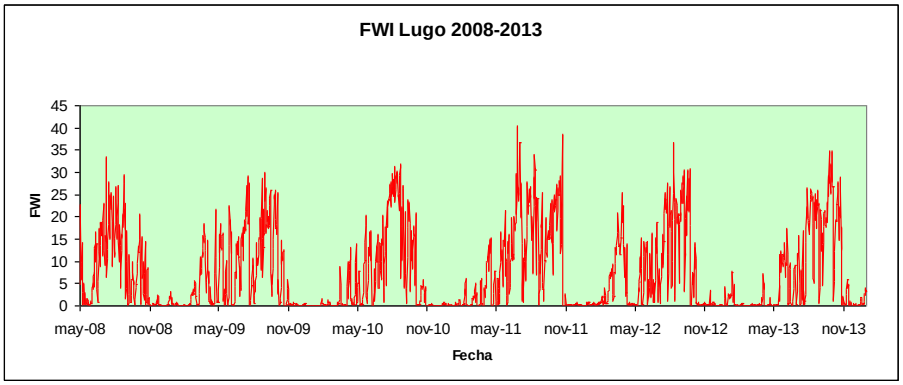

Figure 12. FWI values from January 2009 to December 2013

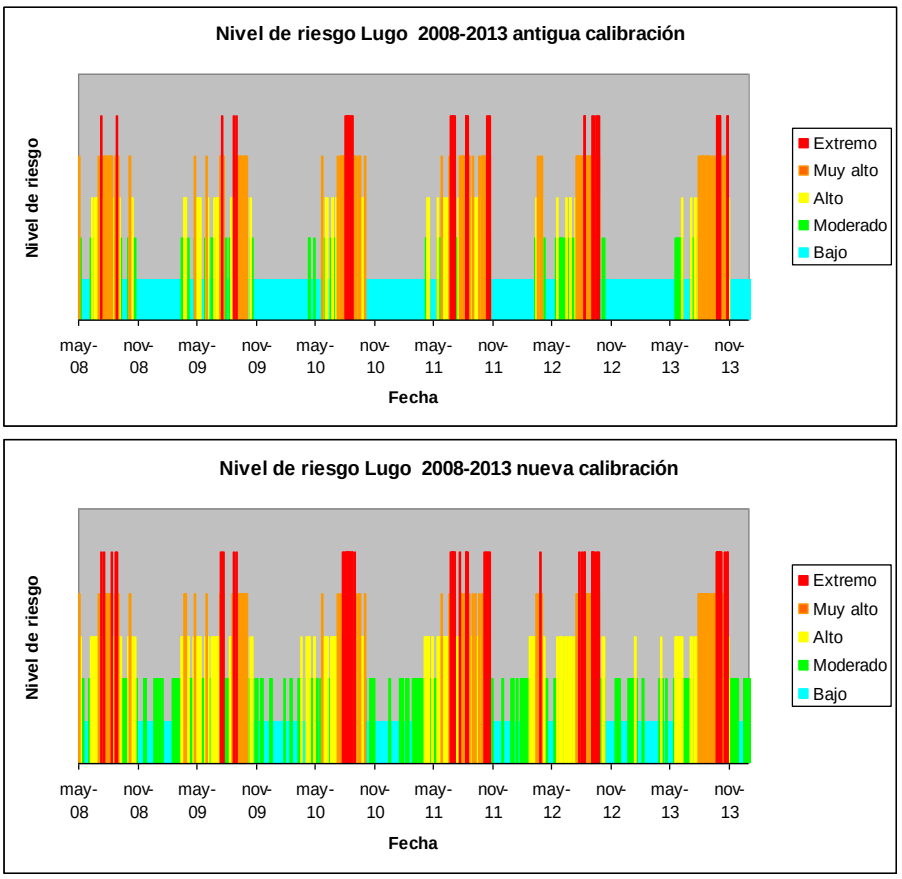

Figure 13. Risk levels January 2009 to December 2013(old calibration-top/new calibration-bottom)

.

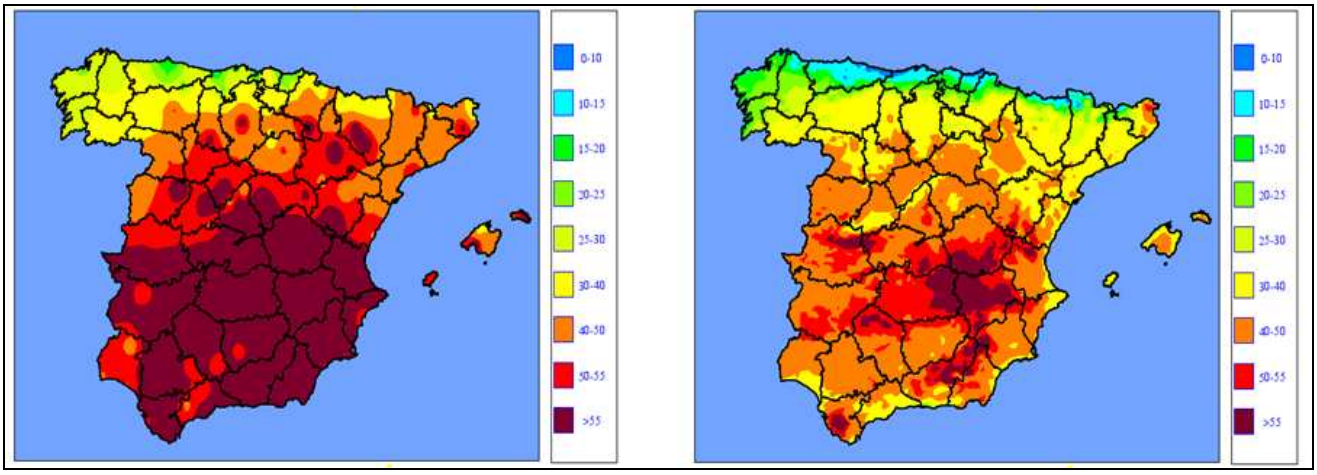

Figure 14. Percentile 95 FWI values. Old Calibration (left / New Calibration(right).

2.3. Old calibration Canary Islands.

Unlike the old calibration previous to 2014 calculate in Peninsula and Balearic Islands, Canary Islands calibration has always been calculated taking into account only meteorological and climatological factors. Again, five danger classes have been established: low, moderate, high, very high and extreme fire risk level. Each class or risk level corresponds with a range of values of FWI between different percentiles. Thus, fire low risk corresponds with FWI values below its percentile 40; moderate risk with FWI values between percentile 40 and 65; high risk between percentile 65 and 85; very high risk between percentile 85 and 95 and extreme fire risk above its percentile 95. In the calculation of the different percentiles, a daily data period from March 2009 until February 2011 has been used by using weather data provided by the numerical weather prediction model HIRLAM.

2.4. New calibration Canary Islands.

The only different with the old calibration is the extension of the period from January 2009 to December 2013. Due to the special characteristic of the Canary Islands climate, FWI values used for percentile calculation and the threshold generation are ranging for the whole year.
This period will be updated with most recent values according to the month pass.

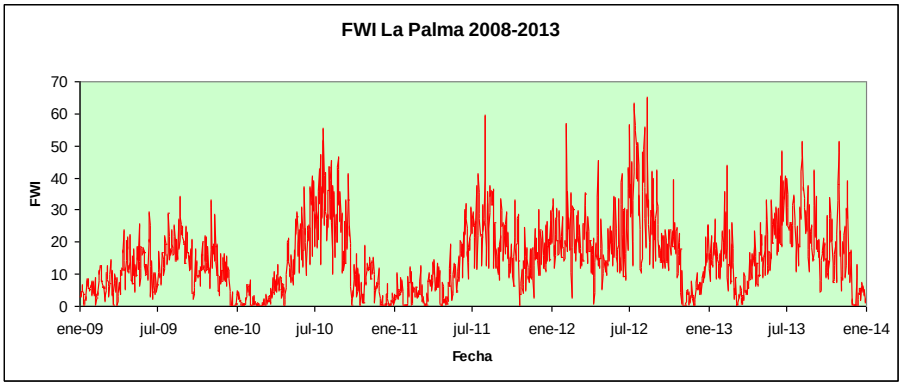

Figure 15– FWI values from January 2009 to December 2013

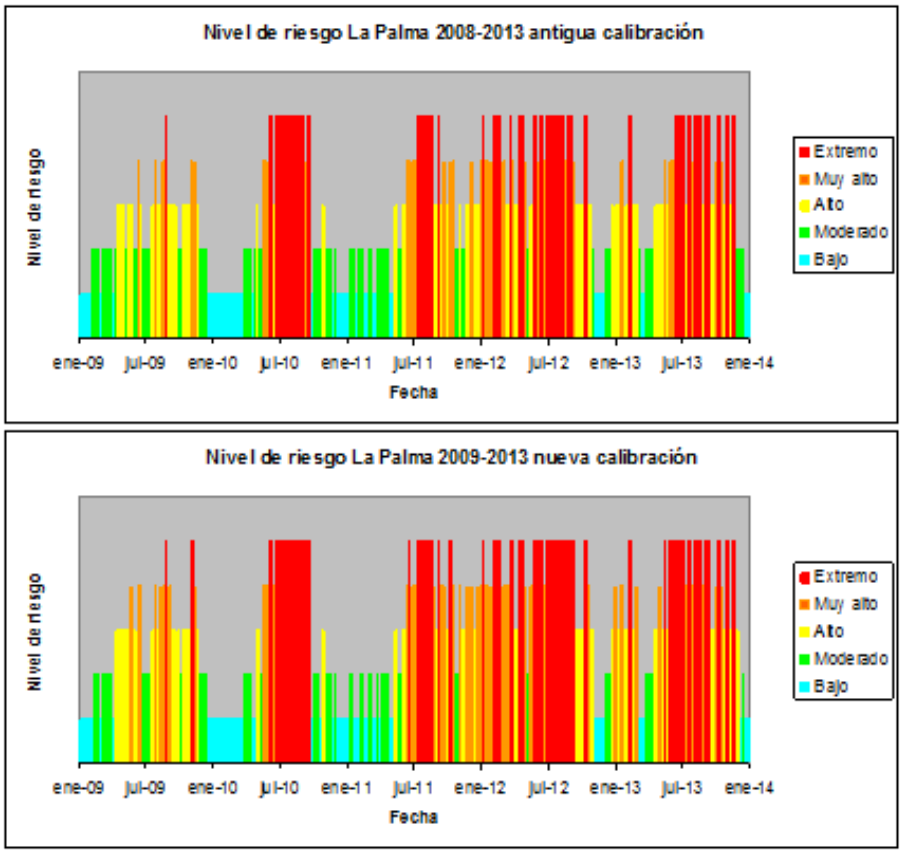

Figure 16. Risk levels January 2009 to December 2013(old calibration-top/new calibration-bottom).

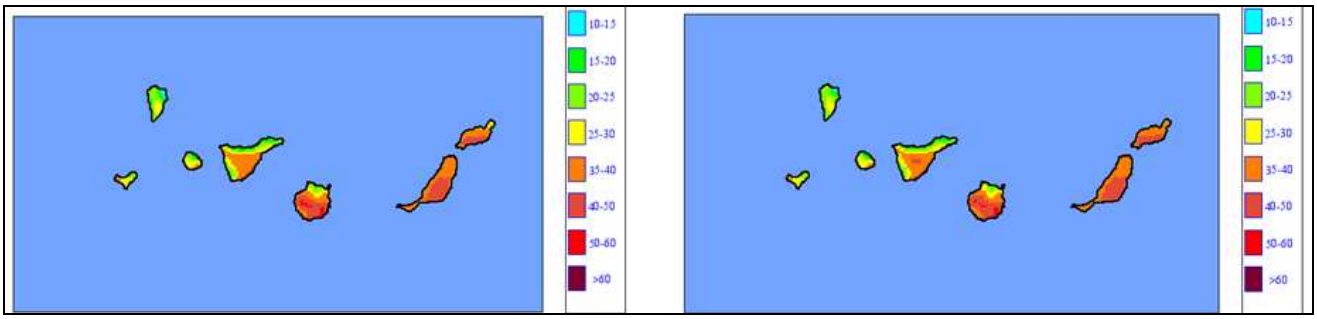

Figure 17- Percentile 95 FWI values. Old Calibration (left)/ New Calibration(right).

3. Results.

3.1. Iberian Peninsula and Balearic Islands.

Fire occurrences during 2010 year have been used in order to validate the new calibration behaviour, taking only into account those ones with burned area greater than 5 hectares, what makes us to have 230 fires spread all over the Iberian Peninsula and Balearic Islands.

For each fire coordinates, FWI value in the nearest grid point has been calculated. Then, two risk levels have been associated to that FWI value, one calculated with the old calibration, and another one calculated with the new calibration. Thresholds obtained for May-October period have been generated from FWI series values ranging from April to November during 2008-2013, thus, 8 months. In the other hand, thresholds generated for November-April period have been calculated from the whole FWI values series (2008-2013). In figures 18 and 19 results are presented by comparing the two different

calibrations for the whole 2010 year. As we can see, the risk level associated to each fire with the new calibration appears, in most of the fires, in a higher danger class.

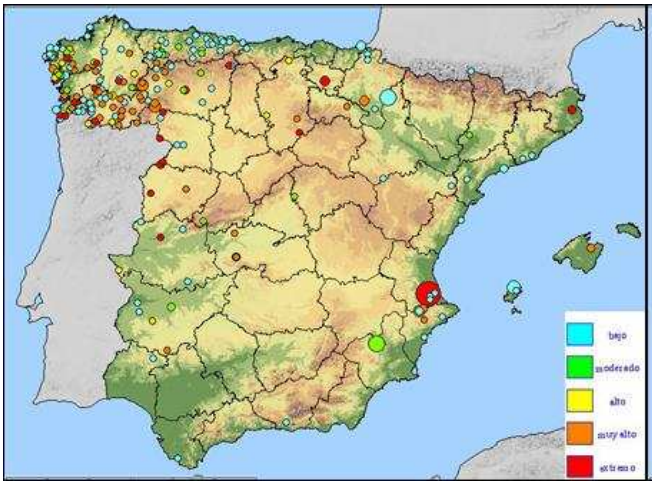

Figure 18. Fire risk level during 2010 old calibration

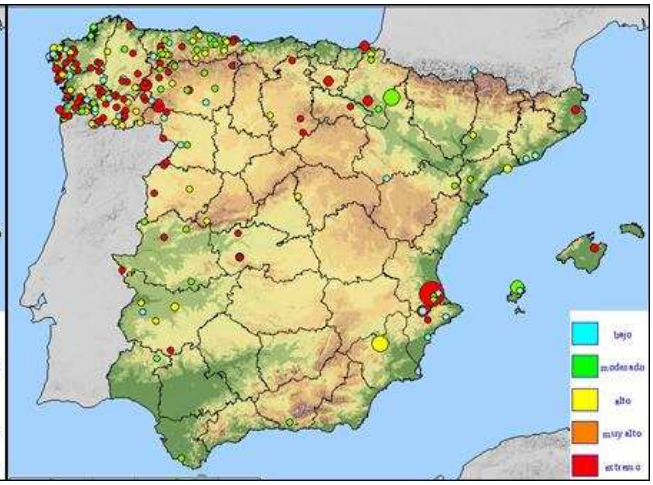

Figure 19. Fire risk level during 2010 new calibration

Later, fire data records were validated by separating two different periods; from May to October, and from November to April. In the next figures we can see the different calibrations for the two different periods as well as the fire risk level associated to each fire.

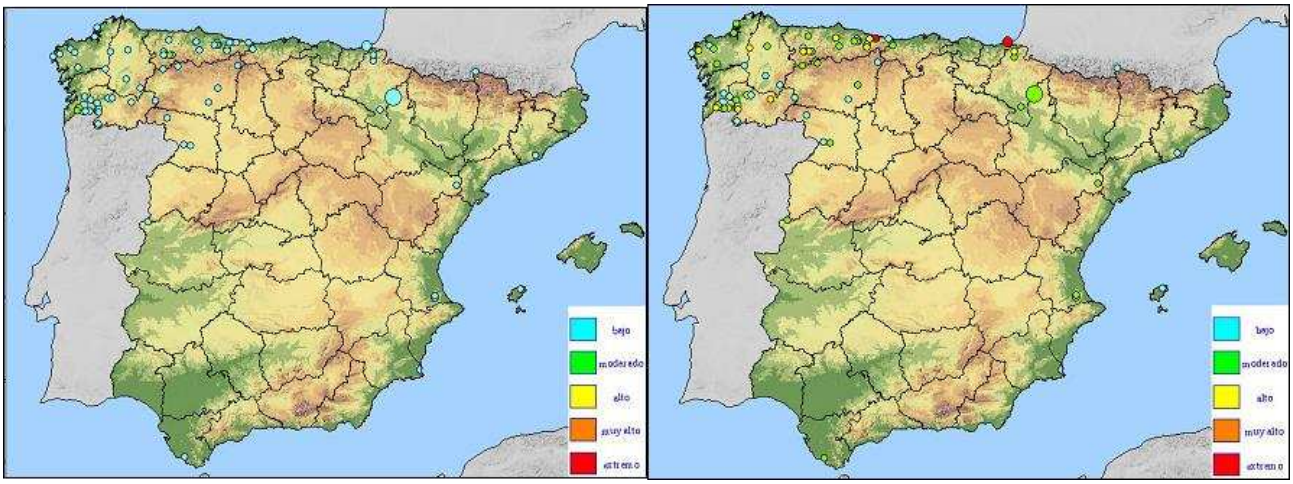

Figure 20. Fire risk level during November-April 2010 period with old (left) and new (right) calibration

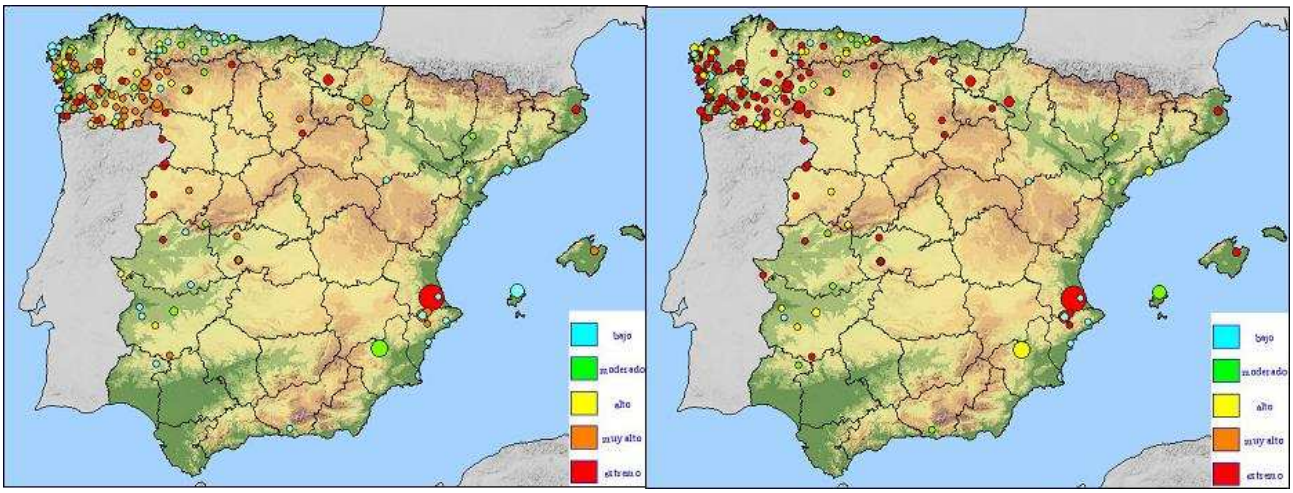

Figure 21. Fire risk level during May-October2010 period with old (left) and new (right) calibration.

Canary Islands.

Same validation procedures have been used for the fire occurrences in the Canary Islands during 2010 year, by comparing the old and the new calibration. Results are presented in the next figures. We can observe similar results to the ones obtained in the Iberian Peninsula and Balearic Islands, where the risk level associated to each fire with the new calibration appears, in most of the fires, in a higher danger class.

Abstract
In the FP7 European project "DROUGHT-R&SPI - Fostering European Drought Research and Science-Policy Interfacing" CEABN works together with partners from other eight countries on monitoring and prediction tools to manage drought impacts at different scales.
The wildfire extent was one of the impacts studied in relation to recent drought events in Portugal. The identification of specific periods where shortage of water is relevant to the extent of wildfires is of prime importance to counteract drought impacts. Meteorological droughts can be characterized using indices such as SPI (Standardized Precipitation Index). In this study we explored the links between area burned by wildfires and meteorological drought indicators using data series from mainland Portugal. Significant correlations were found between wildfire burned area and drought indices (SPIs 1, 3 and 6), which can be useful to understand and manage the risk of forest fires.

Keywords: Portugal, drought, SPI, forest fires

Introduction

Drought is a recurrent climatic event occurring worldwide and intensively perceived by the Mediterranean countries (Pereira *et al.*, 2009). Projections indicate an increased in the observed trend (Sousa *et al*., 2011) towards drier conditions for this region (Van Lanen *et al.*, 2013) with substantial foreseen impacts that need to be properly addressed (EEA, 2012).
"DROUGHT-R&SPI - Fostering European Drought Research and Science-Policy Interfacing" is a FP7 European project aiming at improving drought preparedness across Europe (http://www.eu-drought.org). In this framework, Portugal, along with eight other countries, works on monitoring and prediction tools to manage drought impacts at different scales (from pan-European to sub-national or river basin level).
Meteorological droughts can be characterized using indices such as SPI, Standardized Precipitation Index (Moreira *et al.*, 2008). They calculate anomalies in precipitation, accumulated over several periods: 1, 2, 3, 6, 9, 12, 24 months, compared with its multiyear average (Zargar *et al.*, 2011). In the last 70 years there were ten major drought events in mainland Portugal: 1944-45 (extreme), 1948-49, 1964-65, 1974-76, 1980-83, 1990-92, 1994-95, 1998-99, 2004-2005 (extreme) and 2012 (extreme). The drought episode of 2004-2005 can be considered the most severe in terms of meteorological data, extent of the area affected, and impacts on different socio-economic and environmental sectors (Comissão para Seca 2005, 2006). The wildfire extent was one of the most important impacts of recent drought events in Portugal (MAMAOT, 2013). In fact, precipitation deficits, by reducing soil and fuel moisture, ease up the ignition and spread of forest fires (Shoennagel *et al.*, 2004; Gouveia *et al.*, 2009; Jurdao *et al.*, 2012). The identification of specific periods where the shortage of water is crucial to maximise wildfire extent is of prime importance for counteract drought impacts. However, although the climate drivers of area burned have been extensively studied, both in Portugal (Viegas & Viegas, 1994; Pereira *et al.* 2005; *Trigo et al.*, 2006) and elsewhere (e.g., Flannigan & Harrington, 1988;

Pausas, 2004; Littel *et al.*, 2009), the links between drought indices and wildfire extent have only recently been modeled (e.g., Stagge *et al*., 2014).
The objective of this study is thus to explore the link between area burned by wildfires and meteorological drought indicators using long-term data series (fire and climate) from Portugal analysed at sub-national level (NUTS2).

Methods

The **Standardized Precipitation Index (SPI) as a** drought indicator

The Standardized Precipitation Index (SPI) (McKee *et al.* 1993) is a probability index that was developed to give a representation of abnormal wetness and dryness, and compares precipitation with its multiyear average. It is essentially a seasonally normalized, backwards-looking moving average of precipitation. SPI overcomes the difficulty of comparing sites with different climate and highly variable precipitation distributions by transforming the precipitation distribution record to a normal distribution (Paulo & Pereira, 2006). The first step in calculating the SPI is to determine a probability density function that describes the long term time series of precipitation observations. The series can be for any time duration (typically for total precipitation of 1, 2, 3, 6, 9, 12, 24 months). Once the probability density function is determined, the cumulative probability of an observed precipitation amount is computed. The inverse normal Gaussian function, with mean zero and variance one, is then applied to the cumulative probability. The result is the SPI (Guttman, 1999).
Positive SPI values indicate a wetter than typical period, i.e. accumulated precipitation greater than the median, while negative SPI values indicate a dryer period with less precipitation than normal. A value of zero corresponds to the median accumulated precipitation. The magnitude of the departure from zero is a probabilistic measure of the severity of a wet or dry event that can be used for risk assessment (Paulo *et al.,* 2012). The time series of the SPI can be used for drought monitoring. Accumulated values of the SPI time series are used to analyze drought severity. Threshold values of the SPI define drought beginning and ending (Moreira *et al*., 2008). If SPI reaches a value of -1 or less a drought is said to have occurred. Different duration of SPI reflected different phenomena (Zargar *et al.*, 2011). One month SPI (SPI1) is related to short-term conditions as short-term soil moisture and vegetation stress during growing season. Three months SPI (SPI3) is related to short/medium-term conditions, roughly approximating seasons, while the six-month SPI (SPI6) shows the precipitation across distinct seasons. When the nine months SPI (SPI9) is less than -1.5 substantial impacts occur in agriculture and other sectors, one year SPI (SPI12) is tied to evolution of streamflows and reservoir and groundwater levels (Paulo & Pereira, 2006).

To explore correlations of drought with the areas burned by forest fires in Portugal we used monthly SPIs of different duration: SPI1, SPI2, SPI3, SPI6, SPI9 and SPI12. These SPI values were calculated on the basis of long-term series of monthly precipitation (1979-2009) based on the WFDEI (Watch Forcing Data ERA-Interim) for each NUTS2 (Nomenclature of Territorial Units for Statistics level 2) area of the Portuguese mainland (Norte, Centro, Lisboa, Alentejo and Algarve).

2.2. **Proportional change to standardize continuous variables as crop or forest fire in long-term data series**

Monthly SPIs were used as candidate explanatory variables to model wildfire extent, defined by area burned. Annual area burned by wildfires in Portugal (1985-2010) is the dependent variable, extracted at the NUTS2 level from the European Fire Database (compiled by the EU JRC) and used after log-transformation to rescale the data.

Data from long-term series as areas burned by wildfires typically do not fluctuate around a constant mean. Therefore, in order to detect the signal of drought in wildfire areas, it is important to remove

these multi-annual trends that are not related to drought. This was accomplished by using moving averages, whose length was determined by the structure of the time series data as detected by autocorrelation analyses. Burned area anomaly was defined as:

$$\text{Log(fire area)}_{\text{anomaly}} = \text{Log(fire area)}_{\text{observed}} - \text{Log(fire area)}_{\text{mov.average}}$$

The standardization was accomplished by a proportional change as:

$$\text{Log(fire area)}_{\text{proportional change}} = \\ = (\text{Log(fire area)}_{\text{observed}} - \text{Log(fire area)}_{\text{mov.average}}) / \text{Log(fire area)}_{\text{mov.average}}$$

Proportional change has a minimum value of -1 (when there is no burned area in that year), zero when the observed burned area is equal to the expected value (the moving average), and greater than 0 when the observed burned area is higher than expected.

Once defined the moving average period, we performed a correlation analysis (Pearson r) to detect the most significant links between monthly SPIs (of the current year and the last 3 months of the previous year) and the proportional change of log-transformed annual burned area. This later variable was in turn modelled using a multiple regression model (stepwise method) with all the SPIs as candidate independent variables (Draper & Smith, 1998). Correlation values and regression coefficients were considered statistically significant for $p<0.05$.

Results and discussion

The analyses of long-term series for burned areas (log transformed) in Portugal indicated that statistically significant partial autocorrelations of these data exist for lags 1 and 2 years. These results suggested that four year moving average (2 previous years and 2 following years) was adequate to smooth these data in order to better detect the annual anomaly and calculate the proportional changes in log-transformed burned areas. Figure 1 represents burned area by wildfires in the five NUTS2 for mainland Portugal (1985 - 2009), whereas its log-transformed and standardized trends are depicted in figure 2.

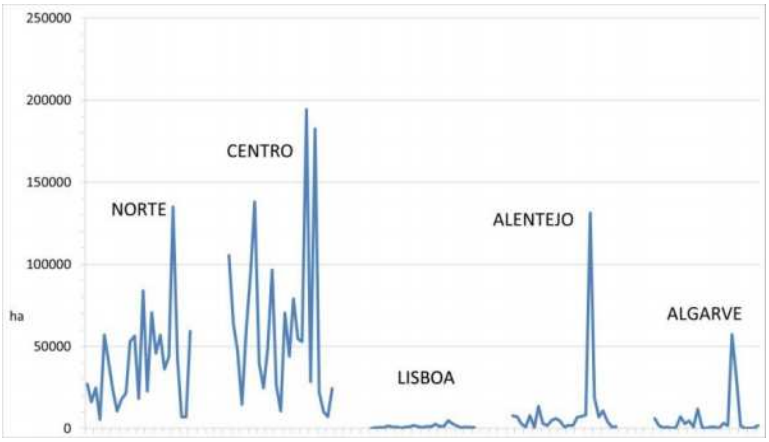

Figure 1. Burned area (ha) by wildfires in mainland Portugal (1985 - 2009) by NUTS2. The x-axis corresponds to the sampling years for each NUTS2.

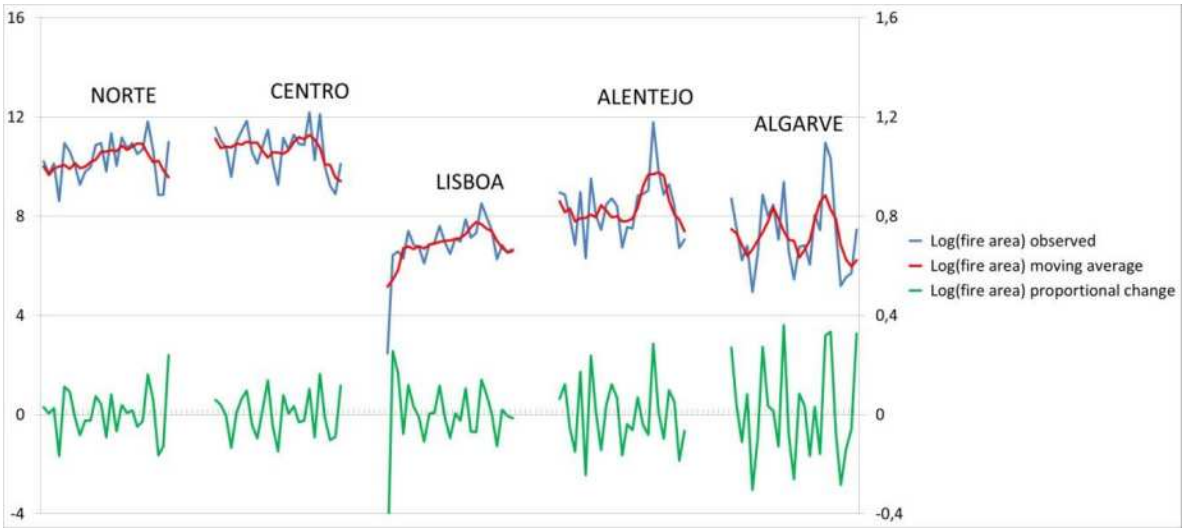

Figure 2. Log(fire area) observed, Log(fire area) moving average and Log(fire area) proportional change, by NUTS2 in mainland Portugal (1985 - 2009). The x-axis corresponds to the sampling years for each NUTS2; the left y-axis correspond to observed and moving average of Log(fire area), the right y-axis to Log(fire area) proportional change.

Investigating the correlations between short-term SPI1 and Proportional Change of log-transformed burned area we found two significant correlations (Figure 3). For short-term meteorological droughts, measured by SPI1, the most significant is the negative correlation occurring in May (R=-0.271). A negative correlation suggests that as meteorological drought severity increases (SPI becomes more negative), the wildfire area burned increases. It can be also speculated that, larger precipitation values in May result in lower areas burned, probably due to higher moisture in soil and vegetation before the summer (Dias *et al.* 2006). While statistically non-significant, all months from Abril to August show negative correlations, with the same interpretation as before.

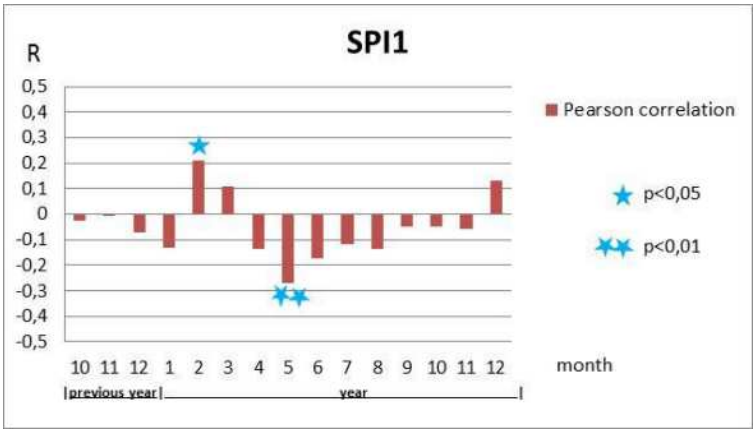

Figure 3. Correlations between Proportional Change of log (fire area) and monthly SPI1

The results also showed a positive (R=0.208) significant correlation, with SPI1 of February, meaning that extensive wildfire burned area is correlated with higher than average precipitation in February. In a Mediterranean country such as Portugal, a water surplus by the end of winter benefits fuel accumulation, namely the biomass of the herbaceous layer, which is easy to burn during the summer (Schoennagel *et al.* 2004; Gouveia *et al.* 2009). A similar explanation, in line with those provided by Viegas & Viegas (1994), can be used for March, even if the correlation is not statistically significant.

SPI3 involves the total rainfall of the current month and of the two previous months. In this case (Figure 4) the significant negative correlations for SPI3 are found between May and August, with

highest values for June (R=-0.348) and July (R=-0.367). Thus according to our results, accumulated deficit of precipitation from May to July is a good candidate for predicting larger annual wildfire area. A significant positive effect of summer drought (especially when evaluated by SPEI) in wildfire extent, was also found by Stagge *et al.* (2014) for several European regions.

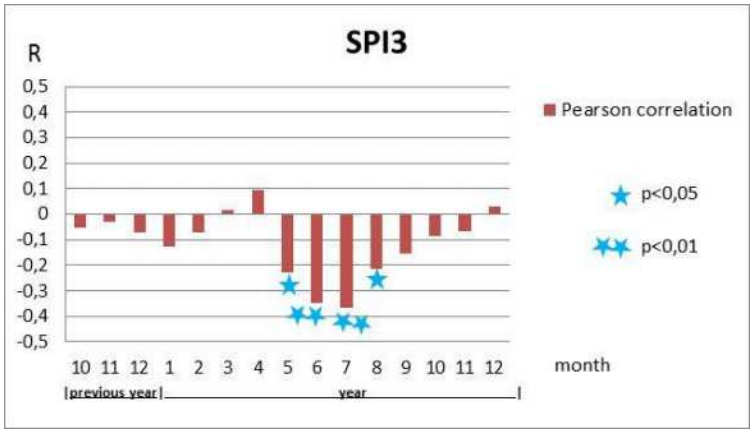

Figure 4. Correlations between Proportional Change of log (fire area) and monthly SPI3

Medium-term SPI6, commonly used to indicate drought impacts in rainfed agriculture, (Zargar, 2011) was also well correlated with burned area. SPI6 involves precipitation of the current month and of the previous five. The highest negative correlations were found from August to October (Figure 5).

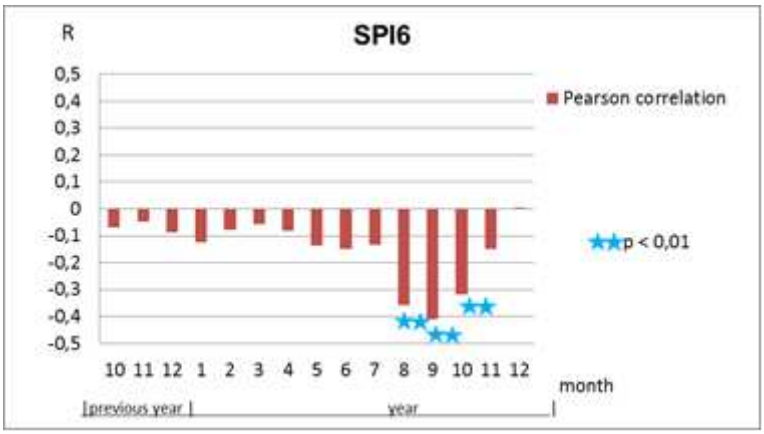

Figure 5. Correlations between Proportional Change of log (fire area) and monthly SP6

The highest negative correlation (R=-0.412) in this study was found for the SPI6 in September. This means that accumulated precipitation deficits from April to September correspond to accumulated dryness of soil, litter and vegetation (Dias *et al.*, 2006; Pellizzaro *et al.*, 2007), therefore triggering larger burned areas (Canyameres *et al.*, 2006; Jurdao *et al.*, 2012).
Though this correlation does not allow for a detailed analysis of the process, it can be useful in making the general association between drought and wildfire extent. In fact, we found that SPI6 of September was the first and only independent variable selected by the multiple regression model where all possible linear combinations of SPI1, SPI2, SPI3, SPI6, and SPI9 were used as explanatory candidates of the proportional change of area burned (log-transformed) in mainland Portugal:

$$Y_{LogFireChange} = -0.047 \times SPI6_{September},\ R = 0.412,\ p<0.001,\ n=125.$$

This indicates that it is possible to establish a solid negative association between cumulative precipitation deficits in late spring and summer months and wildfire extent, and that this association summarizes well the relationship between drought and burned area for mainland Portugal.

Conclusions

Climate scenarios estimate a significant increase in the forest fire danger (Bedia *et al.,* 2014) and in the total burned area (>66%, Amatulli *et al.,* 2013) for the EU-Mediterranean countries by the end of the 21st century. The identified link between meteorological drought and fire impact can be a step towards the improvement of an early-warning system for seasonal wildfire severity for both Portugal and other countries sharing the same climatic conditions.
The medium-term drought index, SPI6, in September provided the best explanation for burned areas in an interpretable way. Accumulated precipitation deficit results in low moisture content in forest fuels and therefore in larger areas burned due to more intense wildfires.
Short-term (SPI1 of May) and short-medium-term indices (SPI3 of May, June, July and August) can be used in real-time, giving some forecast lead time, to evaluate for possible major risk of forest fires and to engage field measures to implement in the forthcoming months.
The assessment of the SPI1 of February can provide important warning information when deciding whether to enact measures, in the four months ahead, to reduce herbaceous biomass, which may increase risk of wildfires.

Acknowledgments

Abstract
Wildfire risk assessments in Spain usually make little or no reference to the uncertainty of the results due to ignition data quality, or the implications that this potential uncertainty may have on wildfire management decisions. In Spain the autonomous regions have historically been the competent authorities in forest management and environmental protection as a result of the 1978 Constitution and, therefore, responsible on the operational application of the criteria defined for the country for wildfire classification and location. This competency framework has generated significant regional differences in the application of the criteria for wildfire classification among the different autonomous regions, arising potential uncertainty on wildfire assessments and fire risk models based on this historical series of data. This work explores six scenarios based on the classification of fire ignition causes and location data, reported in the General Statistics of Wildfires database (EGIF), to address the potential uncertainty from the point of view of the variability in predicted ignition probability and the changes in its spatial patterns. The analysis is focused on analyzing the effects on human-caused wildfires by using Random Forest algorithms to predict the ignition likelihood and cluster and outlier analysis (hot and cold spot) to detect changes in the spatial pattern of probability. Results suggest that there is significant uncertainty both in predicted human-caused ignition and spatial pattern related to the ignition source and location of fire events compiled in the EGIF database. The accuracy of the predictions ranges from AUC values of 0.90, when considering most of the records of the database, to around 0.76 in scenarios characterized by using only known-caused allocated fire events, probably due to differences in the proportions of unidentified and allocated fires within the mainland Spain.

***Keywords**: Uncertainty, wildfire, point location, ignition cause*

Introduction

During the last decades, the Spanish forest fire authorities have encouraged the investigation of fire causes, which is decisive to better understand patterns of fire occurrence and improve fire prevention measures (Martínez *et al*., 2009). However, the 29% of the fire causes remain unidentified in the period 1988-2007. According to Lovreglio *et al*. (2006), little is known about wildfire causes, which often are more diverse than what is assumed by the traditional classifications employed for statistical purposes. In face of the arising uncertainties, a better knowledge on spatial patterns of fire occurrence and their relationships with its underlying causes becomes a necessity to locate and make prevention efforts more efficient (Martínez *et al*., 2009). From a scientific perspective, improving decision quality in natural resource management begins with uncertainty management (Borchers, 2005). Uncertainty is essentially a lack of information; complete ignorance represents one end of the spectrum and perfect information (i.e., certainty) the other (Thompson and Calkin, 2011). However, viewing uncertainty as 'information about information' may be the first step in transforming a problem into knowledge (Bradshaw and Borchers, 2000).
The aim of this paper is to deal with the potential uncertainty linked to location and ignition cause of wildfires, with special attention to the human-caused fires in the mainland Spain. The analysis of human factors in forest fire is widely recognized as very critical for fire danger estimation (Kalabokidis *et al*., 2002; Martínez *et al*., 2009), especially in human-dominated landscapes where anthropogenic

ignitions widely surpass natural ignitions, like the peninsular Spain (Amatulli *et al*., 2007; Chuvieco *et al*., 2010; Chuvieco *et al*., 2012).

In Spain, fire events are recorded in the General Statistics of Wildfires database (EGIF). The EGIF database is one of the oldest 'complete' wildfire databases in Europe, beginning in 1968 (Vélez, 2001), though its data is not considered as completely reliable until 1988 (Martínez *et al*., 2009). The database is compiled by the Ministry of Environment, Rural and Marine affairs (MARM) using forest fire reports of the autonomous regions (Moreno *et al*., 2011). The autonomous regions have received competition in forest fires from the 1978 Constitution (article 148), and therefore are responsible of the application of the criteria and procedures defined for the entire national territory concerning wildfire classification and location. However, the fact that there is no single administration responsible on this topic has led to differences in the application of the criteria among the autonomous regions. A quick overview on the data collected in the historical database arises some inconsistences in the reported information. For instance, the proportion of unknown causes or the proportion of correctly located fire events (located with coordinates) differs from one region to another, becoming a potential source of uncertainty. This is especially important since research on forest fires in Spain is made from data collected in the EGIF database (Amatulli *et al*., 2007; Chuvieco *et al*., 2010; Chuvieco *et al*., 2012; de la Riva *et al*., 2004; Martinez *et al*., 2009; Padilla and Vega-García, 2011; Rodrigues *et al*., 2014; Rodrigues and de la Riva, 2014). Notwithstanding, the influence of uncertainty in historical fire data is scarcely considered (or at least not specifically addressed) and is mainly focused on location precision rather than ignition cause (Amatulli *et al*., 2006; Amatulli *et al*., 2007). Assessing the effects of uncertainty of Spanish ignition data is particularly interesting since it is a component of the wildfire information compiled European Forest Fires System Database (EFFIS), thus analyzing the effects of uncertainty at the Spanish level could be very helpful to understand wildfire patterns in the European scale, even more since Spain is the more fire-affected country within the European Union (Rodrigues *et al*., 2013).

In this work, we will explore six scenarios based on the classification of ignition causes and location data reported in the EGIF database to assess the potential uncertainty from the point of view of the variability in predicted ignition probability and changes in the spatial pattern of probability.

The occurrence probability will be calculated using Random Forest (RF) algorithms (Breiman, 2001) whereas the changes in the spatial probability patterns will be addresses through local Hot Spot analysis. RF algorithms have proved to be a useful tool for wildfire modeling (Bar Massada *et al*., 2012; Rodrigues and de la Riva, 2014), improving the performance of traditional regression techniques (e.g. logit Generalised Linear Models). The comparison of the proposed occurrence scenarios is conducted from the point of view of the accuracy in the classification based on a k-fold procedure (Fielding and Bell, 1997) and according to the variation in variable importance (Breiman, 2001). On the other hand, Hot Spot methods are one of the most adequate for the analysis of large-scale fire occurrence patterns (Allgöwer *et al*., 2005). The analysis of the changes in the predicted ignition probability patterns in each scenario is carried out by cluster and outlier analysis through the Anselin's Local Moran's I (Anselin, 1995).

2. Materials and methods

Study area and fire data

The study area covered the whole mainland Spain excluding the Balearic and Canary Islands as well as the autonomous cities of Ceuta and Melilla, due to the lack of data in those areas. Thus the total area of the study region was around 498 000 km^2. The fire events considered in this work are those occurred during the period 1988-2007.

An overview to the EGIF database

The EGIF database is compiled by the Ministry of Environment, Rural and Marine affairs (MARM) using the forest fire reports from the autonomous regions. The database classifies each fire event following a hierarchy of criteria which first differences between known (K) and supposed (S) cause and then into the most likely ignition source (natural or human). In turn, the ignition source is classified according to six categories: natural (lightning; L), human (negligence, accident or arson; H), restarted fires (R) and unknown or unidentified fires (U). Ideally, only K fires should be considered when developing any kind of fire analysis as they appear to be the most reliable. However, an insight into the classification of fire events in terms of number of fires in each category (Table 1) reveals that the proportion of fires with a S cause is more than 73 % of the total number of fires in the period 1988-2007. Hence, by excluding S fires the majority of fire events are being discarded (Figure 1).

Table 1. Classification of fire events according to its ignition causes (number of fires).

	Lightning	Human	Unknown	Restarted	All
Known	6775	35443	30952	1957	75127
Supposed	7931	228694	44706	2420	283751
Total	14706	264137	75658	4377	358878

This classification system also influences the proportion of fires according to its ignition source. Attending to K source, L fires represent the 9% of the occurrence whereas H fires are only the 47%. The remaining fires mostly correspond to U sources. This proportion changes drastically when S cause fires are accounted for, decreasing the proportion of L fires to 4% and raising H fires to a 73%. However, this 73 % of H fires is still far from the 90% value usually reported for Mediterranean European Countries (San-Miguel-Ayanz *et al*., 2012; San-Miguel-Ayanz, 2009) and, particularly, for Spain (Martínez *et al*., 2009). This fact suggests that there is great amount of U fires potentially related to H ignition factors and thus, when excluding unknown fires in human-caused wildfire assessments, a significant part of the human occurrence is not taken into account. However, while U fires are quite important attending to national overall values, mapping the spatial distribution of these proportions uncovers the existence of high spatial heterogeneity, increasing the uncertainty on the data (Figure 1). On the other hand, a second source of uncertainty is related to the location of fire events. In the EGIF database wildfires are located following to different procedures: (i) geocoding the location on the basis of a reference 10x10 km ICONA grid (used by the firefighting services for approximate location of fire events) and the municipality origin of the ignition; and (ii) georeferencing fire events using spatial coordinates. Again, the existence of coordinates should imply a precise allocation of the ignition points, however not all the fire events are georeferenced –only the 11% (Table 2)– and, as in the case of the ignition source, the proportion of fire events with coordinates varies from one region to another (Figure 2). This situation usually led to face the spatialization of the fire occurrence using geocoded location information (Amatulli *et al*., 2007; Chuvieco *et al*., 2010; Chuvieco *et al*., 2012; de la Riva *et al*., 2004; Martínez *et al*., 2009). On top of this, sometimes the assigned coordinates are incorrect. For instance, 2267 fires are located outside Spain, 23 are assigned a wrong UTM zone and 757 are located in the exact intersection of the ICONA grid (Table 2). This means that the 7.6% of the forest fires with spatial coordinates are mistakenly allocated.

Table 2. Number of fires with coordinates and wrong located wildfires.

	Located	Outside	Wrong zone	Intersects Grid	Total incorrect
Known	16435	962	18	347	1327
Supposed	23581	1305	5	410	1720
Total	40016	2267	23	757	3047

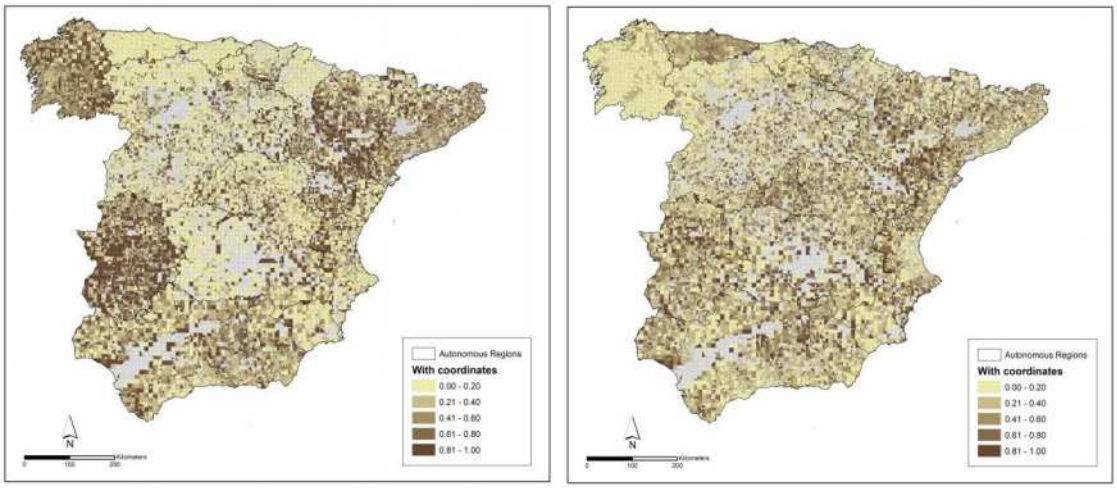

Figure 2. Spatial distribution of the proportion of points with coordinates. Total number of fires (left), fires with known cause (right).

2.3. EGIF scenarios

In this work, we explored six scenarios based on the classification of ignition causes and location data reported in the EGIF database. The proposed scenarios were constructed to simulate the most probable assumptions to select an occurrence sample for wildfire modeling purposes. The criteria followed to design the scenarios were based mainly in three parameters: certainty of the cause (known or supposed), certainty of the source (human or unknown) and presence of coordinates. Thus, the proposed scenarios are:

- Scenario 1: this scenario considers all human-caused fires, including both known and supposed cause, and a proportion of unknown fires according to the observed proportion of human-caused fires in the corresponding autonomous region.
- Scenario 2: this scenario considers all human-caused fire, including both known and supposed cause, excluding those fires with an unknown source.

- Scenario 3: this scenario considers all human-caused fire, but only those with known cause, excluding fires with a supposed cause, but including a proportion of unknown fires according to the observed proportion of human-caused fires in the corresponding autonomous region.
- Scenario 4: this scenario considers all human-caused fire, but only those with known cause, excluding fires with a supposed cause or an unknown source.
- Scenario 5: this scenario considers all human-caused fire, including both known and supposed cause located using coordinates, excluding fires with an unknown source or those which are wrongly located according to Table 2.
- Scenario 6: this scenario considers all human-caused fire, but only those with known cause and located using coordinates, excluding fires with a supposed cause, an unknown source or those which are wrongly located according to Table 2.

2.4. Wildfire modelling

The assessment of human-caused wildfire occurrence was carried out using RF algorithms an ensemble classifier which uses decision trees as base classifiers (Breiman, 2001).

The dependent variable for each scenario was constructed by selecting human-caused fires (e.g. negligence, accident or arson). Then wildfires were spatialized through the assignment of each fire to its respective combination of ICONA grid, municipality and forest perimeter (Amatulli *et al*. 2007; Chuvieco *et al*., 2010,2012; de la Riva *et al*., 2004; Rodrigues *et al*., 2014; Rodrigues and de la Riva, 2014). This allowed the calculation of fire density maps at a spatial resolution of 1 Km^2 by overlaying the random point cloud with the Spanish 1x1 Km UTM grid. The dependent variable was developed for each scenario by classifying the occurrence values into two categories: high occurrence (presence) in locations with two or more fires, and low occurrence (pseudo-absence or background) in locations with only one fire.

The explanatory variables were selected based on the experience of the authors in models at regional and national scales (Amatulli *et al*., 2007; Chuvieco *et al*., 2010, 2012; de la Riva *et al*., 2004; Martínez *et al*., 2009; Rodrigues *et al*., 2014; Rodrigues and de la Riva, 2014). The predictive variables considered were: wildland-agricultural interface (WAI), wildland-urban interface (WUI), density of agricultural machinery (DAM), changes in demographic potential 1991-2006 (CDP; Calvo and Pueyo, 2008), protected areas (PA), forestry area in public utility (FAPU), forestry tracks (TRCK), railroads (RRDS) , power lines (PWR) and land use change 1991-2006 (LUC).

The comparison of the outputs (predicted probability of occurrence) from each proposed scenario was conducted from the point of view of the accuracy in the classification based on a k-fold cross-validation procedure (Fielding and Bell, 1997) and according to the variation in the variable importance (Breiman, 2001). In k-fold cross-validation, the original sample is randomly partitioned into *k* equal size subsamples (*k*=5 in this work). Each time, one of the *k* subsets is used as the test set and the other *k* -1 subsets are putted together to conform the training set. The cross-validation process is then repeated *k* times (the folds), with each of the *k* subsamples used exactly once as the validation data. The *k* results from the folds then can be averaged to produce single error estimation (Bar Massada *et al*., 2012).

Variable importance assessment was carried out by summarizing the influence of the explanatory variables according to the increase in mean square error (*IncMSE*) and the increase in node purity (*IncNP*). *IncSME* is defined as the increase in the mean of the error of a tree in the forest when the observed values of this variable are randomly permuted in the *out-of-bag* samples. *IncNP* is measured using the Gini criterion, from all the splits in the forest based on a particular variable (Breiman, 2001). The variability in variable importance was addressed through the fluctuations in the ranks obtained by ordering the explanatory variables from more to less importance according to *IncSME* and IncNP.

2.5. Spatial variation in the ignition probability patterns

Changes in the spatial probability patterns were addressed through local Hot Spot analysis, one of the most adequate for this purpose (Allgöwer *et al*., 2005). The assessment of changes in the spatial pattern of predicted probability was based on the assumption that one of the key factors in wildfire management was guiding governments or responsible authorities through prioritization across fires and resources at risk. We considered that the identification of areas with high values of occurrence probability (Hot Spot) is linked to the identification of priority intervention areas.

The assessment of the changes in the predicted spatial pattern at each scenario is carried out by cluster and outlier analysis through the Anselin's Local Moran's I (Cluster and Outlier Analysis). This kind of analysis allows identifying and allocating Hot Spot areas as well as characterizes its typology of cluster. Given a set of weighted features, the Cluster and Outlier Analysis tool identifies clusters of features with values similar in magnitude. The tool also identifies spatial outliers. To do this, the tool calculates a Local Moran's I value, a Z score, a p-value, and a code representing the cluster type for each feature. The Distance Band or Threshold established for the cluster detection was 10 km. The results were mapped according to the significant detected cluster typology: Hot Spot (HH), Hot Spot surrounded by Cold Spot (HL), Cold Spot (LL) and Cold Spot surrounded by Hot Spot (LH).

Results

3.1. Predicted probability of occurrence

There is high variability (and therefore uncertainty) in predicted probability values among the six scenarios (Figure 3). In general terms, scenarios characterized by the use of both K and S causes, mainly scenarios 1 and 2, show high performance with AUC values stand above 0.9 (McCune *et al*., 2002). Scenarios 2 and 3, where the occurrence used to construct the dependent variable only consider K causes are less accurate (AUC near 0.83) and values in the high probability interval (0.8 to 1) are almost inexistent. Scenarios where the ignition points are georeferenced using coordinates show the poorest accuracy and probability values are grouped in the first interval (0 to 0.2). In addition, the range of AUC values (difference between minimum and maximum value) shows a similar behavior, with lower values in scenarios 1 and 2, and increasing until scenarios 5 and 6. This means that the models fitted using a dependent variable constructed with both K and S causes are more stable and therefore more reliable. Table 3 summarizes the obtained AUC values. On the other hand, the same comportment is observed when considering the values of Max TPR+TNR. This parameter represents the best threshold to distinguish between presence/absence according to the maximum value of the kappa index i.e. the highest values of true positive rate (TPR) and true negative rate (TNR). In general terms, the higher the threshold the higher the accuracy of the model since it means that the model distinguish more efficiently between presence and background values.

The uncertainty observed in the probability values is also detected in the contribution of the explanatory variables for each scenario. Although the variability is higher in the importance ranks for *IncSME* than in *IncNP* (Table 4) there is a general tendency to promote always the same variables: DAM, CDP, WAI, PA and TRCK (the later only is observed in the *IncNP*). The rest of the variables are swapping ranks among the different scenarios.

Table 3. Summary of k-fold validation with k=5.

	Scenario 1	**Scenario 2**	**Scenario 3**	**Scenario 4**	**Scenario 5**	**Scenario 6**
Max AUC	0.908	0.904	0.838	0.844	0.845	0.784
Min AUC	0.906	0.899	0.827	0.829	0.821	0.746
Max TPR+TNR	0.341	0.324	0.125	0.146	0.123	0.062

Table 4. Importance ranks for the explanatory variables. Top IncSME, bottom IncNP.

LUC	8	8	8	8	9	9	2
TRCK	4	4	4	4	4	4	0

Variation in spatial patterns of probability

Figure 4 shows the spatial distribution of the cluster characterization of the predicted probabilities. In the same way that occurs in the predicted probability of occurrence, there is high heterogeneity in the spatial pattern at each scenario. However, in this case a similar spatial pattern of cluster is observable among the six scenarios, with HH clusters in the northwest of the peninsula and the Mediterranean coast, HL clusters in Pyrenees and the central area of the peninsula and LH in the Cantabrian coast. However, the scenarios using known causes (scenarios 4 and 6) are presenting LL clusters in some regions of the Northwest of the peninsula which is not that would be expectable since this area presents the highest occurrence values (Figure 1).

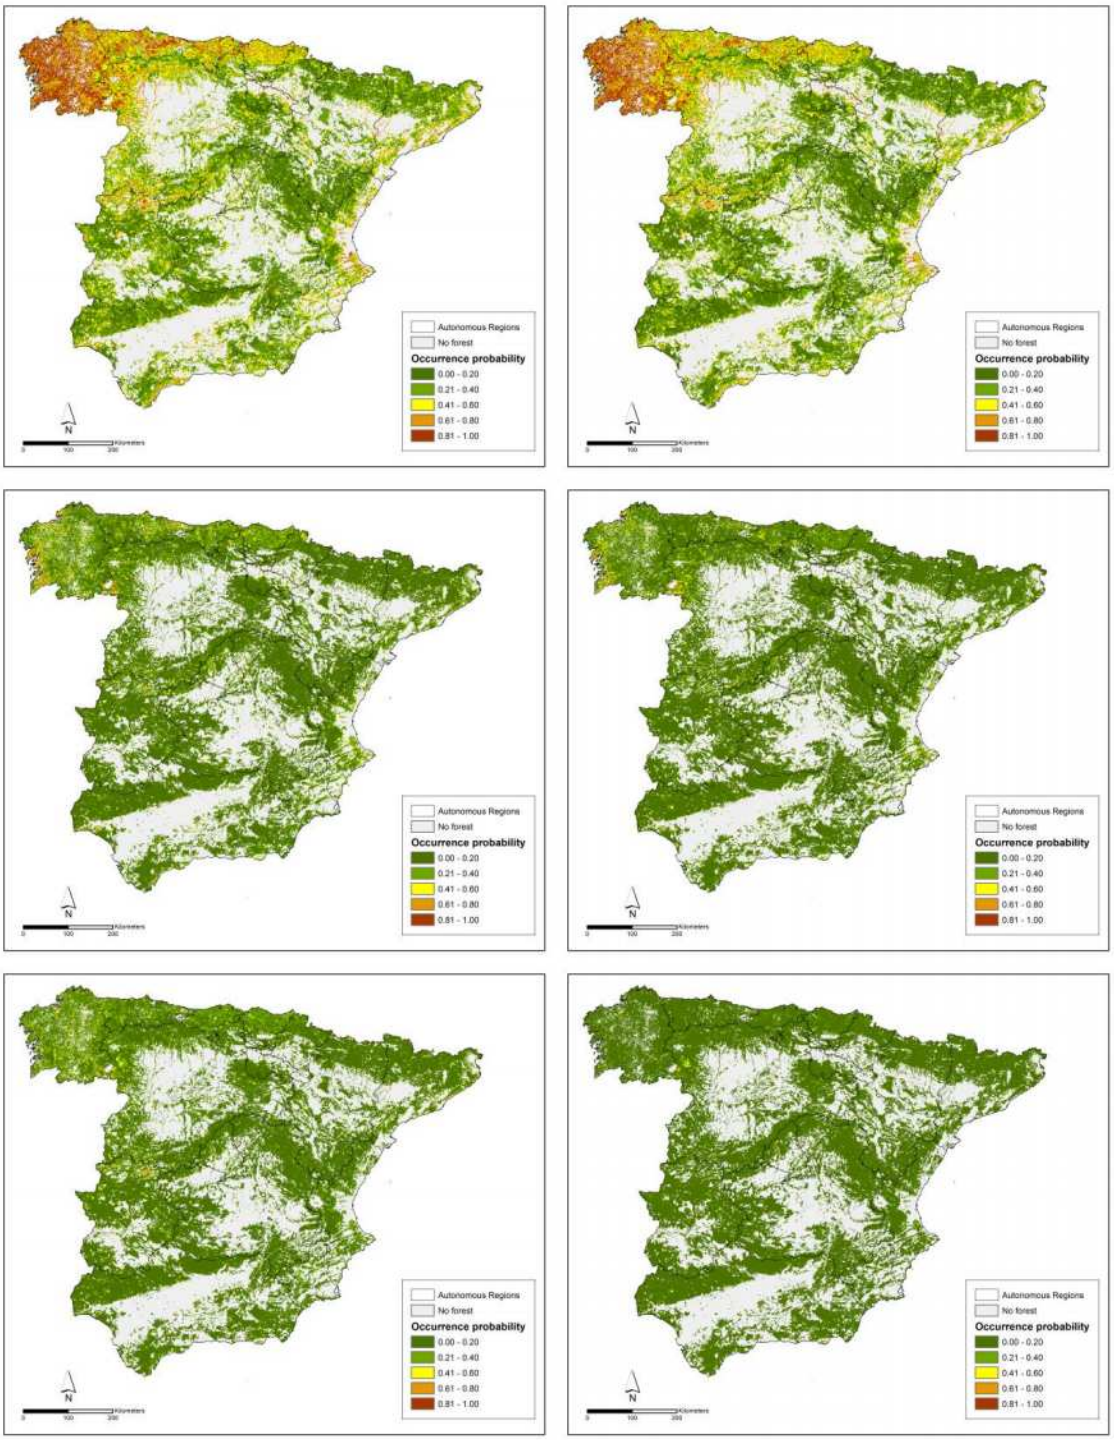

Figure 3. Spatial distribution of the predicted probability values. Scenarios are ordered consecutively left-right-top-bottom.

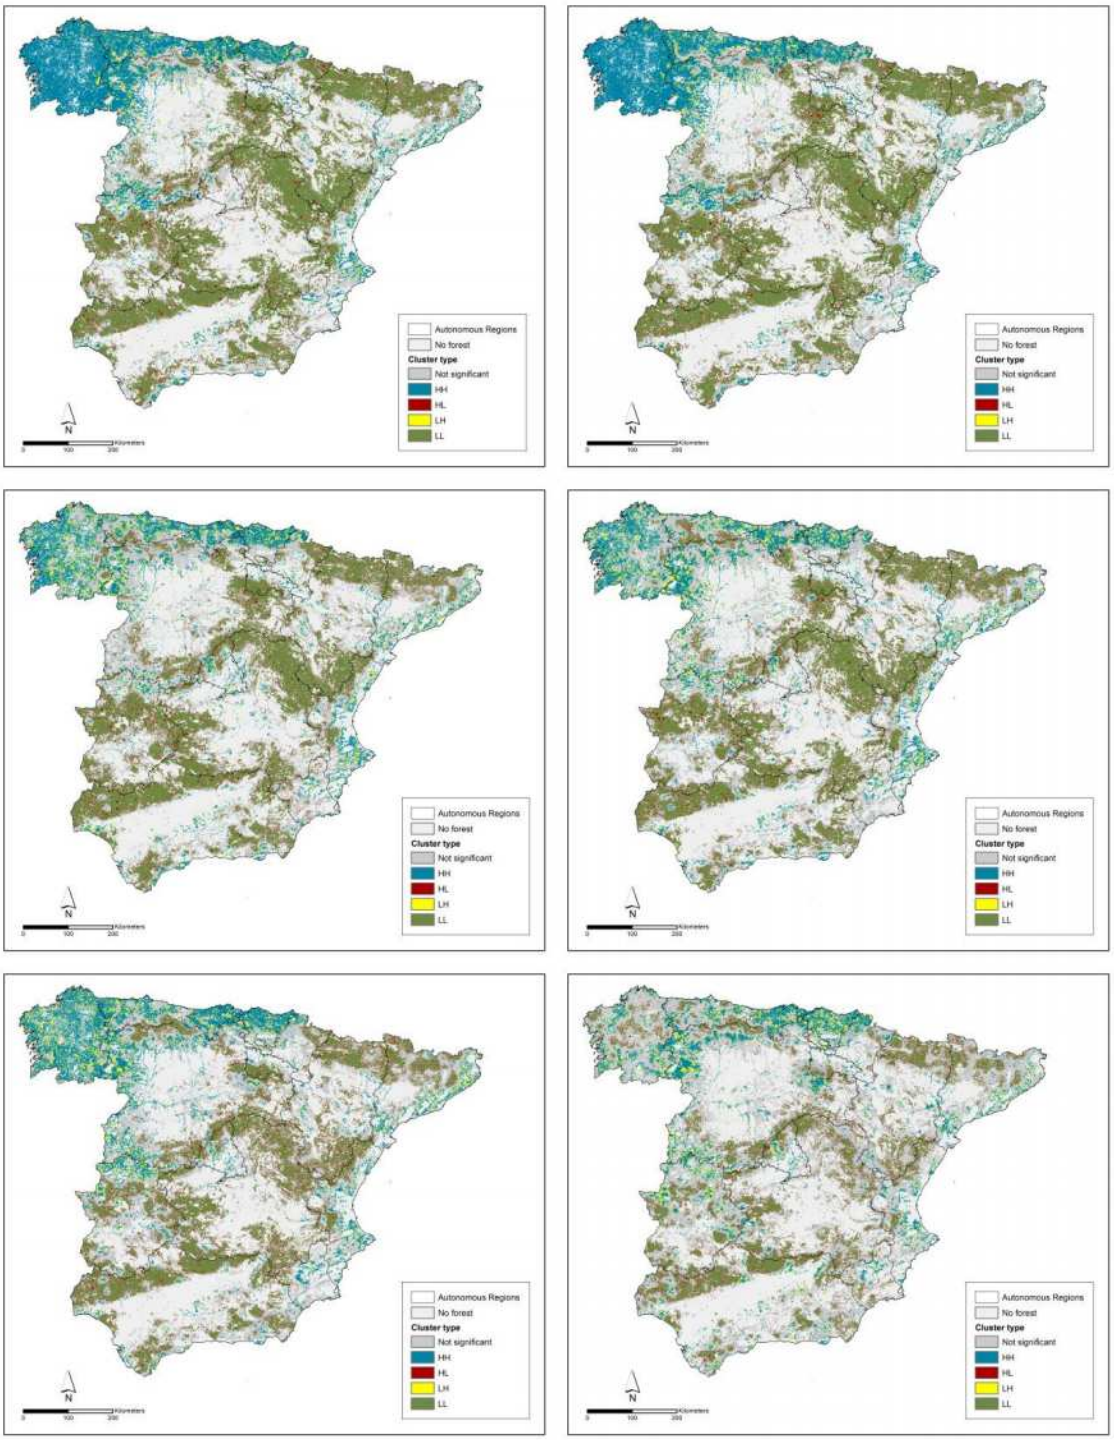

Figure 4. Spatial distribution of the cluster type. Scenarios are ordered consecutively left-right-top-bottom.

Discussion

Multiple sources of uncertainty remain with regard to modelling wildfire occurrence (Thompson and Calkin, 2011). Therefore there is a need to better understand how uncertainty and errors propagate through models (Sullivan, 2009). As little is known about wildfire causes (Lovreglio *et al*., 2006) many authors have chosen to deal globally with human-caused fires, avoiding uncertain specifications of causes, and have been able to derive useful recommendations for management (Stephens, 2005).

Nevertheless, using a coherent framework informs management authorities by facilitating the identification of potential sources of uncertainty and the quantification of their impact.
In Spain, near a 29% of the fire events in the period 1988-2007 have an unidentified cause and the remaining 71% are not fully reliable because the existence of certain degree of uncertainty regarding ignition source and location. This uncertainty is firstly detected while analyzing and mapping fire data; and secondly when occurrence data is used for wildfire modeling. Uncertainty is affecting both to the predicted probability values as well as the spatial pattern of probability.
According to the results may vary greatly depending on to the assumptions made when constructing the dependent variable. Results suggest that the scenarios based on the consideration of all causes (K and S) as well as a proportion of the fires with a U source are more accurate, with AUC values above 0.9. We believe that this is mainly because when considering the whole occurrence, the dependent variable is less 'spatially biased' since there is no partial criterion to leave out a particular set of fire events and, thereby, the spatial pattern should be closer to reality. It is expectable that the scenario with the less uncertainty in its occurrence data, i.e. a scenario with known causes and (scenario 6), would be the most accurate. However, the fact that there are differences in the proportions of unidentified and allocated fires within the Spanish peninsula is harming the quality of the data.
In addition, there is also uncertainty in the contribution/importance of the predictive variables. This might be a big issue in research works aiming to determine the factors that are explaining wildfire occurrence because the assumptions made when constructing the dependent variable are influencing the contribution of the explanatory variables.
Regarding to the predicted probability spatial pattern, although the variability is lower than the detected in the case of the predicted probability, it is still great. As in the case of the probability of occurrence, scenarios based on the consideration of all causes (K and S) including a proportion of the fires with an unidentified source seem to be the most realistic approach.

Conclusions

The lack of uniformity in the application of the criteria among the autonomous regions on forest fire management is a potential source of uncertainty for wildfire risk assessment which is affecting both the predicted probability values as well as the spatial pattern of probability. This is especially significant since research on forest fires in Spain is made from historical data collected in the EGIF database (Amatulli *et al*., 2007; Chuvieco *et al*., 2010, 2012; de la Riva *et al*., 2004; Martínez *et al*., 2009; Padilla and Vega-García, 2011), being more affected the older the data, as technological advances have greatly contributed to improve the quality of the data (such as GPS measurements or database administration capabilities) and, thus, reducing the uncertainty. In any case, some studies have been able to derive useful recommendations for management avoiding uncertain specifications of causes (Stephens, 2005), addressing arising uncertainty in occurrence data can help improve assessments.
The spatial distribution of wildfire ignition greatly varies depending on the assumptions made when considering the ignition cause and source, leading to different predictions. However, it is possible to determine the best scenarios for modeling wildfire occurrence or risk. According with our results the best choice is consider both K and S causes with a proportion of forest fires with unknown source. There is a big amount of unidentified fires potentially related to a human ignition source and thus, when excluding unknown fires in human-caused wildfire assessments, a significant portion of the occurrence is not accounted for. Considering this supposedly human-caused occurrence reduces the spatial biased conducting to more robust and reliable predictions.
Uncertainty is also affecting the contribution of the explanatory variables. Results suggest that DAM, CDP, WAI and PA are the least sensitive variables to variations in the spatial distribution of the occurrence.

Abstract
A crisis situation may be due to the occurrence of a single hazard event with large impacts or due to several hazard events occurring simultaneously. Hazard events occurring at the same time may have independent causes or may result from a sequence of triggering effects. The outcome of a situation for which an adverse event triggers one or more sequential events is generally called "cascading effects".
The perception and understanding of the potential occurrence of cascading effects is of great relevance for planning and response activities since an unexpected scenario in an emergency may worsen the situation endangering people, goods, and may nullify a strategy that was developed accounting for a scenario in which the triggering event was considered as a single occurrence.
This paper presents an analysis of possible scenarios of cascading effects triggered by an earthquake. A detailed quantitative example in which an earthquake causing an electric cable failure that potentially ignites a fire is presented. In particular, a methodology to assess the occurrence probability of the event chain earthquake→cable failure→fire ignition is presented. The final results are presented as conditional probability maps representing each transition, namely: earthquake→cable failure, cable failure→fire ignition, and the assessment of the full path earthquake→cable failure→fire ignition.
This study is a part of a pilot application built to test the integrated crisis management system which is being developed in the FP7 European Integrated Project – CRISMA ("Modelling crisis management for improved action and preparedness").

Keywords*: Forest fire; earthquake, multi risk assessment; multi-hazards, cascading effects, domino effects.*

Introduction

Similarly to other natural and man-made hazard events forest fires can be triggered by some other event or they can themselves trigger one or more hazard events in a situation that is designated by a cascading effect (Marzocchi *et al.*, 2009, 2012). In a cascading process we may have either a series of events occurring in sequence or in parallel at the same time. From the operational and management points of view, the possibility of having cascading effects involving forest fires as triggering or triggered event are of great importance for the following reasons:

- The response forces will have to face two or more simultaneous or sequential events of different nature requiring a distribution of human and material resources;
- The possible diversity of events occurring in a cascading effect scenario claim for a respective versatility of the crisis response system;
- It may be possible that the strategies designed to respond to a single hazard event are not feasible due to the triggering hazard event(s).

For these reasons, it is important to investigate and assess the risk of cascading effects scenarios that may trigger forest fires, in order to improve mitigation procedures and preparation activities, but also to reduce impacts.

In this paper we explore scenarios of cascading event in which forest fires triggered after earthquakes (EQ) are studied and propose a probabilistic framework for their assessment. The presented example is based on the simulation of an EQ occurring in the surroundings of L'Aquila province, in the Italian region of Abruzzo. The spatial domain used for the analyses is shown in Figure 1. This area was affected by a Mw6.3 EQ in 2009 (Pondrelli *et al.*, 2010). This event caused 308 victims, 1,500 injured and the temporary evacuation of more than 65,000 people from their houses in L'Aquila and surrounding municipalities (Alexander and Magni, 2013). Several aftershocks were felt after the main shock compromising the rescue operations. All the available civil protection authorities were allocated in these response efforts. In the proposed scenario the situation is even more stressed assuming the possible occurrence of a forest fire due to damages to the electricity network (cable failure) caused by the EQs. It is assumed that the forest fire spreads in the direction of a village threatening the population, the houses and other assets. An efficient distribution of human resources and equipment is required to face the two interconnected disasters. In addition to earthquake induced risk for people inside houses, also the possibility that people cannot stay outdoors is to be considered because the village can became immersed in smoke. Several options are highlighted and a multi-criteria analysis, based on pre-defined indicators, criteria and costs, is carried out in order to find the most efficient way to deal with the situation.

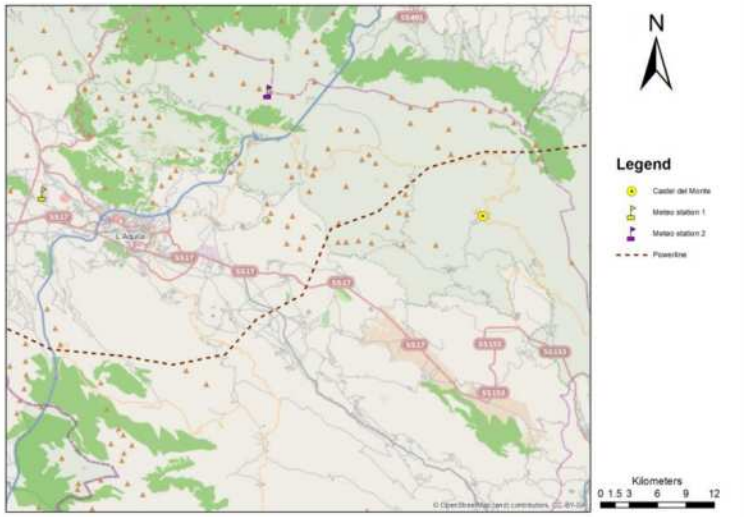

Figure 1. Map showing the area of interest for the study. The location of a hypothetical power line considered for the scenario assessment is also presented.

The analysed scenario refers to a pilot application of the EU-FP7 CRISMA Project. CRISMA focuses on large scale crisis scenarios with immediate and extended human, societal, structural and economic, often irreversible, consequences and impacts. The developed Integrated Crisis Management Simulation System (ICMS) is a simulation-based decision support system for modelling crisis management, improved action and preparedness. In this paper only the part directly related to the cascading effects of the described scenario will be elaborated on.

The methodology herein described for the probabilistic assessment of cascading effects scenarios begins with the selection of the event chain to be assessed. The first step is to identify and to structure the possible event chains and select those of interest for quantitative analyses. The result of this process is illustrated in Figure 2. In this study we focus our attention on the event chain earthquake (EQ)→cable failure (CF)→fire ignition (FI). After selecting an event chain of interest, all the necessary input parameters need to be identified and calculated in order to produce information on the occurrence probability for the scenario(s) of interest. In this case, it is necessary to calculate the following conditional probabilities (hereinafter called "transition probabilities"): EQ→CF: $p(CF|PGA)$, where PGA (peak ground acceleration) is an example of intensity measure used to characterize the EQ hazard,

and CF→FI: $p(FI|CF)$. Using this information is therefore possible to calculate the probability of occurrence of the scenario EQ→CF→FI. The outputs are provided as probability maps in order to facilitate interpretation.
Once the most problematic spots are identified, new simulations may be carried out in order to evaluate the importance of the triggered events. Some indicators may be produced to compare different scenarios and to support the final decisions. These last tasks are a consequence of the cascading effects evaluation and some examples are given in this paper.

Structuring scenarios: the event chains database

After the implementation of a detailed procedure for scenario identification and structuring, a database with various identified possible cascading event chains was created for a set of triggering events, including earthquakes (Figure 2). The sequence of events is often cyclic as a certain event type may occur in the same chain more than once. This repetition may be direct (e.g. EQ→EQ) or indirect (e.g. forest fire →WUI/urban fire →Forest fire). When a potential cycle is verified, the symbol […] was used to indicate the cyclic chain.
The possibility to have certain scenarios strongly depends on the specific case under analysis. For example, the possibility of having an explosion triggered by damages to an industrial facility depends on the type of industrial facility damaged in the area of interest. Under this perspective, the proposed diagrams must be adapted to the characteristics of the hazard event and to the area of interest.
The event chains database is of great importance as it allows the choice of the path of interest and the cascade event analysis that shall be performed. The quantitative example in this paper is centred in the specific scenario of an EQ causing damage to the electricity network (cable failure), leading to fire ignition and triggering a forest fire. In this demonstrative scenario, a Mw5.6 EQ occurring in the NE part of the study area was simulated as the triggering event. In the considered scenario, the EQ may provoke damages to the electricity network, specifically to the cables joints/couplings devices (Figure 3a) near to the pole, which may cause a rupture in the electric cable. As this electric cable is energized, it may ionize the air to the ground and consequently an electric discharge may occur. Figure 3b shows an example of air ionization caused by the proximity of a tree branch and Figure 3c shows a fire ignition caused by an electric discharge. Both examples follow the same principle of the application managed in this paper, however in this scenario we consider the case in which the area reached by the electric arc is covered by surface fine forest fuels where it is possible to trigger an ignition that may develop to a forest fire.

Quantitative data analysis

In this section we assess the occurrence probability of the selected scenario. To assess the scenario of interest, different input information is required, namely information related to the initial world state and information about the probabilities for the occurrence of transition between events. As "world state", in CRISMA, we understand a particular status of the world, defined in the space of parameters describing the situation in a crisis management simulation that represents a snapshot (situation) along the crisis evolvement (Almeida *et al.*, 2014). The change of world state, that may be triggered by simulation or manipulation activities, corresponds to a change of (part of) its data contents.
After the triggering EQ event, the initial world state changes as a consequence of the impacts resulting from it. Some impacted elements may be vulnerable in a time-dependent manner; therefore, the word state may in fact be considered to be continuously changing after the triggering event. Nevertheless, to assess the possibility of cascading effects, the world state at each moment exactly before a plausible triggering effect must be identified.
The transition probabilities are the conditional probabilities required to determine the likelihood of a transition, and primarily depend on the intensity of the triggering events in the chain.
Figure 4 schematically presents the flow of information necessary for the quantitative assessment of the event chain of interest in this work. Besides the probability functions regarding the fragility curve of the electric system and the probability of ignition after the electric cable failure, other three categories of inputs must be previously available in the world state. These are the location of the electricity network (Figure 1), the intensity distribution (shake map) of the EQ (Figure 5), and the fuel cover in the area of interest (Figure 6).

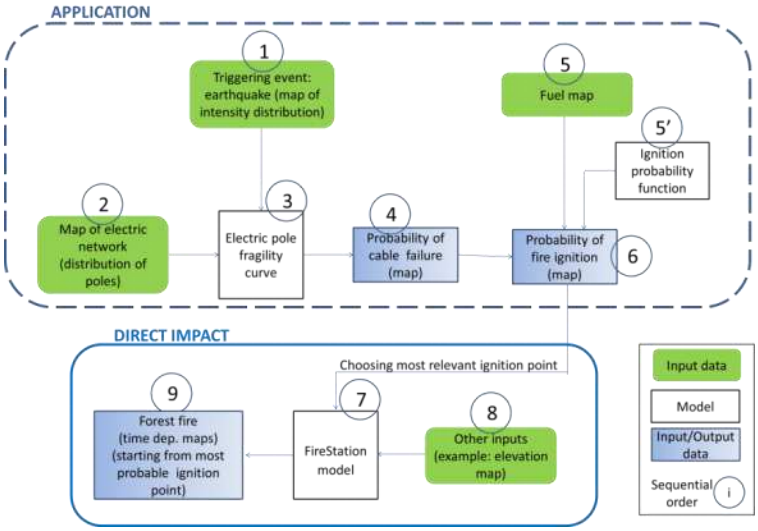

Figure 4. Flow of information necessary for the computation of the selected cascading effects scenario.

The conditional probability of a cable failure in the electric system given the EQ occurrence (and the consequent formation of an electric arc) is estimated considering the intensity distribution of the EQ (shake map) and the fragility function of the electric pole. The intensity of the EQ along the electric network is calculated using regional ground motion prediction equations that provide the intensity measure (in PGA or macro seismic intensity) at each electric pole position. On the other hand, the fragility function relating the intensity of the earthquake to the probability of cable rupture is calculated attaining a limit value of displacement at the pole top varying the intensity of the seismic input. The probability of an ignition started by an electric discharge is estimated considering the fuel classification of the area where the electricity cable failure occurs and the associated ignition model. The fuel classification is part of the world state and is available in form of a fuel map of the area of interest (Figure 6). If the electric discharge occurs in a non-fuel area, as for example a road, the probability of

ignition is zero. However, if the electric discharge occurs in a fuel area, as for example a grass land, the probability of ignition is determined by using the ignition probability model described in Section 3.2.2.

If we address the whole event chain (i.e. EQ-DEN-FI), the probability of a fire ignition due to an EQ is given by the product of the respective conditional probabilities at each node of the sequence, i.e., the probability of fire ignition given an electric cable failure, $p(FI|CF)$, the electric cable failure probability given the intensity of the ground shaking, $p(CF|PGA)$, and the probability of observing the EQ intensity, $p(PGA)$. Note that in this example we do not consider uncertainties in the ground motion prediction equation used and therefore $p(PGA)$ is assumed to be 1.

Input data

Location of the electric network

The location of the hypothetical electric network considered in this study is presented in Figure 1 and was defined at the most opportune location, only taking precautions to not locate a pole in an unlikely place such as in the middle of a river. The separation between two successive poles is 300m.

Map of EQ intensity distribution

The occurrence of a Mw5.6 EQ in the NE part of the study area has been simulated as the triggering event for this scenario. The shake map of this event, represented by the intensity of the ground motion in the area of interest, is shown inFigure 5. Using that shake map, the peak ground acceleration (PGA, in %g) is calculated at the base of each pole of the electric network considered for this study.

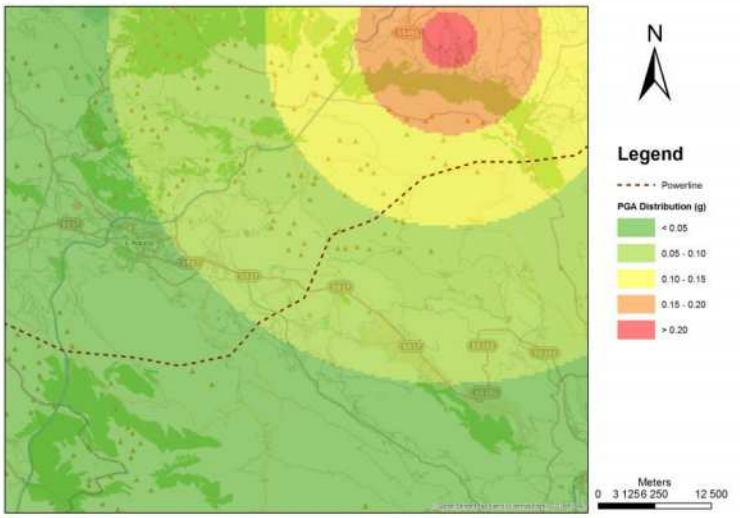

Figure 5. Map of the triggering earthquake intensity distribution with location of the electric power network (distribution lines - smaller poles)

Fuel map

The fuel map is crucial to evaluate the probability of ignition as it includes the information on the class of fuel in the cell(s) where each electricity pole is located. To be harmonized with the fire behaviour prediction model used (FireStation, Lopes *et al.*, 2002), the classes defined in the fuel map are consistent with those used in the FireStation model. As can be seen in Figure 6, in the area of interest there are seven different fuel classes, with grassland being most prominent.

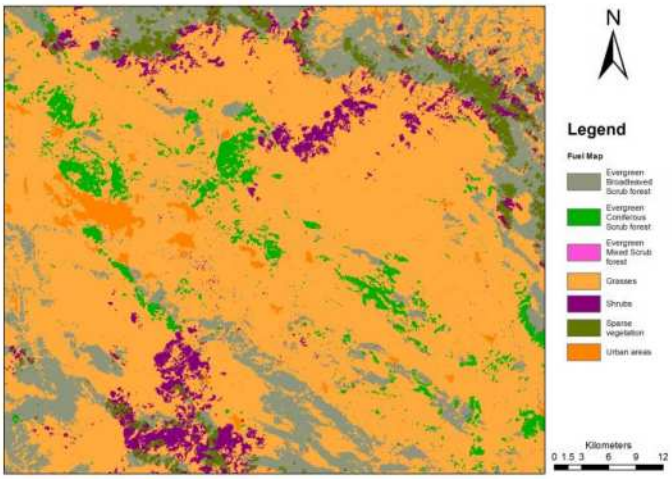

Figure 6. Fuel map for the region of L'Aquila. This fuel map was developed in April 2014 by the ArcFUEL Project Consortium from a cooperation protocol established between CRISMA Project and the European LIFE+ Project ArcFUEL.

Conditional probabilities

Each event transition requires a conditional probability. In the example herein presented, the event "damage to electricity network" is caused by an electric cable disruption (cable failure). However, the same event could also be caused by the fall of a pole. These two different cases require two different probability functions.

3.2.1. *Transition probability function for the cable failure triggered by an earthquake*

The fragility of the electricity poles used in electricity distribution lines is dependent on several factors as their dimensions, material, state of maintenance, etc. The fragility curve represents the probability of cable rupture as a function of the displacement at the pole top varying with the intensity of the seismic input. Such limit value is represented as a fraction of a displacement X_{MAX} (three hypotheses are considered: 0.5 X_{MAX}, X_{MAX} and 1.25 X_{MAX}), where X_{MAX} is defined as the displacement corresponding to the static application of a transversal force. The shaking of a pole may lead to tensions in the cables which may consequently disrupt. Cable disruption normally occurs in the connections which are the most fragile parts of the network.

In Figure 7, the fragility curve of a pole (type: 12B14) as function of the peak ground acceleration (PGA) is shown. In order to simplify the use case, all the electricity poles in the study area will follow the fragility curve X_{MAX}.

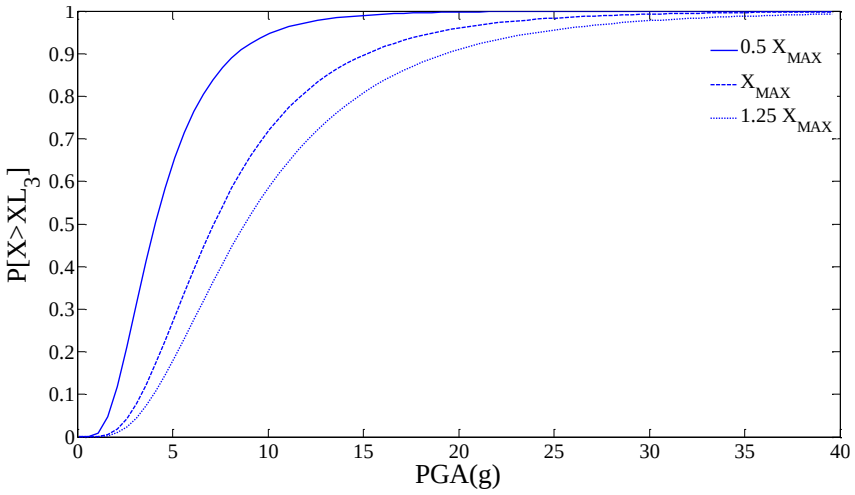

Figure 7. Fragility curves of electric poles to a transversal force T1.

3.2.2. *Transition probability function for fire ignition triggered by cable failure*

The transition from the electric cable failure to a fire ignition has two evolutionary steps: 1) the production of the electric arc from the electricity cable to the fuel bed, and 2) the ignition of the fuel bed by the electric arc.

It is assumed that the failure of an electric cable imperatively causes an electric arc. Due to the existing protection systems, the electric charge is normally interrupted in case of failure and after that, for brief instants, the residual electric charge continues flowing. After the cable breakage, the cable takes some time to land or to reach a sufficient distance to establish the electric arc. The time to ignition by electric arc with high voltage is very short (tenths of seconds) and therefore in this sense it is reasonable to consider the production of an electric arc for a short period as inevitable. On the other hand, the time to ionize the air path from the cable failure to the fuel bed and the consequent production of the electric arc is strongly dependent on the distance and on the resistance of this path. This dependency is a function of many additional factors such as topography, cable height, air humidity, and pressure. For simplification reasons we will not take those aspects into consideration in this paper, but rather assume that the cable failure will always drive to an electric arc that reaches the fuel bed.

In a laboratory environment, several tests were carried out in order to determine the total amount of energy required to ignite a certain amount of fuel. These tests were performed for straw and pine needles (*Pinus pinaster*) for a range of fuel moisture content (FMC) between 9.2% and 12.2%. A bouquet of the fuel material was exposed to an industrial electrical arc of certain power (P [kVA]) as can be seen in Figure 8. The time (t [s]) elapsed from the beginning of discharge until the evidence of combustion was measured. The energy (E[kJ]) required for ignition was determined using Equation 1.

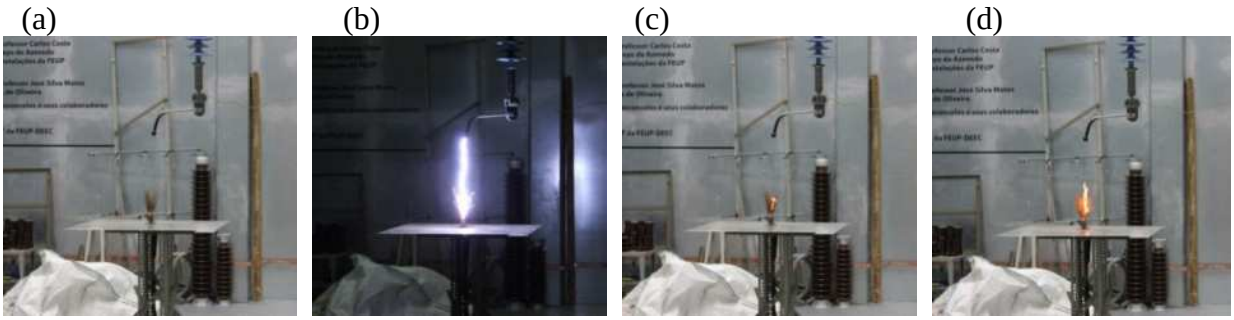

Figure 8. Sequence of images of a laboratorial test to determine the energy required for ignition by industrial electric discharge.

$$E = P \times t \qquad \textbf{[1]}$$

It was found that the probability of ignition was not significantly different for the several tests at different conditions of FMC or different types of fuel (straw or pine needles) and also the fuel load does not seem really relevant for the probability of ignition. This statement should be considered preliminary since not many tests with fuels other than straw and pine needles were carried out and the range of fuel moisture content was not very extensive. It also refers specifically to the situation of a cascading effect scenario, i.e. the possible spot ignition by electric discharge. Findings might be different for other ignition causes where fuel and soil moisture are expected to play a more significant role and are therefore sometimes regionally monitored to identify and address potential susceptible areas (Aubrecht *et al*., 2011).

Using the data collected in the laboratory experiments, we estimated the parameter of different competing probabilistic models in order to find the distribution providing the best description of the laboratory observations. As possible competing models we used the Log-normal, Gamma, Normal, Weibull and Exponential distributions. We estimate the model parameters for each candidate model using a Maximum Likelihood Estimate (MLE) approach, and use the Akaike Information criteria (AIC, Akaike 1974) for the model selection. The AIC is a tool based on the concept of entropy and offers a relative measure of the information lost when a given model is used to describe some data (a trade off between accuracy and complexity of the model).

Table 1 summarizes the functional form of the PDF, estimated (MLE) parameters (and uncertainties), and the AIC for all the probabilistic models considered. Using a Kolmogorov–Smirnov test, we cannot reject the Log-normal, Gamma, and Normal hypotheses (at significance level of 0.05), which means that, from a statistical point of view, all these probability models successfully explain the observed data. However, according with the AIC values, the preferred model (i.e. that with the lowest AIC value) is the Log-normal.

Table 1. Candidate distributions, PDF, estimated (MLE) model parameters and uncertainties, and Akaike Information Criteria (AIC). According to the AIC information, the model that best describes the data is the Lognormal

Model	Probability density	Parameters (MLE)	AIC
Log-normal (μ,σ)	$\boldsymbol{y = f(x\|\mu,\sigma) = \frac{1}{x\sigma\sqrt{2\pi}} e^{-\frac{(\ln x-\mu)^2}{2\sigma^2}}}$	μ=6.334 [6.329,6.339] σ=0.246 [0.243,0.250]	– 62803
Gamma (a,b)	$\boldsymbol{y = f(x\|a,b) = \frac{1}{b^a \Gamma(a)} x^{a-1} e^{-\frac{x}{b}}}$	a=16.68 [16.22,17.14] b=34.84 [33.87,35.83]	– 62845
Normal (μ,σ)	$\boldsymbol{y = f(x\|\mu,\sigma) = \frac{1}{\sigma\sqrt{2\pi}} e^{-\frac{(x-\mu)^2}{2\sigma^2}}}$	μ=581.0 [578.1,583.8] σ=146.3 [144.2,148.3]	– 63319
Weibull (a,b)	$\boldsymbol{y = f(x\|a,b) = \frac{b}{a}\left(\frac{x}{a}\right)^{b-1} e^{-\left(\frac{x}{a}\right)^b}}$	a=637.1 [633.7,640.6] b=3.87 [3.81,3.92]	– 63832
Exponential (μ)	$\boldsymbol{y = f(x\|\mu) = \frac{1}{\mu} e^{-\frac{x}{\mu}}}$	μ=581.0 [569.7,592.6]	– 72815

Figure 9a shows the cumulative probability (CDF) of the candidate distributions and the empirical CDF of the observed data, while the Figure 9b shows the CDF and related uncertainties of the Log-normal model.

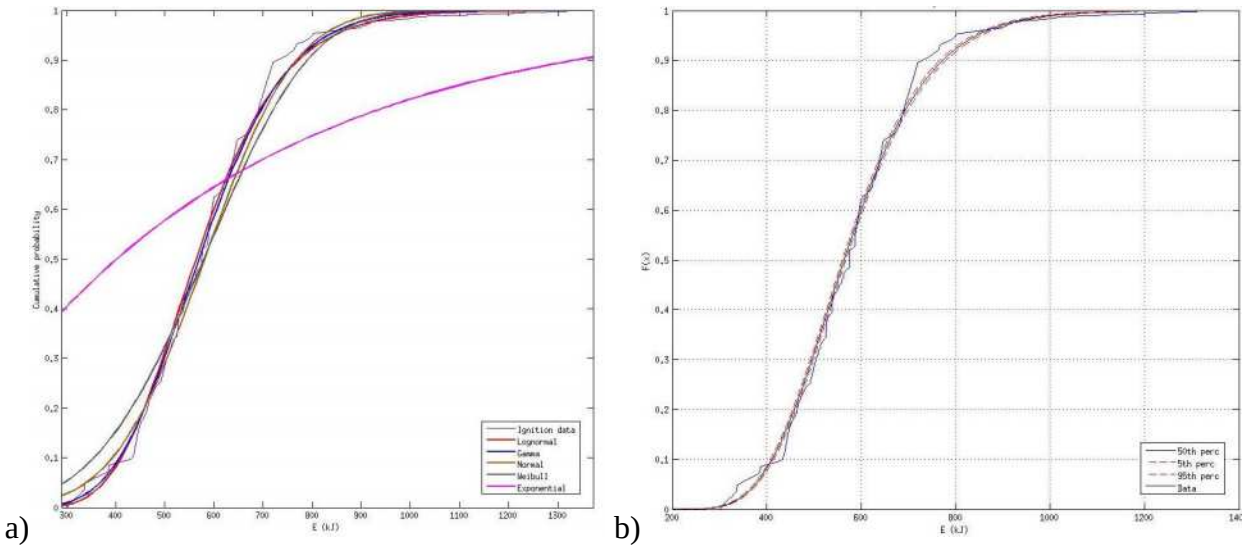

Figure 9. a) Plot of the Cumulative Distribution Function (CDF) of Log-normal, Gamma, Normal, Weibull, and Exponential competing models, and the empirical CDF of the observed data; b) CDF of the Log-normal (with parameters as those presented in Table XX), selected as the best model describing the observations

Therefore, the model selected to describe the energy required to start an ignition is a Log-normal with parameters μ=6.334 [6.329, 6.339] and σ=0.246 [0.243, 0.250], where the values in parenthesis represent uncertainty bounds. The Log-normal model is therefore used for the determination of the probability of fire ignition given the occurrence of an electric discharge. Since for simplicity we consider that an electric cable failure will always generate an electric discharge, this model consequently also represents the probability of a fire ignition given a cable failure.

As previously mentioned, there was no significant difference in the results achieved for pine needles as compared to straw. Therefore, for simplification, we assume that the model can provide the probability of ignition for all fuel classes other than urban areas, where the probability of ignition by electric discharge is assumed to be zero. This assumption seems reasonable as commonly, for prevention reasons, the area below electric cables is cleaned of heavy fuels.

Results

In this section, the maps summarizing the results obtained for event probabilities at different parts of the event chain are presented. Figure 10a shows the map representing the probability of cable failure in the electric network given the occurrence of a Mw5.6 seismic event in the NE part of the study area.

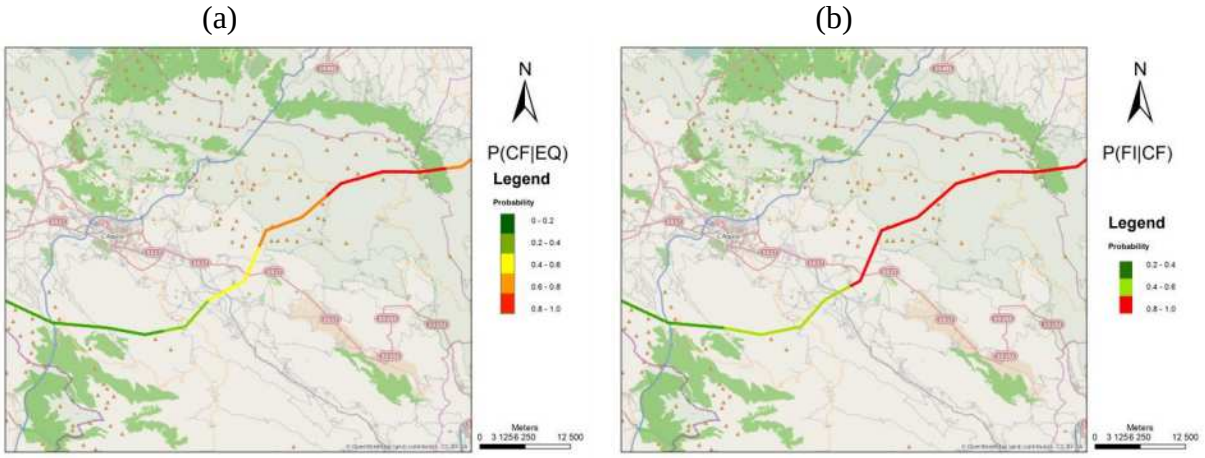

Figure 10. Maps for: a) probability of cable failure, and b) probability of fire ignition due to an electric cable failure

As it was previously explained, cable failures occur close to the electric poles. Therefore, the information on the cable failure probability is presented around the poles. In this case, a single electric poles fragility curve was used (X_{MAX}=1) and therefore the probability of cable failure depends exclusively on the distance between each pole and the seismic epicentre.
Besides the visualization of the map for probability of cable failure due to the triggering EQ event, the assessment of the probabilities of fire ignition due to cable failure also needs to be considered. This information is provided in the form of a distribution map as shown in Figure 10b. The map for distribution of fire ignition by electric cable failure is obtained from the fuel map (Figure 6), the geographic location of the electric network (Figure 1) and the probability function of fire ignition.
It is worth noting that the probability of fire ignition is strongly dependent on the energy released by the electric discharge. The amount of energy released during the discharge was determined by fixing a trigger time (electric interruption) of 0.1s, a power of 8,000kVA (current of 53A and voltage value of 150kV) and consequently 800kJ of energy for the first 20km of electric line (first 67 poles on the right side of Figure 10b). Furthermore, a withdrawal of 100kJ of energy was assumed due to energy consumption and losses for every 20km of electric line, resulting in a decrease of fire ignition probability along the electric network.
Finally, to evaluate the fire ignition probability given the occurrence of the seismic event, the full path of the selected scenario can be assessed. In this case, the probability of fire ignition is the product of the probability of cable failure due an EQ of a certain seismic intensity distribution, the probability of a fire ignition due to a cable failure (Equation 3), and the probability of having the PGA value calculated at the pole site (which in this case is 1 because we neglect uncertainties in ground motion prediction equations). Figure 11 shows the probability map of fire ignition triggered by the occurrence of the seismic event considered in the worked scenario.

$$p(FI) = p(FI|CF) \times p(CF|PGA) \times p(PGA) \quad \textbf{[3]}$$

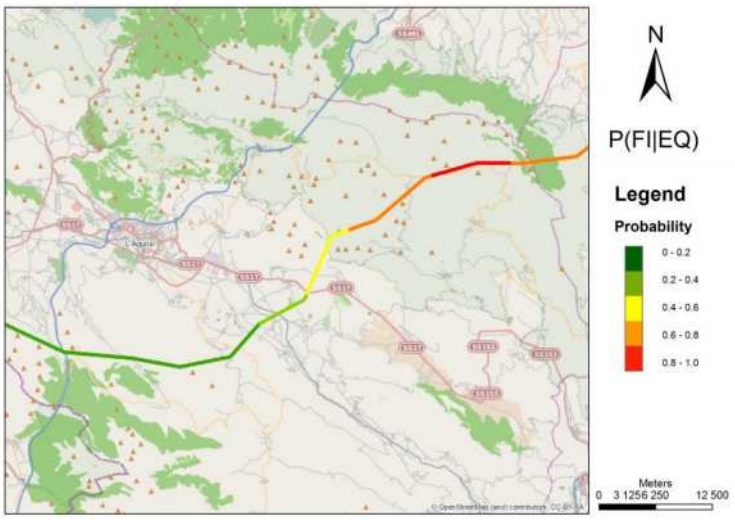

Figure 11. Map for probability of fire ignition due to the Mw5.6 earthquake considered in thestudied scenario

Supported by the information on the probability of a fire ignition around each pole, the simulation of an ignition and the subsequent fire development is commonly the following step. For a given pole with a calculated probability of fire ignition, we perform a fire propagation simulation using the FireStation tool in order to forecast the spread of the fire and other parameters of interest, as shown in Figure 12 The comparison of impacts caused by both EQ and forest fire in a cascade effect event may be an important information to support the decision making process. As outlined by Aubrecht *et al.* (2014), the temporal evolution of the entire cascading effects scenario also provides crucial input for

evacuation planning and societal impact assessment, taking into consideration dynamic population exposure models to cover the respective world state states.

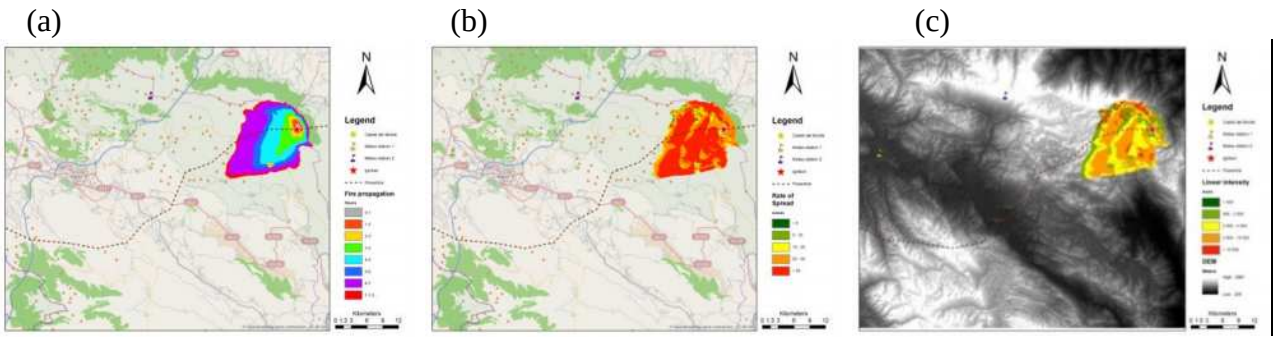

Figure 121 – Map of the evolution of the forest fire (a) after the ignition by the electric discharge from a probable ignition point and other possible outputs from the FireStation software: b) rate of spread, c) linear intensity.

Summary

The occurrence of a surprising cascading event chain may complicate an emergency situation caused by the occurrence of an adverse event since the initial strategy may become useless for the new scenario of multiple hazards occurring in a given chain of events. The probabilistic assessment of cascading effect scenarios is therefore of great relevance for precautionary reasons as this evaluation is useful before the hazard transition occurs. The probabilistic assessment of cascading effects scenarios shall be performed in a short and long term planning phase. Short term planning is related to a scenario where the triggering event has occurred and strategic plans are being designed in order to eliminate or mitigate further impacts. Long term planning is associated to a scenario where the triggering hazard event has not yet occurred but plans are being made in advance for preventive or preparative reasons.
A methodology for the probabilistic assessment of cascading effects was described using a sample scenario of an EQ as triggering event. After collecting the reauired data, it was possible to quantify the probability of fire ignition around the electric poles located in the study area. The anticipated perception of the likelihood of secondary events may support decision-making in order to avoid larger impacts caused by the triggered events (as the wild fires considered here) that would cause additional impacts respect to those directly caused by the triggering EQ event.

Abstract

The impact caused by forest fire, although it is an old subject, but increasingly larger proportions, has stimulated the development of new methods for the prevention and reduction of risks in the environment. The use of a reliable index of risk among the existing preventive measures is fundamental to a more efficient planning of prevention and an effective action of fight. The work involving the forest fire prevention must use all the tools available since it is a complex task and one that shows great variability in the time of occurrence. One such tool is the degree of danger by means of an index that reflects the probability of fire occurrence. Meteorological indices have shown good results in predicting events and contributing to the work of forecasting fire in forests. The aim of this study was to analyze 4 descriptive fire risk indices for the period from 01/01/2006 to 12/31/2012. Each of them was built with 4 hazard classes of risk. The indices used were Formula de Monte Alegre (FMA), Index of Nesterov, Index of Telicyn and P-EVAP According to the results, the rate of P-EVAP performed better in accuracy of forecasts of occurrences within the class of High Risk, while the FMA was the most effective in the forecast of no occurrence in classes of Low Risk and No Risk. The days classified as Medium Risk in Telicyn indices and P - EVAP presented closest to the average of occurrences in the entire series averages. Knowledge of descriptive classes of indices for predicting fire is valuable to communicate with public, help the actions of awareness, prevent and plan accident. The results had shown some similarities with studies of Torres *et al*. (2009). They used the Skill Score (SS) method and concluded that the logarithmic index of Telicyn showed the best results for the study area.

Keywords*: Index of danger, descriptive classes, fires*

Introduction

Forest fires contribute to air pollution, climate change and are among the most damaging to some ecosystems events (Magalhães, Lima & Ribeiro, 2011). In areas of economic development, the pressures that forest areas suffer due to the need for new areas intended for agricultural activities, have greatly increased the number of fires and the extent of burned areas due to bad use of fire as an agricultural tool (Alves & Nóbrega, 2011).

In recent years, debates involving fires have increased significantly because there is a great concern due to the release of CO2 and other gases to atmosphere, which are residues from the vegetation combustion. Brazil, in general, is considered as a great contributor of CO2 emissions resulting from forest fires. Globally fires and emissions cause severe losses of biodiversity, interfere in a water cycle and in carbon cycle in the atmosphere. This cause economic, landscaping and ecological loss, reaching protected areas, farms, roadsides, urban areas and nearby areas of reforestation, besides other places (Souza, Casavecchia & Stangerlin, 2012).

One way to prevent these fires is through knowledge of the degree of the risk, which reflects the possibility of an event to occur. These indices can be supported by environmental variables, usually related to weather conditions and can be estimated by indices constructed with different combinations of variables (Tetto *et al*., 2010).

The risk assessment is based, in general, in an integration of the factors that contribute to the risk of the forest fire model. This method of risk assessment is reflected generally in indexes that can be

materialized in maps which are expressed areas or levels of risk (Antunes, Viegas and Mendes, 2011). Besides to allow the correct planning Borges *et al*. (2011) argue that the use of a risk index reliably fire is critical to the establishment and mapping of risk areas, defining the number and location of fire observation towers and public warning level risk, which is considered an important factor in environmental education programs. The first step is determine the danger of fire occurrence. For this, several methods have been developed and refined over the years and in different countries.
According Carapiá (2006), rates of fire risk are influenced by several factors, usually fuels, topography and weather. The choice of variables and methods used in this combination results in a variety of approaches. Faced with this diversity, several solutions have been proposed for classification. Depending on the input data, two main groups of methods may be identified: 1) weather risk, which is based solely on data of weather conditions (like temperature, relative humidity, rainfall and wind speed) and 2) potential risk, when are considered more advanced approach, and includes as input the state of vegetation, type of fuel and its moisture content.
The aim of this study was to compare the efficiency of 4 weather indices: Formula de Monte Alegre (FMA) (Soares, 1972), Logarithmic Index of Telicyn, Nesterov Index and Cumulative Index P-EVAP. Will be analysed the relationship of hazard classes of each index with the occurrences of forest fires in the urban area of Juiz de Fora, MG, Brazil, whereas the use of a reliable index of danger is a fundamental factor for efficient planning of measures prevention and to adopt quick and effective actions in fighting fires, in order to reduce losses and, consequently, of any financial losses resulting from the occurrence of catastrophic events.

Methods

In this study was analyzed a time series of 01/01/2006 to 31/12/2012. Meteorological data were provided by LabCAA (Laboratory of Climatology and Environmental Analysis) of the Federal University of Juiz de Fora (UFJF). The information on 3,135 occurrences of forest fires in urban area, were provided by the 4th Battalion of Military Firefighters (4th BBM).
An analysis of days according to the hazard class of each index was taken, noting occurrences per day, percentage of days with occurrences and percentage of occurrences of each class in relation to the whole period.
The calculation of each index was performed as follows:

2.1. Fórmula de Monte Alegra - FMA

$$FMA = \sum_{i=1}^{n} (100/Hi)$$

where:
FMA = Monte Alegre index.
H = relative humidity (%).
n = number of days analysed

The index value is subject to restrictions according to the precipitation, as shown in Table 1:

Table 1. Modification in the FMA value in agreement with the precipitation

Rain day (mm)	Modification of the calculation
≤2,4	None
2,5 a 4,9	Shoot down 30% in the FMA calculated before and add (100 / H) of the day
5,0 a 9,9	Shoot down 60% in the FMA calculated before and add (100 / H) of the day
10,0 a 12,9	Shoot down 80% in the FMA calculated before and add (100 / H) of the day
>12,9	Interrupt the calculation (FMA=0), starting over the sum in the next day or when rain to cease.

Source: Torres *et al*. (2009)

Telicyn Logarithmic Index

$$I = \sum_{i=1}^{n} \log (ti - ri)$$

where:
I = Telicyn index
T = air temperature in °C
r = dew point temperature in °C
log = logarithm to the base 10

Restriction Index: whenever a precipitation equal or higher than 2.5 mm occurs, abandon the sum and start calculating the next day or when the rain stopped. In this case the index value is zero.

Nesterov Index

$$G = \sum_{i=1}^{n} di \cdot ti$$

where:
G = Nesterov Index
d = saturation deficit of the air in millibars
T = air temperature in °C
n = number of days analysed

The saturation deficit of the air, in turn, is equal to the difference between the maximum water vapor pressure and the real pressure of water vapor, which can be calculated by the following expression:

$$d = E (1-H/100)$$

where:
d = saturation deficit of the air in millibars
E = maximum pressure of water vapor in millibars
H = relative humidity in%

The sum is limited or changed by the occurrence of precipitation according to Table 2.

Table 2. Modification in the G calculation in agreement with the precipitation

mm Rain day	Modification of the calculation
≤2,0	No
2,1 a 5,0	Shoot down 25% in the G value calculated to the day before and add (dt) of the day
5,1 a 8,0	Shoot down 50% in the G value calculated to the day before and add (dt) of the day
8,1 a 10,0	Abandoning the previous sum and start new calculation, ie, G = (dt) of the day
>10,0	Interrupt the calculation (G=0), starting over the sum in the next day or when rain to cease.

Source: Torres *et al*. (2009)

2.4. P-EVAP

The P-EVAP cumulative index proposed by Sampaio (1991), relates the difference between precipitation (P) and evaporation (EVAP), both daily measured in mm. The restrictions on the calculus are the same of Nesterov index (Table 2).

To normalize the number of classes of indices, the class named as Most High Danger of FMA and Nesterov index was grouped within the class of High Risk. For Index-P EVAP, descriptive classes were determined according to the average of occurrences per day. The descriptive classes of each index are shown in Table 3.

Table 3. Descriptive classes of the indices

Indexes	Hard	Middle	Low	Null
FMA	>8,0	3,1 a 8,0	1,1 a 3,0	≤1,0
Telicyn	> 5,0	3,6 a 5,0	2,1 a 3,5	≤ 2
Nesterov	> 1000	501 a 1000	301 a 500	≤300
P-EVAP	< -44,9	- 17 a - 44,9	- 5 a - 16,9	> -5

Adapted from: Torres *et al*. (2009)

3. Results and Discussion

In the time series, the average was 1.14 events per day. The indices of Nesterov and FMA were those with more days classified as High Risk (Table 4). At Average Risk, FMA and P-EVAP had a greater number of days. Classes of Low and Zero Risk indices with the highest number of days were P-EVAP and Telicyn.

Table 4. Number of days of each index by danger class

Index	Hard	Middle	Low	Null	Total
FMA	1293	495	347	605	2740
Telicyn	990	213	245	1292	2740
Nesterov	1453	295	157	835	2740
P-EVAP	663	487	495	1095	2740

Analyzing the descriptive class of High Risk (Table 5) it is observed that the P-EVAP index showed the highest number of occurrences per day within the period (3.0), and 81% of days classified as High Risk for fires that occurred. On the other side presented the lowest number of occurrences within the period (63%), while Nesterov index record higher percentage of occurrences (88%).

Table 5. Analysis of the descriptive class of High Risk

Index	Events/day	% of days with occurrences	% of occurrences
FMA	2.06	68%	85%
Telicyn	2.42	74%	77%
Nesterov	1.90	64%	88%
P-EVAP	3.00	81%	63%

Regarding the days classified as Medium Risk (Table 6), it was observed that the index of P-EVAP showed the most occurrence per day (1.12), where 54% of days with occurrence and 17% of occurrence on the period. Furthermore, Nesterov and FMA indexes showed less occurrences per day, being classified as Medium Risk (0.56) and percentage of days with events (30% and 31%). However, there was a difference in the percentage of occurrences within the class in relation to the series studied, the FMA had the second highest percentage (9%) while the Nesterov index ranked last (5%).

Table 6. Analysis of the descriptive class of Medium risk

Index	Events/day	% of days with occurrences	% of occurrences
FMA	0.56	31%	9%
Telicyn	0.92	48%	6%
Nesterov	0.56	30%	5%
P-EVAP	1.12	54%	17%

In the days classified as Low Risk (Table 7), the FMA showed the least amount of occurrences per day (0.26), a lower percentage of days with occurrences (14%) and second lowest percentage of occurrences for the period around (3%). The Telicyn index had shown the highest number of occurrences per day (0.82) and percentage of days occurring within the class (42%). The P-EVAP index showed the highest percentage of occurrences in relation to the 2740 days of the series (11%).

Table 7. Analysis of the descriptive class of Low Risk

Index	Events/day	% of days with occurrences	% of occurrences
FMA	0.26	14%	3%
Telicyn	0.82	42%	6%
Nesterov	0.37	25%	2%
P-EVAP	0.68	37%	11%

In the of Null Risk class (Table 8), the FMA and Nesterov index got the best performance in relation to the number of occurrences per day (0.18 and 0.19), percentage of days with no occurrence (92% and 91%) and concentrated the lowest number of occurrences in relation to the whole period (3% and 5%). While the Telicyn index got the highest number of occurrences per day (0.27), a lower

percentage of days without incidents (85%) and the highest concentration of occurrences in relation to the whole period (11%).

Table 8. Analysis of the descriptive class of null risk

Index	Events/day	% of days with occurrences	% of occurrences
FMA	0.18	92%	3%
Telicyn	0.27	85%	11%
Nesterov	0.19	91%	5%
P-EVAP	0.23	88%	8%

The results showed some differences and similarities with the studies by Torres *et al*. (2009) They used the Skill Score (SS) method which is the ratio of the difference between the occurrences in the forecast and the expected number of occurrences; and the difference between the observed number of days and number of days with forecast adjustments. It was concluded that the Telicyn logarithmic index achieve the best results for the characteristics of Juiz de Fora territory. However, in an individual analysis of the occurrences predictions and no occurrences of fires, it is observed that the most effective index was the P-EVAP with 77% of correct predictions, while the FMA was the index that best answered forecasts of not fires occurrences with 90% accuracy.

Conclusion

The data showed a wide variety in the results of each index . However it can be concluded that for days with high fires risks, the rate of P - EVAP performed better in accuracy of forecasts of occurrences also concentrating the highest average successes per day within the period.
Furthermore, the FMA showed the best results for days classified as Low Risk and No Risk , with higher percentage of success in forecasting of non occurrences and lower value of occurrences per day in class.
Analysing the days classified as Medium Risk , P – EVAP and Telicyn indices were closer to the values from the average of daily occurrences on the whole period studied.
The knowledge of descriptive classes of indices for predicting fire can be very valuable in informing the public, helping the actions of awareness and prevention of more serious accidents.

Characterizing pyroregions in south-eastern France

Thomas Curt, Thibaut Fréjaville, Christophe Bouillon

[a] *IRSTEA-EMAX Mediterranean ecosystems and risks, 13185 Aix en Provence (France),*
thomas.curt@irstea.fr, thibaut.frejaville@irstea.fr, christophe.bouillon@irstea.fr

Abstract
Efficient fire policies may rely on good knowledge of the regional variations of fire activity and of fire drivers. South-eastern France comprises a range of pyroclimates, i.e. regions with contrasted fire activity (from fire-prone Mediterranean areas to mountain areas with few fires) and contrasted climate and fire weather. We tested if these pyroclimates also corresponded to specific hierarchy among environmental and human variables which drive fire activity. We used a 1973-2009 georeferenced fire database, and we computed how the landscape compartmentalization, the fuel coverage, the human density and the fire suppression capacity varied at a 2x2 km scale. The first pyroregion regroups two maritime fire-prone mountains (Corsica and the maritime Alps) in which there are no clear limitation to fire activity because of high human activity (i.e. numerous ignitions), no fuel limitation, and no weather limitation. The area is especially fire-prone because the suppression capacity is low to medium, and because the compartmented landscape hinders the activity of firemen. In the second pyroregion (fire-prone Mediterranean plains and foothills), fire activity is neither weather-limited (especially during dry summers) nor fuel-limited. It is clearly controlled by fire suppression which is especially active. In the third pyroregion (cool peri-Mediterranean mountains), fire activity remains low in spite of low fire suppression capacity and high landscape compartmentalization, because human activity is low and fire weather is unfavorable on average. We discuss to which extent the present fire suppression strategy (i.e. fast, hard-hitting initial attack on all fires) is adapted to these different pyroregions. In the fire-prone maritime mountains, it would be useful to increase the fire suppression forces. In fire-prone plains and foothills, the current plan of action is well suited, but large and destructive fire may persist due to the climate change and the fuel accumulation. In mountainous areas with low fire activity, fire suppression forces will likely have to adapt to the forecasted increase of fire activity.

Keywords*: pyroregion; pyrogeography; k-means clustering; fire hazard; France*

Introduction

Wildfires are major disturbances in many terrestrial ecosystems worldwide. In south-eastern France, fires have major impact on humans, infrastructures, and ecosystems (Curt, Borgniet *et al*. 2013). Basically, wildfire activity and fire regime depend upon three main requirements: sources of ignitions, a fuel to burn (i.e. vegetation and land covers), and a favorable climate and weather acting on fire ignition and propagation (Krawchuk, Moritz *et al*. 2009). The chief drivers of fires are thus: (i) climate which promotes the weather conditions favorable to fire ignition and propagation; (ii) human activities which provide a part of the ignitions, which modify land uses and vegetation, but which also suppress fires; and (ii) vegetation and land uses. The environmental conditions as the topography modify fire propagation. Pyrogeography (*sensu* (Krawchuk, Moritz *et al*. 2009) suggests that interactions among these drivers create specific landscape patterns of fire distribution. Here we call 'pyroregion' an area characterized by a typical spatiotemporal pattern of fires driven by a typical hierarchy among fire drivers (weather, fuels, humans).
Characterizing pyroregions is crucial for fire science and fire policy. Actually, it can help understanding the contribution of each fire driver from past to present. The fire policy and the fire suppression strategy may thus adapt to the regional variations of fire regime.
The south-eastern part of France is a good study case because it comprises a range of regions with different fire activity, and presumably different hierarchy among fire drivers. A simple view of the 1973-2009 fire maps shows that fire size, fire pattern, and fire number varies strongly within study

area (Figure 1). The southernmost part of this area comprises Mediterranean-type ecosystems which are especially fire-prone. The peri-Mediterranean areas have less summer fires but more prescribed burning in winter and spring (Fernandes, Davies *et al*. 2013). The mountain areas (southern French Alps, Eastern Pyrénées and Massif Central) are less fire-prone but some of them have experienced increased fire activity during the last decades. A precedent study (Fréjaville & Curt, this issue) partitioned the south eastern France into pyroclimatic regions based on spatiotemporal patterns of fire and climate. We tested to which extent these pyroclimatic regions also corresponded to specific hierarchy in the environmental and human drivers, including fire suppression.

Methods

In this study we characterized how areas characterized by similar fire regime, climate and similar temporal trend (i.e., pyroclimatic regions) depicted hierarchy in environmental and human drivers throughout southern France, i.e. what are the pyroregions. For this purpose we used a georeferenced fire database (1973-2009), and data on human activities, fuels, weather, and topography.

Study area

The study area was the whole south-eastern France (ca. 80,500 km²), including the 15 departments most frequently subjected to wildfires. This area has varied rates of coverage by flammable fuels such as forests and shrublands (15 to 70%). The main forest types are oaks forests (*Quercus ilex, Q. pubescens*), pine forests (*Pinus halepensis, P. sylvestris, P. nigra, P. pinaster*), and mixed oak-pine forests. At higher elevation, forests comprise *Larix decidua, Fagus sylvatica, Abies alba*, *Picea abies,* and *Pinus cembra*. Flammable shrublands (so-called *garrigues* and *maquis*) are common in the southernmost part of the study area. They are dominated by *Quercus coccifera*, *Ulex parviflorus*, *Cistus* spp., and *Erica arborea*. At high elevation, the dominant shrubs are *Vaccinium myrtillus* and *Arctostaphyllos uva-ursi*. The study area covers a large gradient of elevation from the sea level to the subalpine ecosystems of the French Southern Alps (ca. 2500 m asl).

The southern part of the study area along the Mediterranean sea has typical Mediterranean climate with hot and windy summers which favor fire activity. The peri-Mediterranean area has a supra-Mediterranean climate with hot summer temperature but cold winters, and the mountain climate of the French Alps is typically cold in winter and cool in summer.

Wildfire activity heterogeneously impacted the ecosystems and the landscapes in the study area (Figure 1), with a clear gradient from the highly fire-prone coastal areas located near the Mediterranean sea, to peri-Mediterranean mid-elevation mountains which experience frequent fires, then to subalpine mountains which historically experienced fires but at much lower frequency and intensity (Genries, Mercier *et al*. 2009). Fire is a major driver of vegetation dynamics in the Mediterranean part of the study area: about 6% of the wildland being has burned at least once between 1960 and 2011. In this area, stand-replacing fires are predominant and mostly occur in summer (Curt, Borgniet *et al*. 2013). Fire is also frequent in the peri-Mediterranean area all along the coast. Mountain areas (notably subalpine areas of the Pyrenees and Alps) experienced quite frequent fires along the Holocene but these fires were mostly surface fires. All the study area is under the protection of the fire suppression crews and services, but regional variations in fire suppression means exists (see below 2.6).

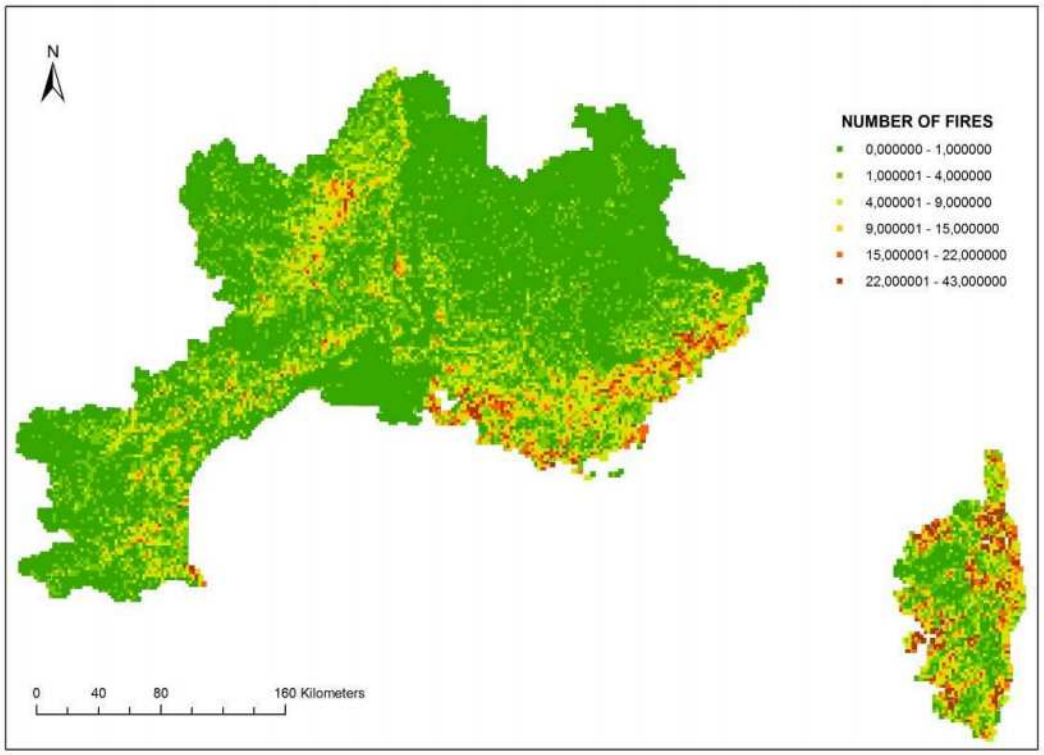

Figure 1. Fire density in south-eastern France (number of fire from 1973 to 2009)

2.2. Fire Data

We used the French Prométhée fire database (Prométhée 2011) which gathers all wildland and forest fires and indicates their date, hour, size, and location on a 2*2 km grid since 1973. We analyzed data for the 1973-2009 period. Fire activity was characterized by three variables: fire density was computed as the number of fires recorded in a 2*2 km pixel, the burned area computed as the total area burned in each pixel (calculated as the sum of all individual fires), and the fire length season which was calculated as the number of days during which fires occurred in a given year in each pixel along the 1973-2009 period.

2.3. Fire Weather

We used the fire weather index (FWI) and its sub-indices (FFMC, DMC, DMC) to assess the mean weather during a fire event, which is crucial for explaining its size and pattern. The FWI is a unitless index that was designed originally to forecast fire risk in Canada on the basis of past and current weather conditions (van Wagner 1987) including air temperature and relative humidity, surface wind speed, and rainfall in the past 24 hours. It provides a uniform, numeric method of rating fire danger throughout an area (Aguado, Chuvieco *et al*. 2003). The FWI aims to predict the probability and ease of ignition and propagation of a fire on the forest floor, taking into account the weather conditions. High FWI values indicate high fire danger.

2.4. Land covers and fuels

The type of land cover may affect the propensity to burn because all land covers do not have the same flammability, and because some land covers are preferentially burned for agricultural purpose or other purposes. The main types of land covers have been assessed using the CORINE 2006 database. We

regrouped the land uses in main categories including forests (pine, oak, and mixings), shrublands, pastures, agricultural lands, urban lands, and other types such as lakes and rivers.
It is of importance to assess the fuel coverage in each pixel of the study area. For this purpose we transformed the CORINE land covers (see above) into flammable fuels (forests, shrublands, and pastures) and non-flammable fuels (i.e. all other types of land cover). Each pixel was assigned a value of fuel coverage computed using a fuel connectivity index for the 8 adjacent pixels. If the central pixel and the 8 adjacent pixels comprised flammable fuels, the fuel coverage was coded as 1, and coded as 0 if fuel was absent from all pixels. Increasing values of fuel coverage suggest higher contagion of flammable vegetation.

2.5. Topography

Topography is acknowledged to affect the likelihood of fire ignition but mostly the behavior of fire (Pyne, Andrews *et al*. 1996). Flat landscapes promote rapid fire rate of spread and large, regular fire shapes while heterogeneous landscapes make fires contours more heterogeneous and generally result in smaller fires. Southern aspects generally favor ignitions and fire propagation since fuels may be drier. Slopes oriented towards dominant summer winds would also favor fire propagation. We assessed three main topographic variables for each pixel: slope, aspect, and a synthetic index of landscape complexity. This index is oriented towards the determination of the extent to which landscape is compartmented and how this may affect fire propagation and size, and the activity of firemen. Actually, a compartmented landscape with steep slopes, deeps valleys, variations of aspect, ridges would both limit fire extension but also hinder the work of firefighters (Pyne, Andrews *et al*. 1996). This index was computed as the cumulated absolute differences in elevation and aspect between each pixel and the eight surrounding pixels. High values of the index of complexity suggest complex fire contours and high difficulty for fire suppression.

2.6. Human activities

Humans have two contradictory incidences on fires. First, they provide most ignitions as lightning fires remain very likely rare in our study area. Secondly, they also prevent and suppress fires. Human activities strongly impact fire activity since fire is both a natural disturbance but also a tool for vegetation management, and sometimes conflicts. Fire causes were not explicitly considered as this information remained fragmentary until the mid-1990s: less than 50% of causes really known (Prométhée 2011). We considered the main variables expressing the pressure exerted by humans on fire activity in each pixel: the density of roads, the density of wildland-urban interfaces, and the population density. Indeed, high density of roads, houses and humans likely increases the number of ignitions.
Data from the French firefighting services were used to assess the regional variations in the fire suppression capacity. We computed a synthetic score using different information. First, we assessed the number of fire suppression forces, specific fire suppression material resources (trucks) and mean annual investment in suppression resource for each of the 15 departments of the study area (corresponding to districts of 3,567 to 6,925 km²). These data were recoded as scores from 1 (very low) to 5 (very high) according to iso-range values. Secondly, in order to get a more detailed view of the location of the fire suppression forces, we used a georeferenced database of all firehouses. Each firehouse was affected a code according to the number of fire crew (1 = low; 2 = medium; 3 = high). Then, we computed an inverse distance weighted function from each firehouse, which represents the capacity or the time needed to suppress a fire from each firehouse. Finally, we combined these two sets data to get a map of the score of fire suppression capacity. It indicates the number and location of human and mechanical means that can suppress a fire in any pixel of the landscape, under the assumption that higher and closer fire suppression resources would suppress more effectively fires, and prevent them from becoming large and destructive.

2.7. **Data Analyses**

A precedent study (Fréjaville & Curt, this issue) partitioned the south eastern France into pyroclimatic regions based on spatiotemporal patterns of fire and climate (Figure 2). We used this pyroclimatic classification as a basis to test if the different pyroclimates corresponded to specific hierarchies in the environmental and human drivers, including fire suppression. In a first step, we used a principal component analysis (PCA) in order to determine the redundant variables, and to select the most influential environmental and human variables. The fire and climate variables were put as supplementary variables because they were prior used to discriminate pyroclimatic regions. In a second step, we plotted the values of these influential variables as a function of the pyroclimatic groups in order to determine which variables discriminated each pyroclimatic group.

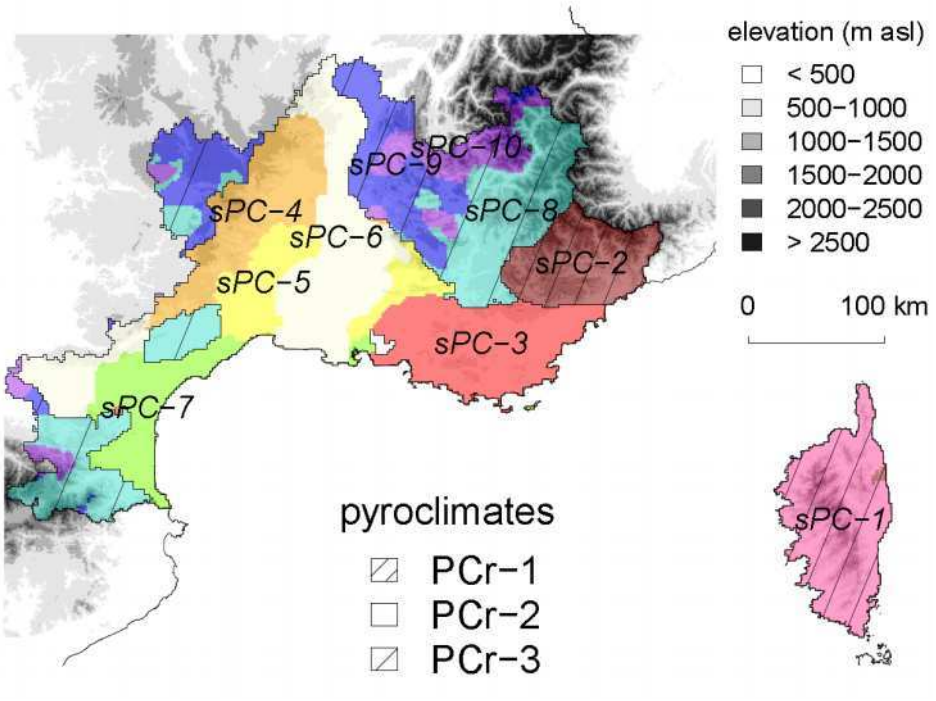

Figure 2. Pyroclimatic regions of south-eastern France. (From Fréjaville & Curt, see this special issue and Table 1)

Table 1. Main characteristics of the pyroclimatic regions of south-eastern France1973-2009 (From Fréjaville & Curt, see this special issue)

	PCr-1	PCr-2	PCr-3
Fire activity	Maximal fire density Medium and large fires Long fire season	High fire density Small to large fires Long fire season	Low fire density Small fires Short fire season
Fire activity trend	Increasing fire density at spring and autumn	Decreasing fire density and size in almost all seasons	Increasing fire density in summer, decreasing fire size in summer and winter
Climate	High summer and winter precipitation	Hot summer temperature, high 95th percentile FFMC and FWI	High spring and summer precipitation
Climate trend	High increase 95th percentile FWI and DMC	Decreasing FWI in spring	Increasing summer temperature, decreasing winter precipitation

Results

The PCA allowed determining the most influential environmental and humans variables, and discarding the redundant variables. Finally, the PCA indicated two main groups of environmental and human variables (Figure 2). The first comprises high fuel coverage, wildland flammable vegetation (predominantly forests and shrublands), and compartmented terrains which are difficult to access. This group corresponded to areas with high mean annual rainfall. At the opposite, the other group corresponded to areas with high human activity (high housing density, high road density), and high capacity of fire suppression. It corresponded to high mean annual temperature and high values of FWI and the associated indices (FFMC, DMC, DC).

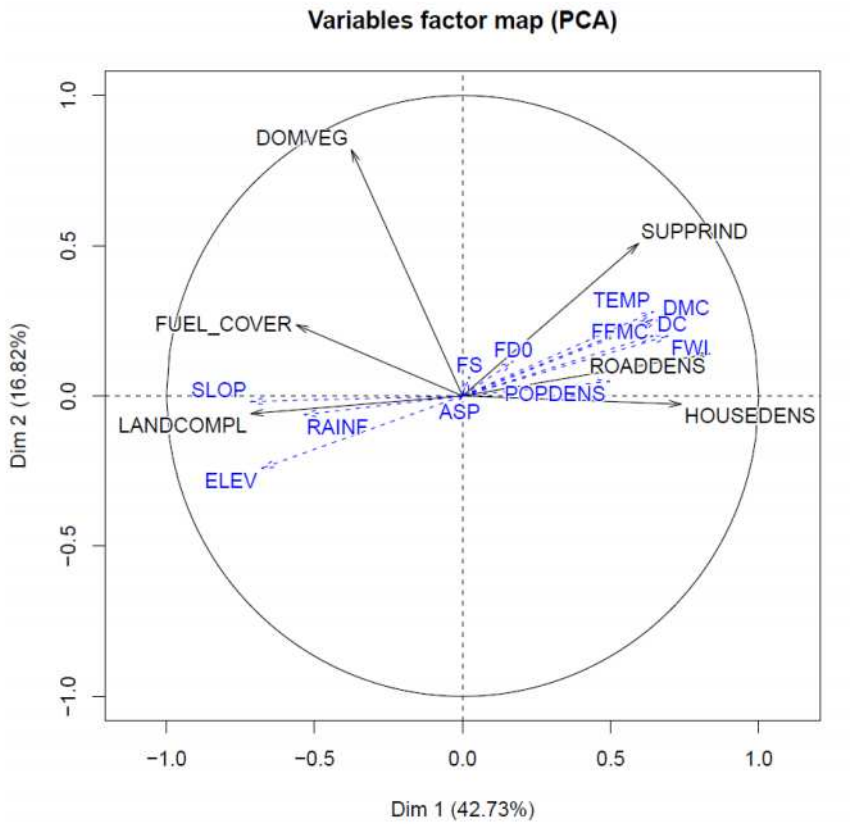

Figure 3. Principal component analysis of the main fire drivers in south-eastern France. Variable in black are active variables (FUEL_COVER: fuel coverage, LAND_COMPL: compartmentalization of the landscape, IND_LUTTE: fire suppression capacity index, Lroute: road density, SUM_Sbati: surface of habitations). Variables in blue are supplementary variables

The comparison of the main environmental and human variables for the three pyroclimatic regions (Figure 4) indicated that the first pyroclimatic region was characterized by a medium to high human activity, a very high fuel coverage and a highly compartmented landscape, but a low to medium fire suppression capacity. The second pyroclimatic region was characterized by high human activity but high fire suppression capacity, a low compartmented landscape, and low fuel coverage. The third pyroclimatic region was characterized by high fuel coverage and highly compartmented landscape but a low human activity and fire suppression capacity.

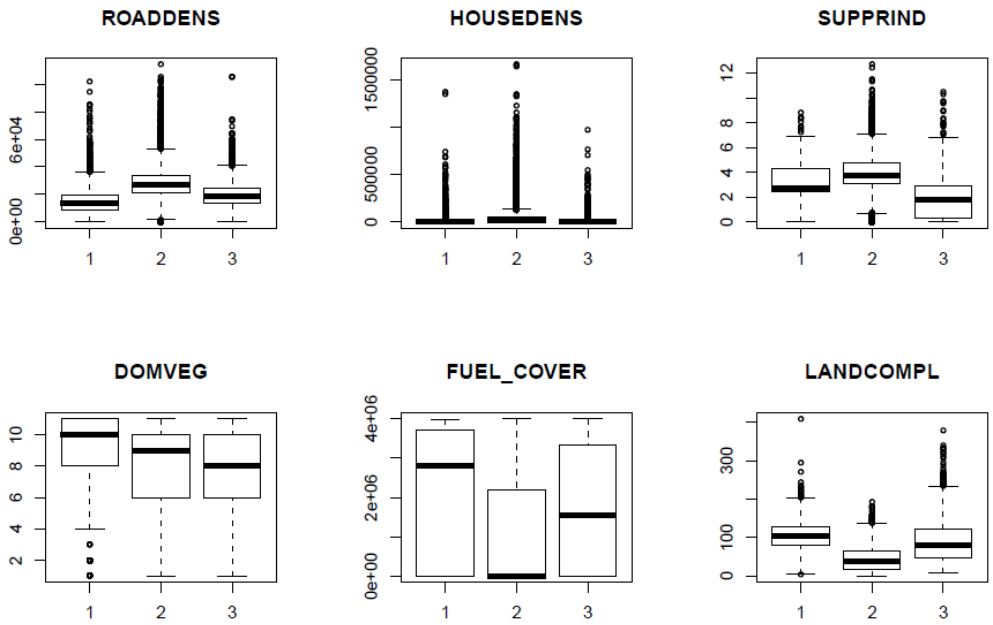

Figure 4. Boxplots of the main fire drivers for the three pyroregions of south-eastern France

Discussion

4.1. Pyroregions

The combination of the pyroclimates regions with human and environmental variables provided a description of three main pyroregions, which all have a specific combination of fire activity, fire weather and climate with specific features of human activity, fuel coverage, land compartmentalization, and fire suppression capacity.

The first pyroregion regroups two maritime fire-prone mountains: Corsica and the maritime Alps. Both areas have high fire density, medium to large fires, and a long fire season. Fire density increased in spring, autumn and winter along the past decades. Climate is favourable to fires and the climate-based fire danger indices increased strongly along the 1973-2009 period (Frejaville *et al*., this issue. Human activity is strong, fuel coverage is high, the landscape is difficult to access, and the fire suppression fire is low to medium. These maritime mountains have thus many factors conducive to fire, and a limited ability to suppress them. In brief, this pyroregion has a high probability of human-caused ignitions, no major fuel limitation, and no major weather limitation. In addition, the forecasted increases of fire weather indices seem favourable to an extension of the fire season.

The second pyroregion regroups the fire-prone Mediterranean plains and foothills. These areas have medium-to-high fire density, fires of all size, predominantly in summer. Fire weather is characterized by hot summer spells and extreme values of FWI during few weeks in summer. Fire size and fire density have strongly decreased along the recent decades while climate-induced fire danger has increased. This pyroregion has very high human activity and very high fire suppression capacity, low fuel coverage (due to landscape fragmentation) and a low-compartmented landscape. In brief, fire activity is neither weather-limited (especially during dry summers) nor fuel-limited. Fire activity is clearly controlled by fire suppression which is especially efficient and favoured by a relatively flat landscape, and a dense road network.

The third pyroregion regroups the cool peri-Mediterranean mountains with low fire activity. However, fire density has locally increased during the two past decades in parallel to an increase of annual FWI means and extremes. In this pyroregion, fuel coverage is non-limiting to fire activity. The high landscape compartmentalization and the low fire suppression capacity may favour fires, which are clearly limited by low ignition (due to low human activity) and low by fire unfavourable fire weather in average. Fire suppression means, even low, are likely to be adapted to the present low fire activity.

4.2. Implications for fire policy

This study demonstrated that fire activity varies in south-eastern France, in parallel to fire weather, human activity, and fuel coverage. Fire activity and fire drivers vary strongly within a rather small geographic area. Indeed, fuel limitation exists in lowlands dominated by agricultural lands and urban areas while weather limitation exists in mountain environments. A major implication of these findings is that all pyroregions do not require exactly the same fire suppression effort. Fire prevention can be efficiently applied anywhere, but the fire suppression strategy could be adapted to local features.

The present suppression strategy in south-eastern France relies on a fast, hard-hitting initial attack on all fires to prevent them becoming large and destructive. In the highly fire-prone areas, fire prevention is especially active with terrestrial fire patrols, lookout towers, and the regulation of public frequentation in wild-land area during the fire peak season (generally July and August). In addition, specific and reinforced means have been established with the pre-positioning of fire suppression crew at strategic places where fires occur preferentially, a dense network of lookout towers, and fire trackers planes flying during all the peak fire season to detect fires as rapidly as possible. This study suggests that enhancing fire suppression means would help controlling fire activity in the maritime mountains (Corsica and Maritime Alps), which have high fuel loads and compartmented landscapes limiting firemen activity. It should be noted that recent progress has been done for controlling pastoral and agricultural fires during the fire danger peaks. This progress has likely contributed to the recent decrease of fire activity, especially in Corsica. In fire-prone Mediterranean plains and lowlands, fire prevention and suppression is especially active. It has likely strongly contributed to the decrease of fire activity. However, this efficient fire policy can paradoxical effects referred to as the ‘fire paradox’ (Sande Silva *et al*. 2011): if fire suppression is effective and reduces the area burned yearly, then wildland fuels accumulate and fuel connectivity increases across the landscape. In turn, this will increase the likelihood of large fires when fire suppression forces cannot control them at the initial stage. In cool peri-Mediterranean mountains, fire activity will likely remain limited but it will likely increase, and fire season will likely expand due to climate change. In the mid-term, it is of importance to increase prevention, surveillance, and the fire suppression capacity in order to prepare to future.

Abstract
Here we present a procedure that allows the operational generation of daily maps of fire danger over Mediterranean Europe. These are based on an integrated use of vegetation cover maps, weather data, and fire activity as detected by remote sensing from space. It is demonstrated that statistical models based on two-parameter Generalized Pareto (GP) distributions adequately fit the observed samples of fire duration and that these models are significantly improved when the Fire Weather Index (FWI), that rates fire danger, is integrated as a covariate of scale parameters of GP distributions. Probabilities of fire duration exceeding specified thresholds are then used to calibrate FWI leading to the definition of five classes of fire danger. Fire duration is estimated on the basis of 15-minute data provided by Meteosat Second Generation (MSG) satellites and corresponds to the total number of hours fire activity is detected in a single MSG pixel during one day. Defined classes of fire danger provide useful information for wildfire management and are on the basis of the Fire Risk Mapping (FRM) product that is being disseminated on a daily basis by the EUMETSAT Satellite Application Facility on Land Surface Analysis (LSA SAF).

Keywords*: Fire danger; Weather; Fire management; Generalized Pareto distribution; Remote sensing.*

Introduction

Representing more than 85% of burned area in Europe, the Mediterranean is one of the regions of the world most affected by large wildfires that burn half a million of ha of vegetation cover every year causing extensive economic losses and ecological damage (San-Miguel-Ayanz *et al.* 2013).
Fire in the Mediterranean is a natural phenomenon linking climate, humans and vegetation (Lavorel *et al.* 2007). Fire activity is therefore conditioned by natural and anthropogenic factors. Natural factors include topography, vegetation cover and prevailing weather conditions (San-Miguel-Ayanz *et al.* 2003) which are linked to several atmospheric mechanisms working at different temporal and spatial scales (Trigo *et al.* 2006). At the regional and at the seasonal or inter-annual time scales, rainy and mild winters, followed by warm and dry summers, lead to high levels of vegetation stress that make the region particularly prone to the occurrence of fire events (Pereira *et al.* 2005). At the local and daily scales, extreme weather conditions (e.g. temperature, wind speed, atmospheric stability, fuel moisture and relative humidity) play in turn a key role in the setting and spreading of wildfires (Amraoui *et al.* 2013).
Since 1990 the European Commission has been implementing actions aiming at the organization of a Community forest-fire information system and at the development and implementation of advanced methods for the evaluation of forest fire danger and the estimation of burnt areas at the European scale (San-Miguel-Ayanz *et al.* 2012).

Forecasts of fire danger over Mediterranean Europe up to three days in advance are also currently being disseminated within the framework of the Satellite Application Facility on Land Surface Analysis (LSA SAF, Trigo *et al.* 2011) which is part of the distributed Applications Ground Segment of EUMETSAT (the European Organization for the Exploitation of Meteorological Satellites).
The goal of the present study is to quantify and predict the randomness in the distribution of duration of fire events using statistical modelling, and therefore provide a robust estimation of fire danger instead of a simple characterization using basic FWI statistics.

Background

Fire prevention requires adequate knowledge about time when and location where a fire event is likely to happen as well as on the potential damage that may result on wildland and urban values (Finney 2005). These two aspects, respectively referred to as fire danger and vulnerability, constitute the two main components of fire risk assessment (Chuvieco *et al.* 2010). The first component deals with fire behaviour probabilities and wildfire potential assessment that encompasses potential fire ignition, propagation and difficulty of control. The vulnerability component includes the assessment of the negative effects which mainly relate to socio-economic values, degradation potential of soil and vegetation conditions and landscape value.
The focus of the present study is on wildfire potential assessment that is usually based on fire danger rating systems (Fujioka *et al.* 2009), which provide indices to be used on an operational basis for fire prevention management. Because of the availability of near-real time weather observations and forecasts, most of danger rating systems make use of indices that are based on meteorological parameters (Bovio and Camia 1997).
Here, fire danger is rated based on the Fire Weather Index that is part of the Canadian Forest Fire Weather Index System (CFFWIS, Van Wagner 1974). CFFWIS has shown to be particularly suitable as a fire rating system for Mediterranean Europe. Dimitrakopoulos *et al.* (2011) have shown that CFFWIS components, in particular FWI, are suitable to rate fire danger in the eastern Mediterranean. Since 2007, FWI is the main component of the EFFIS Danger Forecast module (San-Miguel-Ayanz *et al.* 2012).
When applied to ecosystems other than Canadian forests, CFFWIS must be calibrated to the new environmental conditions by means of a reliable database of fire events (Carvalho *et al.* 2008). The process of calibration usually involves establishing a set of break points that result from the analyses of fire weather history and time series of the CCFFWIS components, namely FWI (van Wagner 1987). Established break points are then used to define fire danger classes (Kiil *et al.* 1977). In the present study, breakpoints of FWI are based on estimates of fire danger provided by statistical models of fire activity based on the FD&M product from the LSA SAF. The proposed approach has the advantage of rating fire danger based on statistical models of extreme fire events, which allow quantifying the contribution of meteorological factors in terms of increasing or decreasing the probability that the duration of a fire event exceeds a given threshold.

3. Data and methods

3.1. Study area and period

Encompassing Mediterranean Europe, the study area (Figure 1) is delimited by the latitude circles of 35º and 45ºN and the meridians of 10ºW and 37ºE. In order to be consistent with related LSA SAF products, all data fields are mapped in the so-called Normalized Geostationary Projection (NGP) of MSG (EUMETSAT 1999). The MSG pixel resolution is 3 km at the nominal sub-satellite point (0º lat, 0º lon), progressively deteriorating with increasing distance, reaching values of about 5 km over Mediterranean Europe.

Baseline information about land cover is obtained from the 1 km resolution Global Land Cover 2000 (GLC2000) dataset as derived from SPOT-4 VEGETATION (Bartholomé and Belward 2005). GLC2000 data comprise 22 land-use types which were grouped into three main classes of vegetation cover (Figure 1): forests (GLC2000 classes 1, 2, 4 and 6); shrubs (classes 11, 12 and 14); and cultivated areas (class 16). The three main classes were mapped from the original 1 km resolution to the NGP of MSG by assigning to each (~5 km) MSG pixel the most frequent class falling inside that pixel.

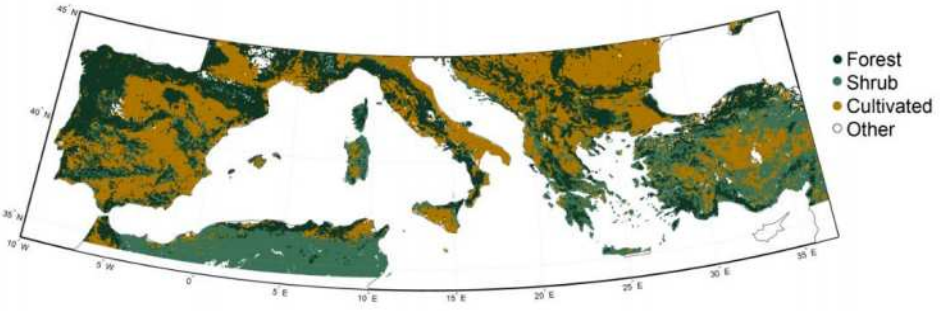

Figure 1. Geographical distribution of the three main vegetation types as derived from GLC2000.

The study covers the months of July and August of 2007, 2008 and 2009. This period may be regarded as representative of fire activity in Mediterranean Europe taking into account the official statistics of burned area provided by the European Commission for Portugal, Spain, France, Italy and Greece.

3.2. Meteorological data

Daily values of FWI over the study area are derived from meteorological fields provided by ECMWF operational model for 12 UTC, covering the period of July and August, from 2007 to 2009. Originally obtained over a 0.25°×0.25° latitude/longitude grid, the meteorological fields were re-projected onto NGP. Data consist of 2-meter air temperature, 2-meter dew point temperature, 10-meter wind speed and 24-hour cumulated precipitation; temperature and dew point were topographically corrected by applying a constant lapse rate of -0.67ºC/100m to the difference between ECMWF (coarser) orography and NGP pixel altitude. Relative humidity of air was computed by combining dew point temperature and temperature according to Magnus' expression (Lawrence 2005). For each pixel and day, anomalies of FWI, hereafter referred to as FWI*, were computed as departures from the 30-year means for the reference period 1980-2009, i.e., the anomaly FWI^*_{pd} for MSG pixel *p* and day *d* is defined as:

$$FWI^*_{pd} = FWI_{pd} - \overline{FWI}_p \quad (1)$$

where FWI_{pd} is the value of FWI for pixel *p* and day *d* and $\overline{FWI}_p$ is the time mean performed for that pixel and day over the 30-year reference period.

3.3. Fire activity and duration

Information on fire activity every 15 min on an MSG pixel basis is available from the above-mentioned FD&M product that is currently generated within the framework of the LSA-SAF (Trigo *et al*. 2011). Duration of fire δ may be estimated by summing the number detected fires in a given pixel *p* and a given day *d* during the study period. For each pixel *p*, at day *d*, there are 96 observations (one every 15 min) made by the SEVIRI instrument on-board MSG. Let $\mathbf{I}_{pd}(i)$ be an indicator function that is equal to one if the i^{th} MSG image has captured fire activity inside pixel *p* during day *d* and is equal to zero otherwise. The fire duration δ_{pd}, for pixel *p* during day *d*, is defined as:

$$\delta_{pd} = 0.25 \times \sum_{i=1}^{96} \mathbf{I}_{pd}(i) \quad (2)$$

Units of δ are hours, the coefficient 0.25 converting into hours the sampling interval of 15 min between consecutive MSG images. Fire duration δ may be viewed as a proxy of fire intensity and burn extent but it should be noted that δ is not to be interpreted as the duration of individual fire events.

3.4. Statistical models of fire duration

The statistical distribution of fire duration δ is modelled using the Peaks Over Threshold (POT) approach (Pickands 1975), which is a commonly used tool to quantify fire danger (de Zea Bermudez *et al.* 2009). The POT approach uses the Generalized Pareto (GP) distribution as a model to assign probabilities to the exceedances of duration δ over a threshold, *i.e.* to values $x=\delta-\delta_{min}$ (with $\delta>\delta_{min}$) where δ_{min} is a prescribed minimum value (de Zea Bermudez and Kotz 2010b).
The GP probability density function g is given by:

$$g(x \mid \alpha,\sigma) = \frac{1}{\sigma}\left(1+\frac{\alpha}{\sigma}x\right)^{-1-\frac{1}{\alpha}} \tag{3}$$

where x is the exceedance, and α and σ are the shape and scale parameters. The corresponding GP cumulative distribution function is:

$$G(x \mid \alpha,\sigma) = 1-\left(1+\frac{\alpha}{\sigma}x\right)^{-\frac{1}{\alpha}} \tag{4}$$

When $\alpha<0$ the distribution is upper bounded, with $0 < x < -\sigma/\alpha$. A complete description of the GP distribution may be found in de Zea Bermudez and Kotz (2010a).
The minimum threshold δ_{min} is estimated using a graphical approach (Coles 2001) where the chosen value is such that the sample mean of the values exceeding successive thresholds larger than δ_{min} becomes a linear function when plotted against the respective thresholds.
Once δ_{min} is determined, the shape (α) and the scale (σ) parameters are estimated using the maximum likelihood method (Grimshaw 1993); 95% confidence intervals for α and σ are asymptotically estimated using normal distributions for α and for log(σ) (Kotz and Nadarajah 2000). Goodness of fit is assessed by means of the A^2 test (Anderson and Darling 1952), a nonparametric test that is especially appropriate to models based on long-tailed distributions.
For each vegetation type, POT is applied to the exceedances x of all fire pixels that were recorded during the study period (July-August 2007-2009). Obtained models, hereafter referred to as static models, may be improved by incorporating daily anomalies, FWI*, as a covariate of scale parameter in the GP distributions, in particular by assuming a linear dependence of σ on FWI*:

$$G(x, FWI^* \mid \alpha,a,b) = 1-\left(1+\frac{\alpha}{a\times FWI^*+b}x\right)^{-\frac{1}{\alpha}} \tag{5}$$

Estimates of shape parameter (α) and of coefficients of the linear relationship $\sigma=a\times FWI^*+b$ are again obtained using the maximum likelihood method. Performance of the new alternative models, hereafter referred to as daily models, is compared against the respective null models (i.e. the original static models) by using the so-called standard likelihood ratio test (Neyman and Pearson 1933). The test is based on statistic Λ defined as:

$$\Lambda = 2(\ln L' - \ln L) \tag{6}$$

where L is the maximum likelihood function of the static model and L' is the maximum likelihood function of the daily model.

3.5. Meteorological danger

Static models allow estimating baseline danger D_{b0} which represents the probability that exceedance x is above a given fixed threshold x_0:

$$D_{b0} = D_b(x_0) = 1 - G_{static}(x_0 \mid \alpha, \sigma) \quad (7)$$

Conversely, the threshold value of exceedance x_0, corresponding to a specified level of baseline danger, D_{b0}, may be estimated, for each vegetation cover, by inverting the previous relationship:

$$x_0 = x(D_{b0}) = G_{static}^{-1}(1 - D_{b0}) \quad (8)$$

In a similar way, daily models allow estimating daily danger D_d which represents the probability that exceedance x is above a given fixed threshold x_0 for a given value of FWI*:

$$D_d(x_0, FWI^*) = 1 - G_{daily}(x_0, FWI^* \mid \alpha, a, b) \quad (9)$$

The role played by meteorological conditions on wildfire potential may then be uncovered by defining meteorological danger D_m, which combines information about static and daily danger for a given day and pixel according to the following procedure:

1. A given threshold of baseline danger, D_{b0}, is fixed over the entire study area;
2. For each vegetation cover, baseline thresholds of exceedances x_0 are computed using the appropriate static models of fire duration (Eq. 8);
3. For each day and pixel location, daily models are then used to estimate daily danger, D_d, based on the corresponding baseline threshold and the observed daily value of FWI* (Eq. 9);
4. Meteorological danger, D_m, is finally defined by the ratio of daily danger D_d to prescribed baseline danger D_{b0}:

$$D_m(x_0, FWI^*) = \frac{D_d(x_0, FWI^*)}{D_{b0}} \quad (10)$$

Meteorological danger provides a coherent basis to set break points in FWI* to be used in the definition of classes of meteorological fire danger. Given a baseline danger D_b, break point BP_L will be defined as the value of FWI* associated to meteorological danger L, i.e.

$$D_m(x_0, BP_L) = \frac{D_d(x_0, BP_L)}{D_{b0}} = \frac{1 - G_{daily}(x_0, BP_L \mid \alpha, a, b)}{D_{b0}} = L \quad (11)$$

Values of BP_L may be estimated by inverting the previous equation e.g. using the bisection method (Faires and Burden 1985).

Results

4.1. General characteristics of fire duration

Duration of fire activity for the three vegetation types (Table 1) is characterized by long tailed distributions, with values of δ <3 h representing about 85, 82 and 94% of the sample in the case of forest, shrub and cultivated areas, respectively . Besides being less frequent in both absolute and relative terms, duration of fire activity in cultivated areas has a shorter tail than duration in forest or shrub. For instance the relative frequencies of very long lasting fire activity (δ>12 h) over forest and shrub are 0.52 and 0.89% respectively, about three times and more than five times the value of 0.17% corresponding to cultivated areas. Long-lasting fire episodes are therefore more expected through shrub land and forests than over agricultural areas, a result in close agreement with findings in previous works either at the scale of the Mediterranean basin (Fernandes, 2013) or at the national levels of Portugal (Barros and Pereira 2014), Spain (Moreno *et al.* 2011) and Italy (Bajocco and Ricotta 2008). Such differences in land cover burning are likely to be driven by different interacting factors which include fuel connectivity, topography, population density, meteorological conditions and fire suppression (Brotons *et al.* 2013). For instance, the proximity of agricultural lands to populated areas and the social and economic value attributed to agricultural activities is expected to steer an increase

of the level of effort in fire suppression and therefore to a decrease in the likelihood of large fire events (Moreira *et al.* 2010).

Table 1. Distribution frequencies of fire activity for the three types of vegetation. The distributions of fire activity refer to the study period of July-August 2007-2009; for each class the absolute frequency is shown together with the relative frequency (% in brackets).

Classes of duration δ (h)	0.25 to 3.00	3.25 to 6.00	6.25 to 9.00	9.25 to 12.00	12.25 to 15.00	15.25 to 18.00	18.25 to 21.00	Total
Forest	3 321	387	128	34	15	4	1	3 890
[%]	*[85.37]*	*[9.95]*	*[3.29]*	*[0.87]*	*[0.39]*	*[0.10]*	*[0.03]*	*[100.00]*
Shrub	2 240	292	114	47	17	7	0	2 717
[%]	*[82.44]*	*[10.75]*	*[4.19]*	*[1.73]*	*[0.63]*	*[0.26]*	*[0.00]*	*[100.00]*
Cultivated	2 205	118	23	4	3	1	0	2 354
[%]	*[93.67]*	*[5.01]*	*[0.98]*	*[0.17]*	*[0.13]*	*[0.04]*	*[0.00]*	*[100.00]*

4.2. Static models

Results from the previous exploratory analysis suggest choosing POT and use GP distributions to model the exceedances of duration δ for each vegetation type. For each vegetation type, a common minimum threshold of 3 h was therefore set for δ_{min}. The largest scale (σ) parameter is the one for shrub, followed by forest and cultivated areas (Table 2). The shape (α) parameters are negative for all vegetation cover types, indicating that exceedances are upper limited. The largest negative value is also the one for shrub, followed by forest and cultivated areas. The predominant effect of the scale (σ) parameter on the fitted GP models becomes apparent when plotting the cdf curves for the three vegetation cover types (Figure 2), the shrub model presenting the longest tail, followed by forest and cultivated areas.

4.3. Daily models

The role played by meteorological factors may be assessed by looking at the impact of FWI on fire activity. The dataset of exceedances x for each vegetation type was subdivided into subgroups associated with different ranges of FWI; 51 groups of fire pixels were defined as respectively associated with values of FWI between percentile 0 and percentile 50, between percentile 1 and percentile 51, and so on up to between percentile 51 and percentile 100. GP distributions were then adjusted to each subset and plots were made of estimated values of scale σ versus the mean value of FWI in the considered range.

For all types of vegetation cover, the scale (σ) parameter tends to linearly increase with increasing FWI. Each type presents a characteristic range of FWI, the largest values being observed for shrub and the lowest for forest. There is a close relationship between vegetation cover and range of FWI. However the spatial distribution of FWI is affected by other factors than vegetation. For instance, the Eastern and Southern borders of the Mediterranean basin present higher values of FWI. The impact of regional effects other than vegetation may be mitigated by replacing daily values of FWI at a given pixel by respective departures (FWI*) from 30-year means for the reference period 1980-2009.

Table 2. Static GP models for each vegetation type. Columns 1-5 indicate the following: vegetation type, sample size and corresponding percentile of original data sample (% in brackets), estimated values and 95% confidence intervals (in brackets) of the shape (α) and scale (σ) parameters, and confidence levels (CL) of the Anderson-Darling tests.

Vegetation type	Sample size [Percentile]	α	Σ	CL
Forest	569 *[85%]*	-0.06 *[-0.13,0.02]*	2.92 *[2.61,3.26]*	98%
Shrub	477 *[82%]*	-0.14 *[-0.22,-0.05]*	3.70 *[3.27,4.18]*	93%
Cultivated	149 *[94%]*	-0.01 *[-0.15, 0.12]*	2.31 *[1.87,2.86]*	91%

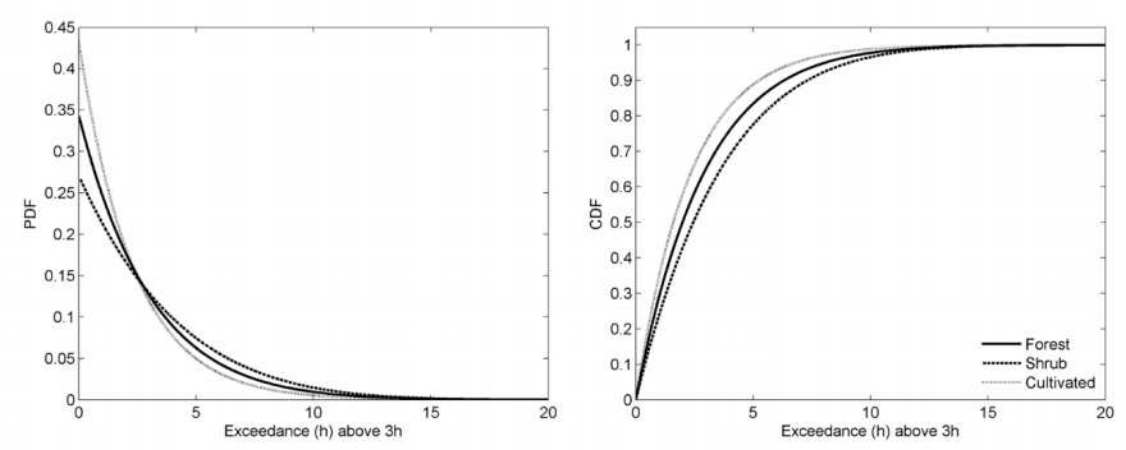

Figure 2. Probability density functions (left panel) and cumulative distribution functions (right panel) of fitted GP models of exceedances x=δ-δmin (with δmin = 3 h) for forests (solid curve), shrubs (dashed curve) and cultivated areas (dotted curve).

Impact of meteorological conditions was therefore modelled by introducing FWI* as a covariate of the scale parameter of the GP models using linear relationships of the type σ=a+b×FWI* (Table 3). In all cases p-values of the maximum likelihood ratio test are lower than 0.5% meaning that the null hypothesis that the daily models have a better fit than the corresponding static ones cannot be rejected at the 0.5% significance level. The sensitivity of scale parameters to changes in FWI* also reflect on the probabilities of exceedance of duration (Figure 3).

Table 3. Daily GP models for each vegetation type. Columns 2-4 indicate the following: shape (α) parameter, dependence of scale (σ) parameter on FWI* and p-values of the maximum likelihood ratio tests.

Vegetation type	α	σ=a+b×FWI*	p-value (%)
Forest	-0.074	σ=2.04 + 0.038×FWI*	1.39×10^{-5}
Shrub	-0.15	σ=2.37 + 0.052×FWI*	1.20×10^{-6}
Cultivated	-0.027	σ=1.33 + 0.042×FWI*	0.46

4.4. Calibration of FWI

For each vegetation type the respective static and daily models were used to compute the dependence of meteorological danger D_m on FWI* (Eq. 10). For a fixed baseline danger D_b = 33%, four break points of FWI* were obtained, respectively associated to levels of meteorological danger of 0.25, 0.50, 0.75 and 1.00. Estimates of break points (Table 4) were obtained by solving Eq. (11) using the bisection method. The three vegetation types present differences that are worth being noted. The largest value of the baseline threshold of fire duration (associated to baseline danger D_b=33%) is the one of shrub (x_0=3.8 h) followed at similar intervals of about 0.6-0.7 h by forest (x_0=3.1 h) and cultivated areas (x_0=2.5 h). The four defined break points allow defining five classes of meteorological fire danger, respectively "low" when $D_m < 0.25$, , "moderate" when $0.25 \leq D_m < 0.5$, "high" when $0.5 \leq D_m < 0.75$, "very high" when $0.75 \leq D_m < 1$ and "extremely high" when $D_m \geq 1$.

Table 4. Break points of FWI* for each vegetation type. Lines 2-6 indicate the following: baseline threshold of fire duration (x0) associated to a fixed baseline danger (D_b=33%) and break points of FWI* ($BP_{0.25}$, $BP_{0.50}$, $BP_{0.75}$ and $BP_{1.00}$) corresponding to different levels (L) of meteorological danger D_m (0.25, 0.50, 0.75 and 1.00, respectively).

	Forest	Shrub	Cultivated
x_0	3.1 h	3.8 h	2.5 h
$BP_{0.25}$	-17.5	-10.4	-6.5
$BP_{0.50}$	-4.7	0.8	-2.9
$BP_{0.75}$	8.7	12.6	12.8
$BP_{1.00}$	24.0	26.2	24.1

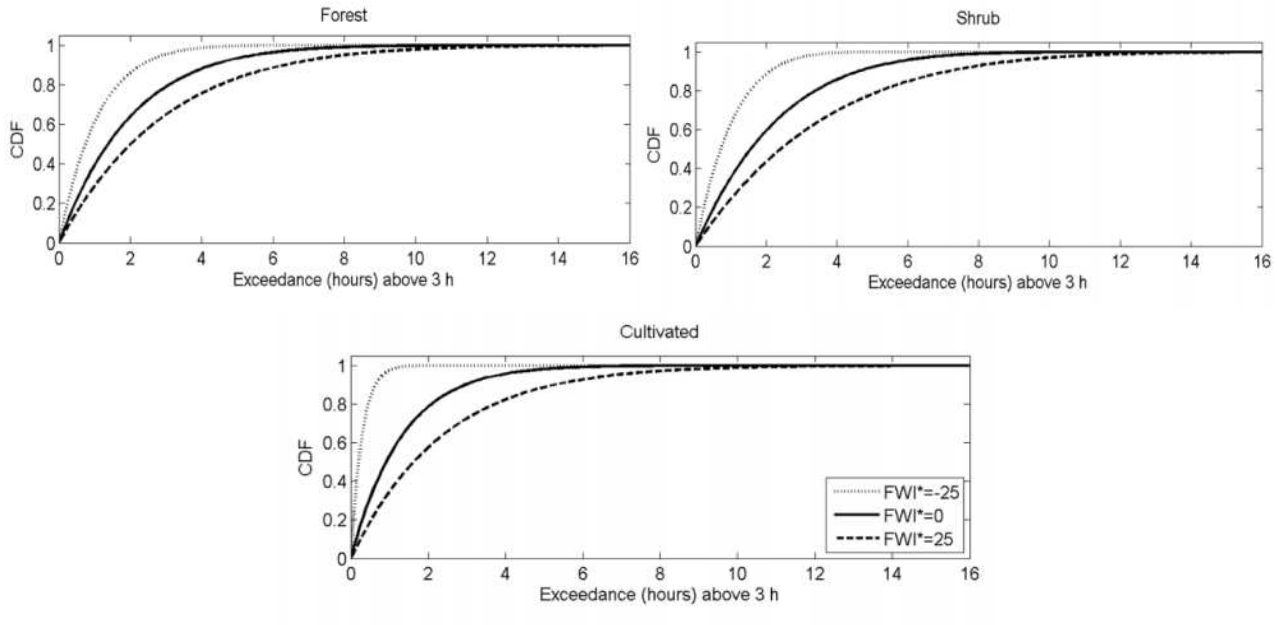

Figure 3. Cdf curves for three fixed values of FWI* (-25, 0 and +25) in the case of the daily GP model for forests (top left panel), shrubs (top right panel) and cultivated areas (bottom panel).

Discussion

The case of August 25th 2007, when Greece and Albania were struck by very severe fire events, provides an interesting example of the obtained product that is worth analysing in detail. Two impressive clusters of fire pixels with duration longer than 6 hours may be observed over Greece

(Figure 4, bottom panel). The larger cluster spreads over western Peloponnese and contains a large number of fires that lasted more than 12 hours, and the other one locates over eastern Attica and Evia. The map of classes of fire danger (Figure 4, top panel) shows that both clusters are part of a large core labelled "extremely high" which covers the entire territory of Greece and extends eastwards into Anatolia and towards the northeast over Bulgaria and Romania up to Crimea. An event lasting more than 12 hours also occurred in Albania, inside a large patch labelled "very high" which covers the territories of Albania, Montenegro and Bosnia and Herzegovina, and extends towards the northeast up to Ukraine. No fire events occurred in regions labelled "low", and "moderate".

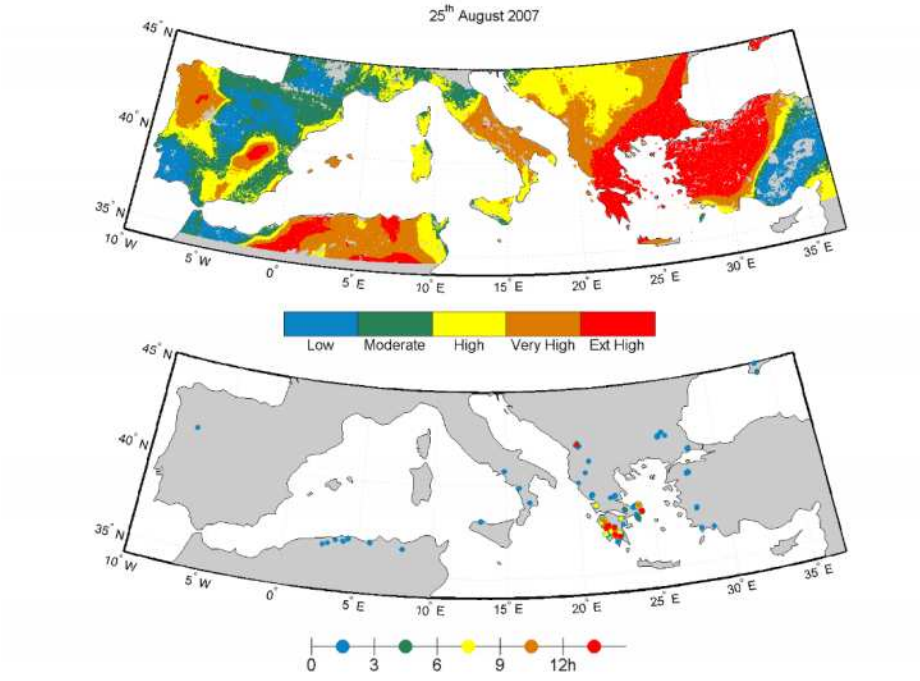

Figure 4. Map of classes of fire danger (top panel) and corresponding spatial distribution of observed fire events and respective duration (bottom panel) for August 25th 2007. Colorbars identify classes of fire danger (upper panel) and fire duration (lower panel).

An assessment of the global consistency (in space and time) of results obtained was performed by analysing, for the entire study area and the entire study period, the number of observed events that belong to a given interval of fire duration and were assigned to a given class of fire danger (Table 5). The percentage of fires within any given duration interval (***bold italics***) steadily decreases with decreasing danger, with the exception of fires of very short duration (less than 1h) where the "high" class is the modal one. Such decrease is especially steep in the cases of the upper intervals of duration. With the exception of fires of very short duration where the fraction is only 1%, there is no fire activity in the case of "low" danger. When considering fixed classes of danger, it may be noted that the percentage of events associated with any given duration interval (*underlined italics*) always decreases with increasing duration, the steepest declines being observed in the lower danger classes.
When looking at maps of classes of fire danger (Figure 4) it may be noted that areas of "high" and "very high" fire danger spread over regions where no fire activity is detected. This is to be expected since both static and daily models allow computing probabilities of exceedance provided there is an event with minimum duration of 3 h.

Conclusions

The calibration approach adopted in this study is based on an integrated use of information about meteorological conditions provided by the European Centre for Medium-Range Weather Forecasts (ECMWF), vegetation land cover from Global Land Cover 2000 (GLC2000) and fire duration as detected by the SEVIRI instrument on-board Meteosat Second Generation (MSG) satellites. The main difference of the proposed methodology to existent others is that it takes full advantage of the temporal resolution of SEVIRI that allows detecting fire events every 15 minutes. This information is used to make daily records of fire duration that are essential to calibrate meteorological danger and establish classes of fire danger. Traditional approaches rely on calibration procedures performed through analyses of fire weather history based on ground observations of amount of burned area or number of fire occurrences. Several factors may affect the reliability of ground observations; recorded values are not only determined by visual inspection which may nevertheless affect their accuracy but they are also determined by the policy of individual countries, which may further change in time (Pereira *et al.* 2011). Approaches based on the use of satellite data have the advantage of being more consistent in space and time. They also benefit from not depending on the availability of ground fire records from each country, which are neither easily obtainable, nor available in the short term.
Finally, it is worth stressing that the Fire Risk Mapping (FRM) product is entirely based on a set of estimated probabilities, in particular meteorological danger. These probabilities are derived from statistical models that may be readily updated and continuously tuned, which represents an advantage from the operational point of view. The fact that the FRM product is currently being disseminated within the framework of the Land Surface Analysis Satellite Application Facility (LSA SAF) will also allow tailoring the product according to specific needs of a broad community of users.

Table 5. Distribution of fire events by classes of fire danger and by fire duration. Each cell contains the number of observed daily fire events (first line), the corresponding fraction (%) of the total number of events with the same fire duration interval (second line, bold italics) and the corresponding fraction (%) of the total number of events in the same class of fire danger (second line, underlined italics).

Abstract
Dead fine fuel moisture content is a key parameter for wildfire ignition and behaviour: the higher the fine fuel moisture content, the more activation energy has to be spent on the evaporation of this moisture before the fuels can ignite and release their energy of combustion. Thus, high fuel moisture leads to a lower probability of ignition and a more moderate fire behavior.
These facts have been recognized for a long time and fine fuel moisture has become an essential part of several fire danger rating systems (e.g. 1- and 10-hour dead fuel moisture in the National Fire Danger Rating System (NFDRS) and Fine Fuel Moisture Code in the Canadian Forest Fire Danger Rating System (CFFDRS)). Additionally, dedicated fine fuel moisture models are available as well.
Nevertheless, direct information on dead fine fuel moisture can be valuable for monitoring, scientific research as well as during exceptional conditions, e.g. extreme fire danger with exceptional temporal or spatial distribution of fire danger, for the management of large wildfires. However, dead fine fuel moisture measurements are hard to obtain since common methods involve manual sampling in the field and potentially oven-drying, adding a time delay before the results become available.
In this study, a thorough evaluation of the Campbell Scientific, Inc. instrumentation for automated 10-hour dead fuel moisture (CS506-L fuel moisture sensor) has been carried out. Ten fuel moisture sensors and associated *Ponderosa pine* dowels were obtained and subjected to tests in a constant climate chamber as well as at two field sites in Central Europe for one fire season. The comparability of the values determined from these ten different dowels as well as a potential influence of weathering were investigated along with correlations to manual-gravimetric fuel moisture.
Results show that dowel-to-dowel comparability is relatively good but may be further increased by additional calibration. In the field, there was an excellent correlation between 10-hour fuel moisture as measured by the CS506-L sensors and fast-drying dead fuels such as needle litter and dead grass (R^2 0.81 and 0.82, respectively). Weathering effects during the study period had no major influence on sensor performance.

Keywords*: fine fuel moisture, 10-hour fuel moisture, automatic measurement*

Introduction

Fine fuel moisture has been recognized as a key parameter for forest fire danger, ignition and behaviour and thus also for fire-fighting (Pyne *et al.* 1996). This is because most fires start and spread, at least initially, in fine fuels located on the forest floor and their water content plays an important role for ignitability and combustibility. Wet fuels tend to ignite less easily and to burn more moderately (if there is sustained combustion at all), since a large amount of energy has to be spent on evaporating the moisture (Pyne *et al.* 1996). This additionally leads to a cooling effect (Britton *et al.* 1973) and to a dilution of combustible gases (Chandler *et al.* 1983). Thus, fine fuel moisture is an important parameter in the field and the basis of several forest fire danger rating systems, such as the National Fire Danger Rating System (NFDRS, USA (Bradshaw *et al.* 1983)) and the Canadian Forest Fire Danger Rating System (CFFDRS (Van Wagner 1987)).
Despite its high significance, there is no straightforward way of measuring fine fuel moisture automatically in the field. Gravimetric measurement following manual sampling is the standard procedure (Britton *et al.* 1973; Norum and Miller 1984; Viegas *et al.* 2006), which however requires

a person to travel to the respective field site(s) and to take fuel samples. These samples need to be transported back to a laboratory, weighed wet, oven dried and weighed again in a dry state. In addition to the multitude of steps required, drying time (24 hours in many studies) leads to an additional delay before the fuel moisture measurements become available, rendering them useless for any immediate prevention or fire management decisions.
Several methods have been developed to overcome these problems. One of them is based on an observation made by early US fire researchers in Scandinavia, where local foresters used wood as a reference material that was easier to observe that the fine fuels (Hardy and Hardy 2007). This method was extended by Gisborne (1933), who set up rules to standardize the so-called fuel moisture sticks and trimmed them to exactly 100 g dry mass (Fischer and Hardy 1976; Hardy and Hardy 2007). Following this standardization, moisture content of the reference sticks could be determined using a simple balance in the field. Later on, the dead fuel moisture components of the NFDRS were based on those measurements and on theoretical considerations for drying and wetting of cylindrical objects (Bradshaw *et al.* 1983; Burgan 1988; Cohen and Deeming 1985). However, an influence of wood decay on the long-term stability of the measurements was detected (Haines and Frost 1978). Finally, several instrument manufacturers (e.g. Campbell Scientific (North Logan, UT, USA), Vaisala (Helsinki, Finland) and Forest Technology Systems (Victoria, BC, Canada)) have found ways to automatically measure the stick's moisture content, e.g. using capacitive sensing. Although some of the manufacturers had to adapt the stick dimensions to their techniques, this widely increases the potential use of fuel moisture measurements. For example, automated fuel moisture sensors are part of many RAWS stations in the US (NWCG 2009). Nevertheless, the precision, reliability and long-term performance of these systems remain somewhat dubious (Gibos 2010) and are examined in this study.

Methods

The measuring system developed by Campbell Scientific consists of a fuel moisture stick (26601 CS506, also called "dowel") connected to a so-called fuel moisture sensor (electronics unit, CS506-L) and associated data logger. In order to evaluate the measuring system, a total of 8 fuel moisture sensors, 10 fuel moisture sticks and three data loggers (CR800) were acquired. The fuel moisture sticks are made of *Ponderosa pine* wood into which two stainless steel electrodes are pressed and secured by cable ties. They have a nominal dimension of 1.3 cm (0.5") diameter and 50.8 cm (20.0") length and are meant to represent the 10-hour fuel moisture class of the NFDRS. The RMS error and maximum usage time reported by the manufacturer are 0.75-2.27% and one season, respectively. The sensors were tested in two forest sites in Bavaria, southern Germany, for one fire season, during which manual gravimetric measurements of fine fuel moisture were made regularly. Before and after the field tests, reference measurements were made in a climate chamber. At the end of the study, the fuel moisture sticks were separated in hygroscopic (wood) and non-hygroscopic (electrodes and cable ties) material and the wood parts were oven-dried.

2.1. Reference measurements in the climate chamber

In the climate chamber, only one fuel moisture sensor (electronics unit) was used, to which the 10 fuel moisture sticks were connected sequentially. This was performed regularly during the two desorption runs before and after the field measurements, which included the following conditions: soaking the fuel moisture sticks for one hour, subjecting them to 23°C and 90, 80, 70, 60, 50, 40, 30, 20% relative humidity until equilibration before the field measurements and to 23°C and 90, 55, 20% relative humidity (shortened desorption run) after the field measurements. Equilibration of the sticks' moisture content was assessed using both the automated measurements and additional manual weighing. The climate chamber was of a walk-in type (3.9 m² floor space) and had a typical accuracy of ±0.2°C and ±5% relative humidity, respectively.

2.2. Field measurements

Following the initial climate chamber tests, the two forest climate stations "Altdorf" (49.4175° N, 11.3125° E, approx. 15 km east of Nuremberg, pure Scots pine (*Pinus sylvestris*) stand) and "Freising" (48.4102° N, 11.6595° E, approx. 30 km north of Munich, mixed European beech (*Fagus sylvatica*) and pedunculate oak (*Quercus robur*) stand) of the Bavarian State Forest Institute (Bayerische Landesanstalt für Wald und Forstwirtschaft, LWF) were equipped with three fuel moisture sensors and sticks each. The measurements were carried out from end of March until end of October 2013, and after each third of the measuring period, one fuel moisture stick was exchanged by a spare that had been stored in a laboratory for this purpose. The fuel moisture sensors were mounted according to the manufacturer's instructions at a height of 30.5 cm (12") above the ground, facing south. The setup at the Altdorf station is shown in Figure 1 as an example. Their values were measured and stored at 15-minute intervals, according to the measurement intervals of the existing forest climate stations.

Figure 1. Arrangement of fuel moisture sticks at the forest climate station Altdorf.

During the measuring period, fuel moisture samples of litter (Altdorf and Freising) and dead grass from the previous season (Altdorf only) were taken regularly. While it was our aim to sample in the early afternoon, at least weekly during wet periods and at least every other day in dry periods, a certain variation occurred due to the availability of sampling personnel. Additionally, dry grass sampling at Altdorf had to be terminated in the end of August as the grass had decayed in a way that it was no longer relevant to fire danger and that sampling became impossible. For each day and fuel, three samples were taken, which were stored in air-tight polypropylene bottles and shipped to the laboratory within a maximum of 7 days. The fuel moisture was calculated gravimetrically (in % of dry mass), following oven-drying at 105°C for 24 hours.

2.3. Data analysis

The data thus gathered were combined, processed and analyzed in a way that the relationship of the automatically measured fuel moisture values to relative humidity and gravimetric stick moisture in the climate chamber before and after the field measurements could be shown. The field measurements themselves are presented as progressions of the measured stick moisture over time and as correlations of stick moisture and gravimetric fine fuel moisture content. Linear regressions are used for showing and modelling relationships between the different measurement variables, where appropriate. All data processing, statistics and plotting were performed in R, version 3.0.3, and its packages xlsx, doBy, and RODBC.

Results and discussion

Reference measurements before the field campaign

Before the field campaign was started, a relatively high resolution desorption run was carried out in a climate chamber in order to compare the fuel moistures of each stick, measured both by the automatic system and gravimetrically. The gravimetric moisture values were obtained by weighing the fuel moisture sticks repeatedly and combining these values with the mass of the non-hygroscopic material and the oven-dry mass of the wood determined at the end of the study. Results for both automatically measured and gravimetric moisture of the sticks are shown in Figure 2.

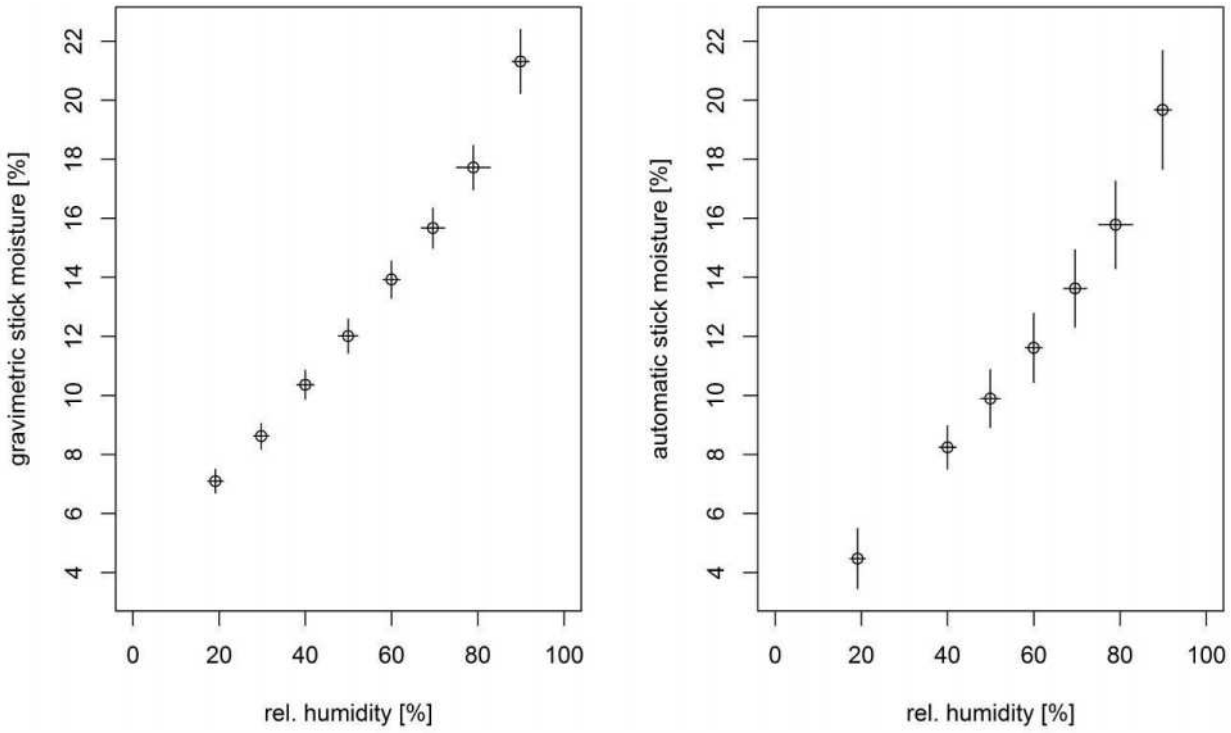

Figure 2. Results of the initial climate chamber desorption run. Left graph: gravimetric fuel moisture, right graph: fuel moisture as measured by the automated system.

The left graph in Figure 2 represents the gravimetric fuel moisture during the desorption run and is thus a classic sorption isotherm. In contrast to isotherms from literature for wood (Kollmann *et al.* 1986*;* Forest Products Laboratory 1999) and fine fuels (Van Wagner 1972; Anderson 1990; Blackmarr 1971; Lopes *et al.* 2010), it lacks the typical sigmoid shape. Apart from this, an increasing standard deviation with increasing relative humidity can be observed. Comparing this to the automated measurements in the right chart of Figure 2, their absolute values are not identical to the gravimetric measurements and the standard deviations are substantially higher. This is not surprising as the gravimetric technique is by far more accurate than the capacitive sensing of the automated measurement. Additionally, the dry mass of the sticks (not shown) had a variation >5%, influencing the automated measurements as they in fact react to the density surrounding the electrodes.

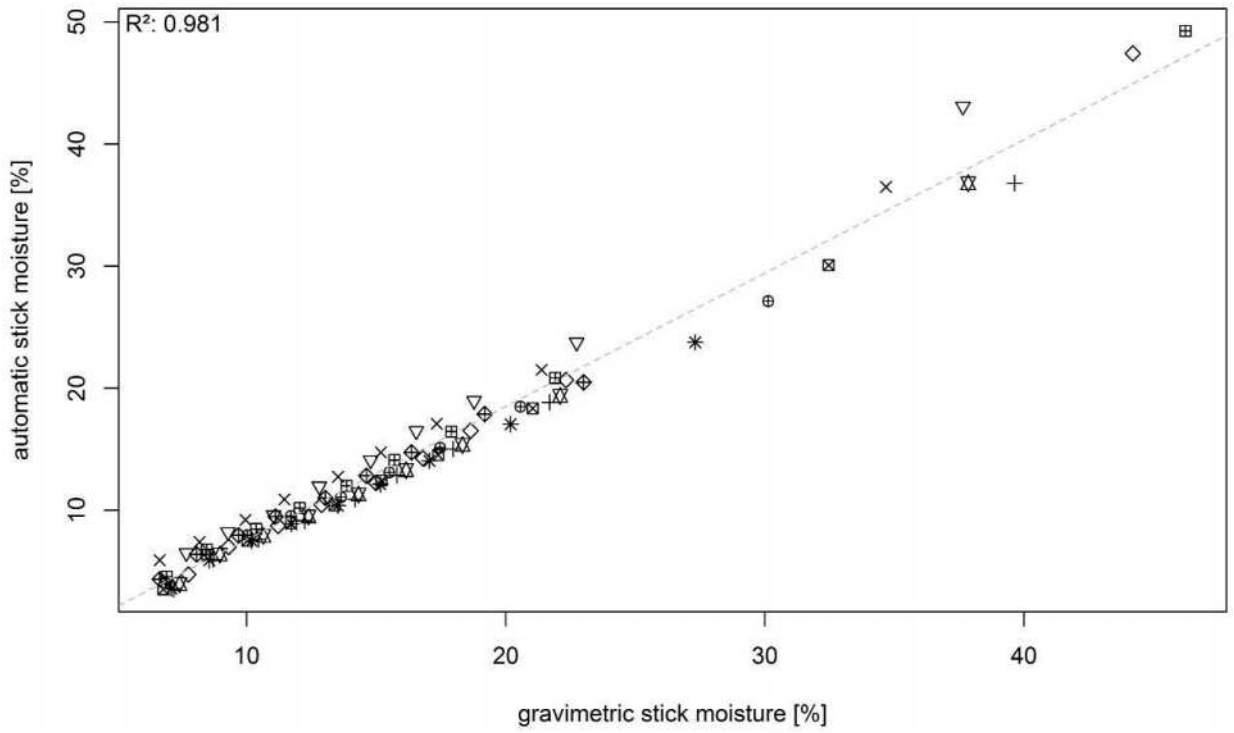

Figure 3. Automated fuel moisture values of the initial desorption run in dependence of the gravimetric fuel moisture. The different symbols correspond to the individual fuel moisture sticks.

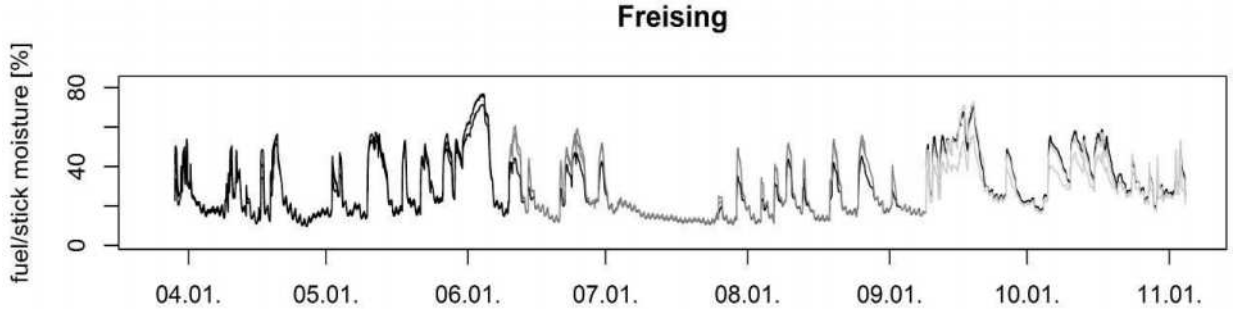
When the automated values are shown in dependence of the gravimetric fuel moisture (Figure 3, including the values of the soaked sticks), a distinct and highly significant correlation of these values (R^2 0.981) is obvious. However, not all individual fuel moisture sticks follow a common regression line. Linear calibration for each stick can be used to correct this and to make the absolute automated fuel moisture values identical to the gravimetric moisture content of the sticks (not shown). However, this procedure is very laborious, as a full desorption run and an estimation of the stick's dry mass is necessary.

Field measurements

The progression of the automatically measured fuel moisture during the field campaign is shown in Figure 4. Whenever a new fuel moisture stick was used, all values until the first substantial precipitation event were removed. It can be seen that the accordance of the individual fuel moisture sticks is quite good and that there are no obvious shifts when the sticks were exchanged (lighter shades of gray represent longer ageing and use in the field). However, high moisture contents are usually accompanied by a higher variation from stick to stick than low moistures. During dry conditions, a daily cycle of fuel moisture can be observed that corresponds to textbook examples (cf. Pyne *et al.* 1996).



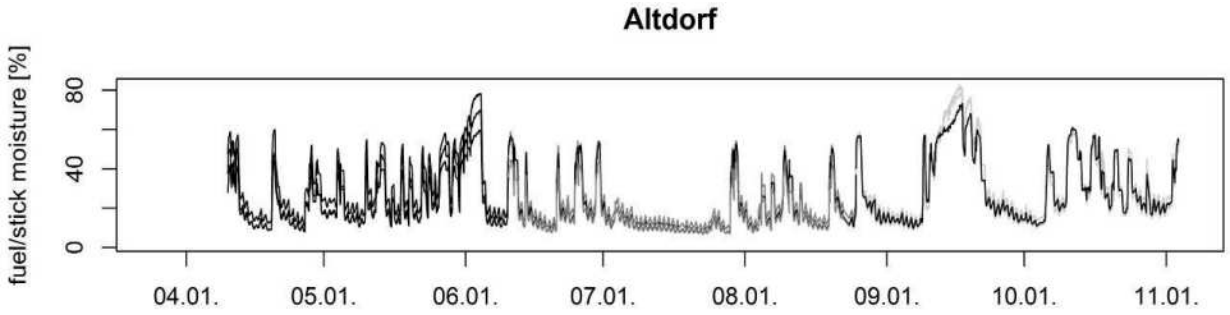


Figure 4. Progression of fuel moisture during the field measurements. Lighter shades of gray represent longer ageing of the sticks and thus longer use in the field, i.e. black-coloured lines represent fuel moistures that have been determined during initial exposure of any fuel moisture stick; dark gray lines an extended exposure of another third of the measuring period and light grey lines an exposure over the whole measuring period.

When the automated fuel moisture measurements are compared to simultaneously sampled gravimetric values of local dead fine fuels (Figure 5), correlations of varying strength and significance can be observed. For the thick, rather slow drying layers of European beech and pedunculate oak leaves at Freising, R^2 of the linear regression is smaller (0.44) than for the values of Scots pine litter and dead grass from the previous season (Altdorf, R^2 0.81 and 0.82, respectively). These are good, despite the fact that the type of material, dimensions, and arrangement are substantially different.

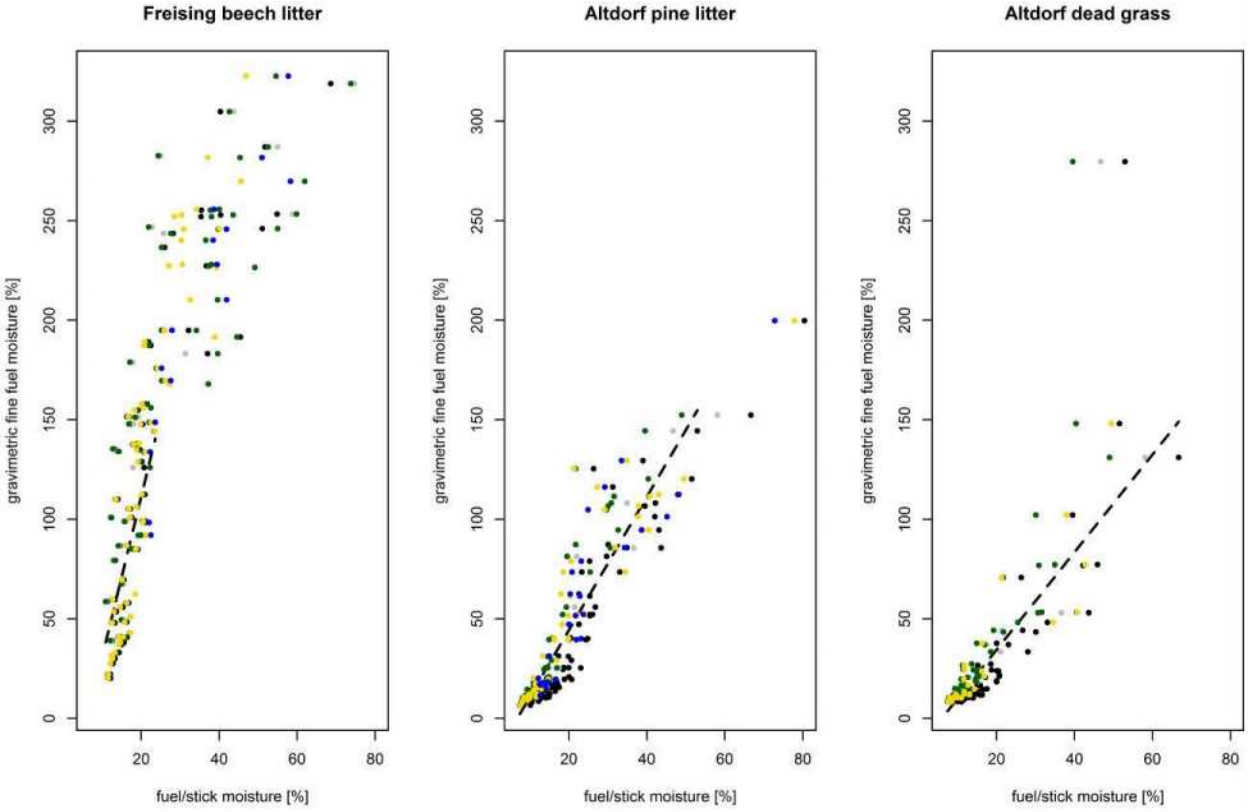

Figure 5. Correlations of (left to right) automatically measured and manually determined fuel moisture for European beech (Freising) and Scots pine (Altdorf) litter, as well as dead grass from the previous year (Altdorf).

3.3. Reference measurements after the field campaign and long-term stability

Besides comparing the continuity of the measuring signal when the fuel moisture sticks were replaced in the field (cf. Figure 4), additional reference measurements were made in the climate chamber after the field exposure of the sticks. These are compared to the initial desorption run in Figure 6, where the initial values are shown in black, the associated confidence intervals as dashed orange lines and the final reference values as red circles.

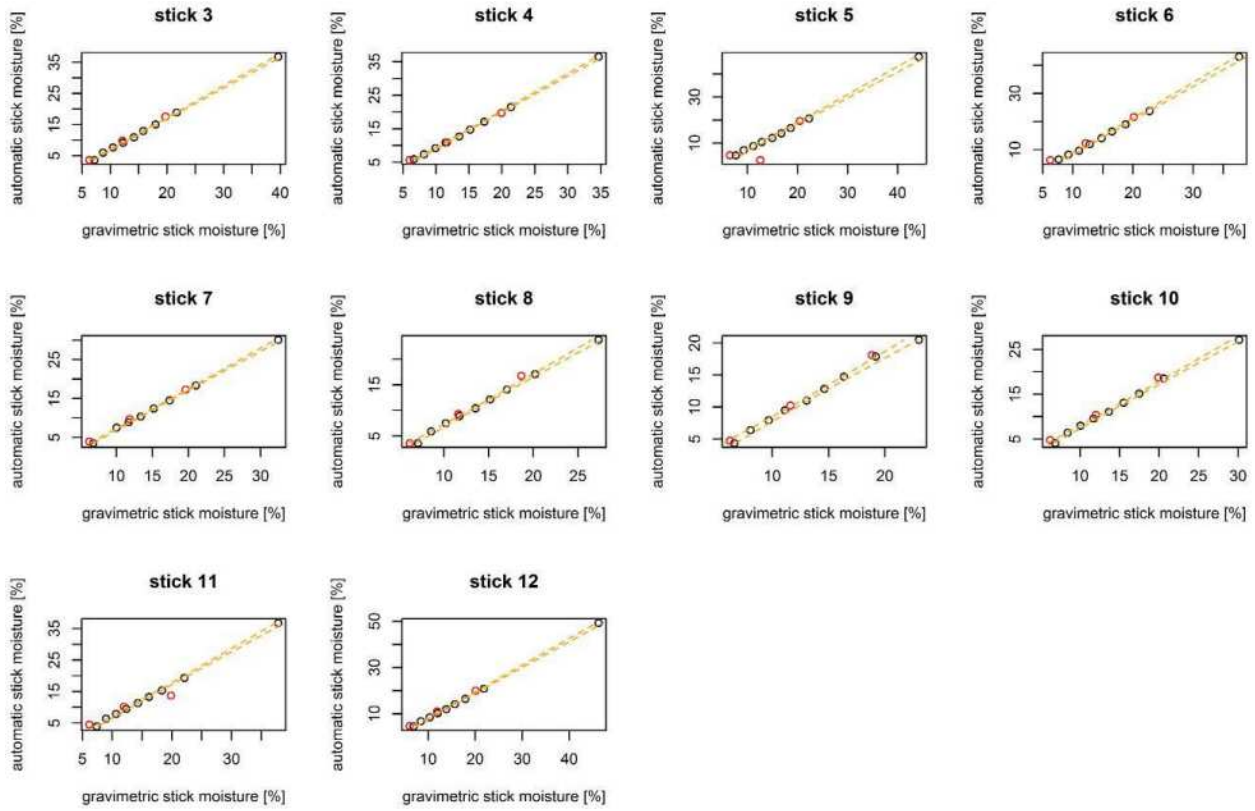

Figure 6. Correlations of automatic and gravimetrically measured fuel moisture of the sticks before (black circles) and after (red circles) the field campaign, determined in steady-state conditions in the climate chamber. The orange dashed lines correspond to the confidence interval of the initial measurements.

Except for very few outliers that were probably caused by measuring errors, no relevant differences in the signal before and after the field exposure can be discovered. Thus, the long-term stability of the fuel moisture sticks can be constituted as sufficient for (at least) one fire season under conditions similar to this central European setting.

Conclusions

This study was carried out to evaluate the performance of the automated Campbell Scientific fuel moisture measurement system (CS506-L). Using measurements in controlled environments, at field sites and a comparison to manual sampling and gravimetric moisture content determination, it could be shown that the stick-to-stick deviation is tolerable, no relevant ageing effects are expected to occur during one fire season and there is a correlation of the automated 10-hour fuel moisture values to common dead fine fuel moisture (ranging from R^2 0.44 to 0.88 depending on the type of fuel). Overall, this system is a satisfactory option when a direct measure of an (analogous) fuel moisture value is required, yielding values that can be deemed at least acceptable for this hard-to-measure parameter. The automated operation as well as the possibility for immediate data transmission and availability is

a great benefit of this system. However, even changing the fuel moisture sticks annually is rather cost-intensive when the original fuel moisture sticks are used. Additional work (not reported here) has shown that replacement sticks could be self-manufactured relatively easily. However, ensuring correct calibration/repeatability is an issue in this case.

Acknowledgements

The authors would like to thank all persons who helped carrying out the project, in particular the local fuel moisture samplers Klaus Oblinger and Helmut Rüger at Altdorf and the colleagues of the Bavarian State Forest Institute (LWF). Financial support is acknowledged from the Bavarian State Ministry for Food, Agriculture and Forestry through project ST288 and from the European Research Council under the European Union's Seventh Framework Programme (FP7/2007-2013)/ERC grant agreement no. 282250. The authors furthermore gratefully acknowledge the support of the Institute of Advanced Study and the Faculty Graduate Center Weihenstephan of TUM Graduate School at Technische Universität München, Germany.

Abstract
Owing to increased computational capacity and other factors, wildfire simulation methodologies are becoming increasingly sophisticated, and are subsequently seeing increasing use for federal fire management within the United States. State-of-the-art simulation systems account for the occurrence, topological spread, and behaviour of wildfire, all within a spatially-explicit, stochastic framework. Leveraging these advancements in burn probability modelling, researchers and managers alike are better able to assess the hazards and risks associated with wildfires and to identify effective and efficient risk mitigation opportunities. In this paper, we review the role of stochastic simulation modelling in wildfire risk assessment, focusing on how simulation results can be used to support risk-informed decision making across planning contexts. Our principal focus will be describing how novel assessment tools can be brought to bear to analyse risks to the wildland urban interface and to municipal water supplies. We will review how assessment results can inform high-level prioritization and allocation decisions, as well as more in-depth, spatial suppression response and fuel treatment planning.

Introduction

Wildfire is a global phenomenon with potentially devastating consequences to human life, air quality, water quality, homes, infrastructure, and natural and cultural resources. At the same time, wildfire is an important component of many ecosystems, potentially resulting in substantial ecological benefits. There is a critical need, therefore, to understand where and under what conditions alternative fire management strategies should be employed to balance costs and the impacts of fire, both positive and negative.

Recognizing the inherent uncertainty associated with wildfire processes, federal wildfire management in the United States, the primary focus of this paper, is increasingly adopting risk analysis principles. Principally this entails implementation of a quantitative, integrated wildfire risk assessment framework – the primary components of which are depicted in Figure 1. The likelihood and intensity of wildfire, along with the susceptibility of resources/assets to wildfire, collectively define the three legs of the "wildfire risk triangle." Stochastic wildfire simulation is therefore a foundational component of wildfire risk assessment.

A key aim of this paper is to demonstrate the value of stochastic wildfire simulation to support risk-informed land and fire management decisions. Recent advances in burn probability modelling have enabled the estimation of spatially-resolved fire likelihood and intensity metrics across landscapes, with a growing array of applications. Prominent uncertainties and informational needs vary across planning context, and resultantly a variety of simulation approaches exist, which will be compared and contrasted. In addition to highlighting several real-world planning examples focusing on risks to human life and health, this paper will identify emerging and future applications of stochastic wildfire simulation.

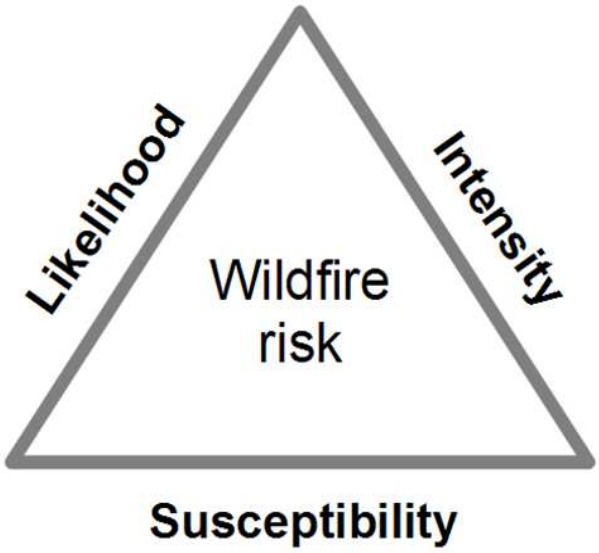

Figure 1. Wildfire likelihood and intensity, along with resource/asset susceptibility comprise the three legs of the "wildfire risk triangle." (Scott et al. 2013)

The Role of Simulation and Risk Analysis to Support Planning

Figure 2 identifies the primary sources of variability and their relation to wildfire risk mitigation and planning contexts. In pre-fire environments, the ignition date and location, as well as fire weather conditions influencing fire behaviour are uncertain. The date of the ignition is important because fires earlier in the season may have a longer temporal horizon over which to grow given the right weather conditions, whereas ignitions late in the fire season may be less of a concern as temperatures and dryness levels decrease. The location of an ignition is important relative to fuels and topographic conditions capable of supporting large fire spread, as well as proximity to fire-susceptible resources and assets. By contrast, after a wildfire incident has been detected, the primary source of uncertainty is fire weather, which is generally less uncertain relative to pre-fire contexts due to availability of short-term weather forecasts..

Figure 2 also identifies three primary types of wildfire management decisions: pre-fire fuel treatment planning, which entails manipulation of vegetation and fuel conditions to modify fire behaviour; pre-fire response planning, which entails the stratification of objectives and strategies according to possible wildfire scenarios as well as the location of firefighting resources (e.g., crews, dozers, helicopters); and wildfire incident response, which entails the implementation of strategies and tactics to achieve objectives, and the ordering and deployment of firefighting resources. Ideally these three planning processes are linked, so that for instance fuel treatments are designed to enable safe and effective firefighting response. Not included in this figure, although potentially important depending upon context, are efforts aimed at preventing human-caused ignitions.

Expanding upon the sources of variability depicted in Figure 2, Figure 3 displays the primary inputs and outputs feeding stochastic wildfire simulation models. As described above, ignition patterns, fire weather patterns, and the conditions of fuels and vegetation all influence the likelihood and intensity of wildfire across the landscape. The fundamental unit of simulation is a wildfire event and/or a wildfire season, the latter of which may entail multiple wildfire events in a given season. Fire spread modelling is built upon pixel-based, or rasterized, geospatial data, where each pixel represents a composite of topographic and vegetation-related variables, and the continuity of fuels across pixels

along with weather patterns drives simulated fire spread. There are two primary sources of outputs: pixel-based outputs that aggregate results across simulated fire events to characterize localized burn probabilities and fire intensity distributions; and event-level or polygon-based outputs that summarize simulation results for individual fires or individual fire seasons.

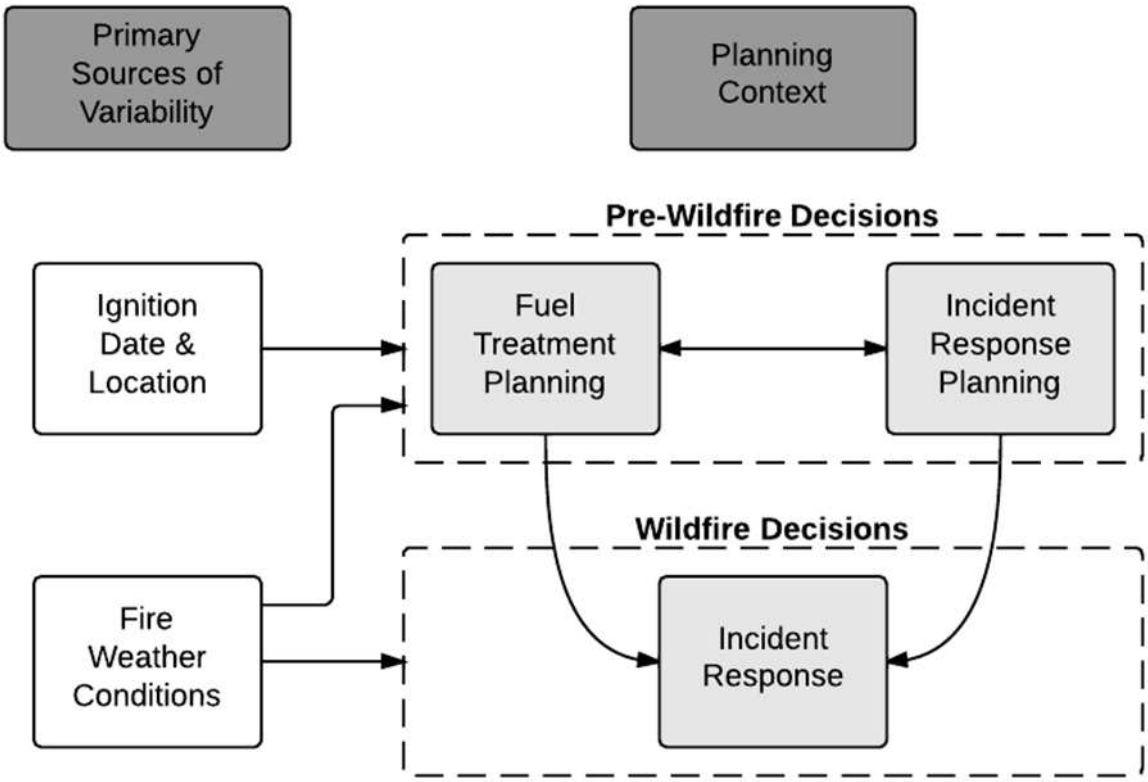

Figure 2. Primary sources of variability concerning wildfire occurrence and behaviour, and their relation to wildfire management planning contexts.

The advent of widespread burn probability modelling for wildfire management in the United States came with the development of the Fire Spread Probability (FSPro) modelling functionality within the Wildland Fire Decision Support System (WFDSS), used for active large wildfire incidents (Calkin *et al*. 2011). Referring to Figure 2, this entails ensemble simulations accounting for thousands of possible realizations of fire weather conditions, given an observed ignition. FSPro simulations depict contours of equal burn probability given fire spread potential over a given time duration, which roughly resemble concentric circles augmented by factors such as topography and forecasted wind direction. Figure 4 displays example FSPro burn probability contours for a large wildfire event in California, USA.

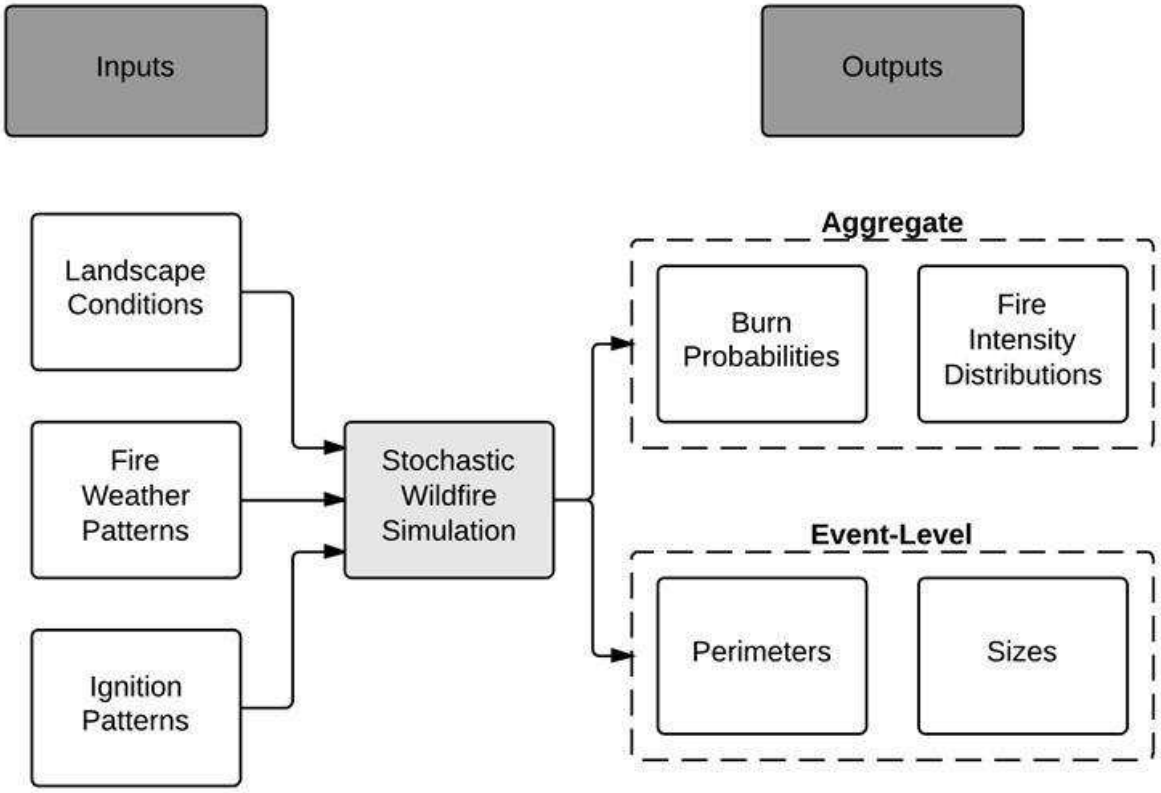

Figure 3. Primary inputs and outputs of stochastic wildfire simulation modelling

As adoption of risk analysis principles has increased, attention has turned to the application of stochastic wildfire simulation to pre-fire planning contexts. Figure 5, for instance, displays spatial burn probability modelling results for a landscape encompassing the Bridger-Teton Nation Forest in Wyoming, USA. Note the stark differences in patterns of probability between Figures 4 and 5, with the results presented in the latter figure capturing multiple ignitions along with variable fire weather conditions. The use of stochastic simulation in pre-fire planning contexts allows for more deliberative, structured decision processes (e.g., Marcot *et al*. 2012), incorporating not just fire modelling results but also information on resource/asset exposure, potential fire effects, and managerial priorities (Thompson *et al*. 2013a). Risk-based assessments built upon pixel-based burn probability results are now being widely used to support land and fire management decisions, in various geographic locations and at various planning scales (Thompson *et al*. 2011; Salis *et al*. 2012). Further, stochastic simulation can be used in comparative analysis frameworks to evaluate the impacts of alternative management strategies and to evaluate how past fuel treatments may have altered fire outcomes (Ager *et al*. 2010; Cochrane *et al*. 2012).

Another major expansion in application of stochastic wildfire simulation has been the transition to utilizing event-level results. That is, instead of focusing on localized burn probabilities and flame length distributions, analyses have focused on aggregating results across simulated events themselves. One prominent example is using simulation outputs to feed economic models predicting suppression costs based upon individual fire sizes, among other variables (Thompson *et al*. 2013b). Use of perimeters is also useful, particularly for capturing the range of variation for possible fire outcomes. For instance, whereas the expected area burned within a given polygon of interest (e.g., municipal watershed) can be captured by summing the product of pixel area and pixel burn probability for all pixels within the area, the use of simulated perimeters can characterize the entire distribution of conditional polygon area burned (Thompson *et al*. 2013c).

One promising application of perimeters is in capturing risk transmission across landscapes and identifying potential fire spread pathways (Ager *et al*. 2012). This type of analysis can estimate the likelihood of ignitions in various locations reaching some resource/asset of interest, for instance isolated patches of wildfire habitat or the wildland-urban interface (Scott *et al*. 2012; Thompson *et al*. 2013c). Spatially identifying the area within which ignitions can reach an area of interest can lead to delineation of a "fireshed" boundary, or the area within with ignitions can transmit risk to the area of interest. As an illustration, Figure 6 displays the location of all simulated ignitions whose perimeters can reach the municipal watershed for Helena, Montana, USA The outer boundary of these ignitions is delineated using a convex hull, with the left panel indicating all ignition locations and right panel further indicating the percentage of watershed burned associated with each ignition.

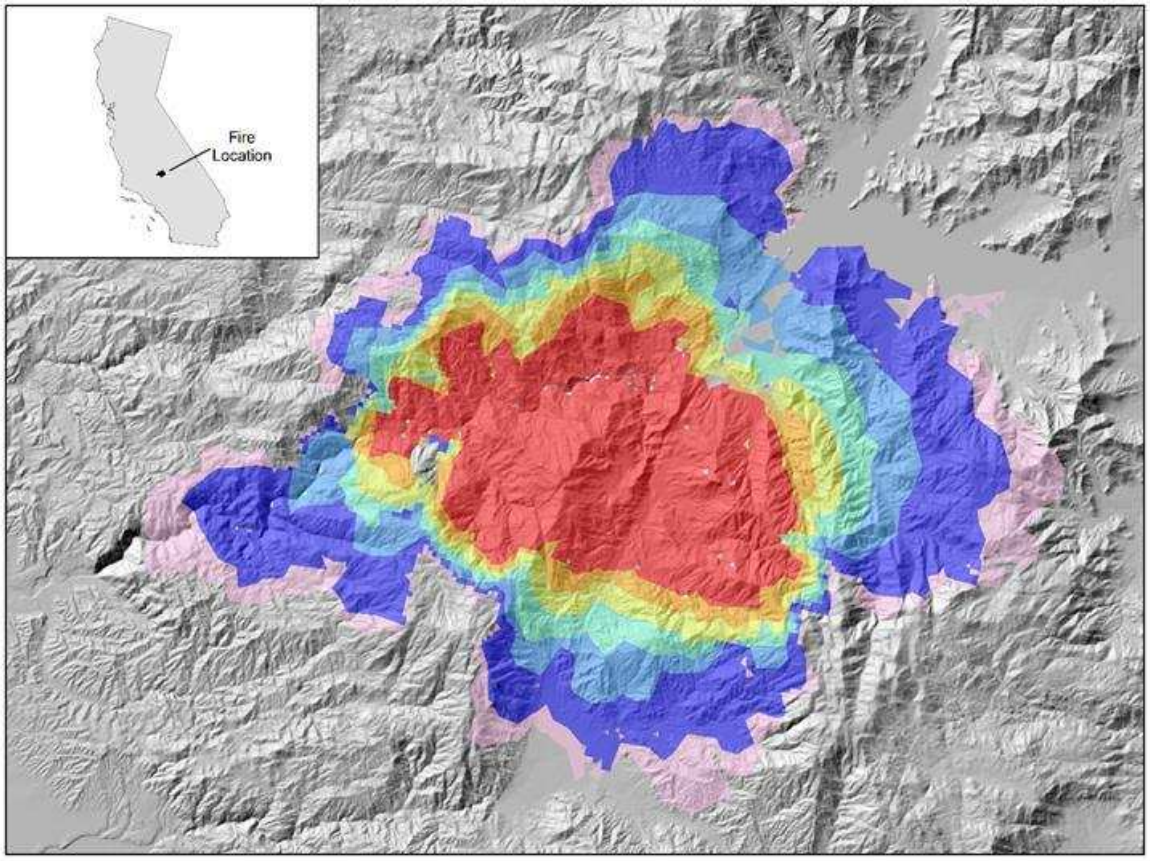

Figure 4. Simulated burn probability contours for a large wildfire event, given an ignition and fire weather forecasts. (Thompson et al. 2012)

The attribution of fire-level impacts to ignition locations has great potential to identify and differentiate areas of high risk transmission, and further to inform pre-fire strategies for mitigating risk. One prominent question in wildfire management, for instance, is which landowners comprise the greatest share of contributed risk and therefore bear the greatest burden for investing in risk mitigation. Figure 7 presents results from an analysis in the Front Range of Colorado, USA, examining the potential amount of human population affected within each simulated perimeter. The figure presents probabilities of exceeding a given amount of population impacted, charts which are commonplace in other arenas such as flood modelling but are only now being integrated into fire modelling. In this case, the impacts of ignitions are partitioned according to whether the fire ignited on federal or non-federal land, with results indicating non-federal ignitions have a greater potential to impact populated areas, due to geographic patterns of land ownership and human development in this region.

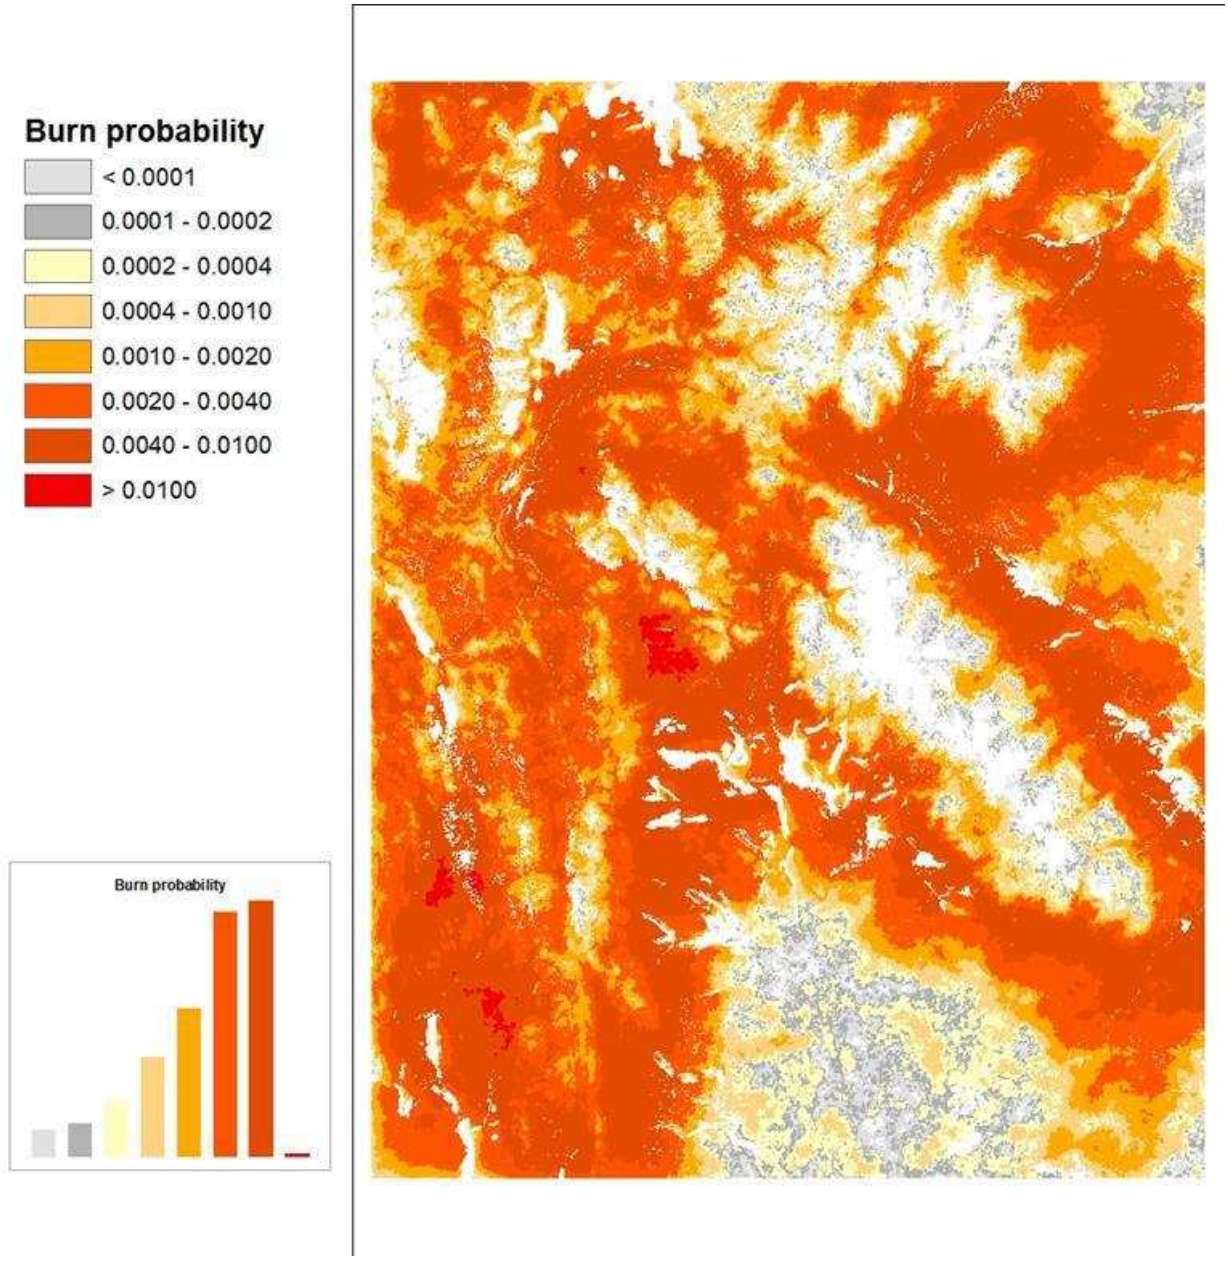

Figure 5. Annual burn probability results for thousands of simulated large wildfire events, with variable ignitions and fire weather conditions. (Scott et al. 2013)

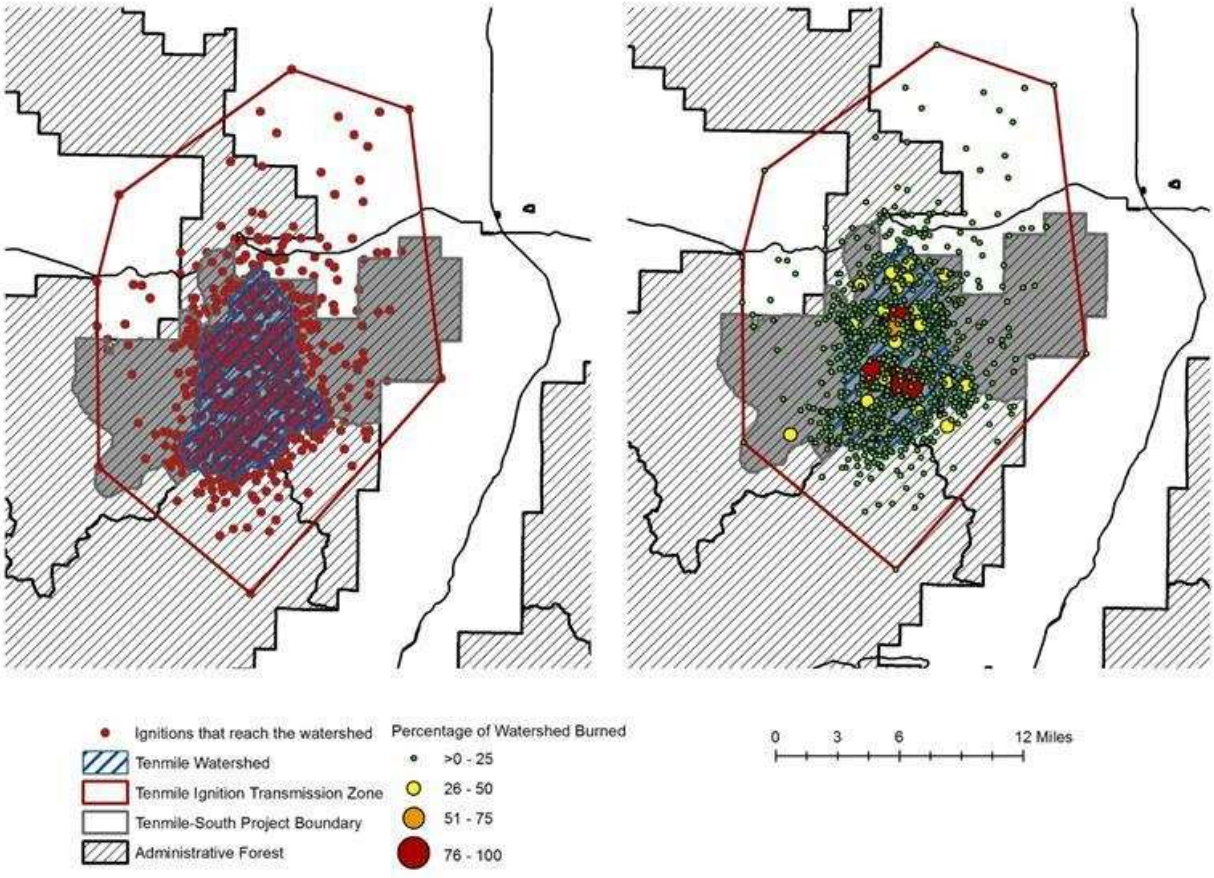

Figure 6. Fireshed (ignition transmission zone) delineation for all ignitions reaching the municipal watershed, along with area burned attributed to ignition.

3. Future Research Directions

Practically speaking, one key future direction of stochastic simulation is expanded application to other geographic regions throughout federally managed lands in the United States and elsewhere. Early adopters have largely reported beneficial outcomes, setting the stage for broader-scale adoption in a variety of contexts and planning scales. Notably, many of the assessments performed to date have occurred within collaborative planning environments, which in the ideal scenario will lead to less conflict and more streamlined implementation of risk mitigation activities. The availability of fire and fuel modellers, geospatial analysts, and process experts may largely determine the application rate of stochastic wildfire simulation and geospatial risk assessment frameworks, an area ripe for science delivery and technology transfer from the research world to land and fire managers.

Three arenas of active research are worth mentioning. First, decision makers would benefit from increased application of stochastic wildfire simulation and associated modelling efforts to better understand the impacts of fire management policies. Such efforts are by necessity interdisciplinary, for instance combining risk analysis, fire ecology, and economics, to better understand the likely costs and benefits of alternative strategies. Second, stochastic wildfire simulation outputs can help better characterize the range of potential post-fire consequences, and in particular can help with probabilistic characterization of nested disturbance processes such as post-fire debris flows. Third, stochastic wildfire simulation, in combination with other modelling efforts, can help better capture spatiotemporal dynamics of ecosystems and wildfire impacts. These questions are far more complex

and uncertain, and require consideration of vegetation succession, disturbance processes, the impacts of current decisions on future conditions, and climate change. There are clear roles for expanded application of sensitivity analysis, scenario analysis, and uncertainty analysis, among other approaches.

Abstract
Forest fuel moisture content is a fundamental parameter in forest fire research and management. Due to the complexity of fuel moisture content modelling, direct field measurement is a necessary step to establish a monitoring program for fire risk applications or to assess the validity of existing models applied to different environmental conditions.
In the present study partial results from a long-term program with direct field measurements performed in Central Portugal were used to improve the knowledge on fine forest fuel moisture content.
The objective of this study is to describe seasonal and spatial patterns of the moisture content and to analyse the relation between the moisture content of the studied species.
In terms of seasonal variation, it was found that dead tree species foliage moisture content behaves in a similar way during the year. and that the average live foliage moisture content of these species is nearly constant during the year. For the shrub species, in the period between August to September, fuel moisture content decreases till its minimum yearly value.
The relation between the studied species moisture content was analysed. The relation between the dead tree species and between the shrub species presented the best correlation performance.

***Keywords**: Fine fuels, moisture content.*

Introduction

Forest fuel moisture content (FMC) is a fundamental parameter in forest fire research and management given its implication in many aspects of fire risk including ignition probability, number and extension of fires, mode of fire spread, fire line intensity, ease of extinction and mop up (e.g. Blackmarr 1972; Rothermel 1972; Van Wagner 1987; Viegas *et al.* 1992; Dimitrakopoulos and Papaioannou 2001; Chuvieco *et al.* 2004). Due to the complexity of FMC modelling, direct field measurement is a necessary step to establish a monitoring program for fire risk applications or to assess the validity of existing models applied to different environmental conditions.
In order to assess fire risk several prediction methods that give satisfactory results, such as the Canadian Forest Fire Weather Index (Van Wagner 1987), can be used. This index mimics the moisture content trends of relevant types of fuels but direct measurements of FMC guarantee more reliable data. Despite its difficulty and cost, direct measurement of FMC does not have some of the limitations of the prediction models (Viegas *et al*. 1992).
In the present study partial results from a long-term program with direct field measurements performed in Central Portugal since 1986 (Viegas *et al*. 1992; Viegas *et al*. 2001) were used to improve the knowledge on fine forest fuel moisture content. The FMC variation range of the studied species, the seasonal FMC variation, the relations between the studied species and the relations between meteorological data and FMC will be analysed for more than 15 years of the monitoring program.

Methods

In the present study, sampling was carried out in Central Portugal, near Lousã for the period between 1996 and 2012, near Silvares and near Olho Marinho for the period between 1996 and 1999. The sampling site of Silvares is distant 5.5 km from the Lousã site, the sampling site of Olho Marinho is distant 7.7 km from Lousã site (*vide* Figure 1 and Table 1).
In the present research program, the moisture content of living and dead tree foliage from *Pinus pinaster* and *Eucalyptus globulus* and living shrub foliage and extremities from *Calluna vulgaris* and *Chamaespartium tridentatum* that are very common in the forests of Central Portugal was measured by field sampling throughout the year from 1986 to present date. In this paper the available values for the period 1996-2012 were systematized and analysed.
Living tree foliage correspond to needles of *Pinus pinaster* and leaves of *Eucalyptus globulus*, as well as small branches and leaves of *Calluna vulgaris* and *Chamaespartium tridentatum*. Dead tree foliage corresponds to needles of *Pinus pinaster* and leaves of *Eucalyptus globulus* from the litter.
Samples were daily collected at Lousã during the summer months (June to September) and once or twice a week during the rest of the year (October to May), between 12:00h and 14:00h LST.

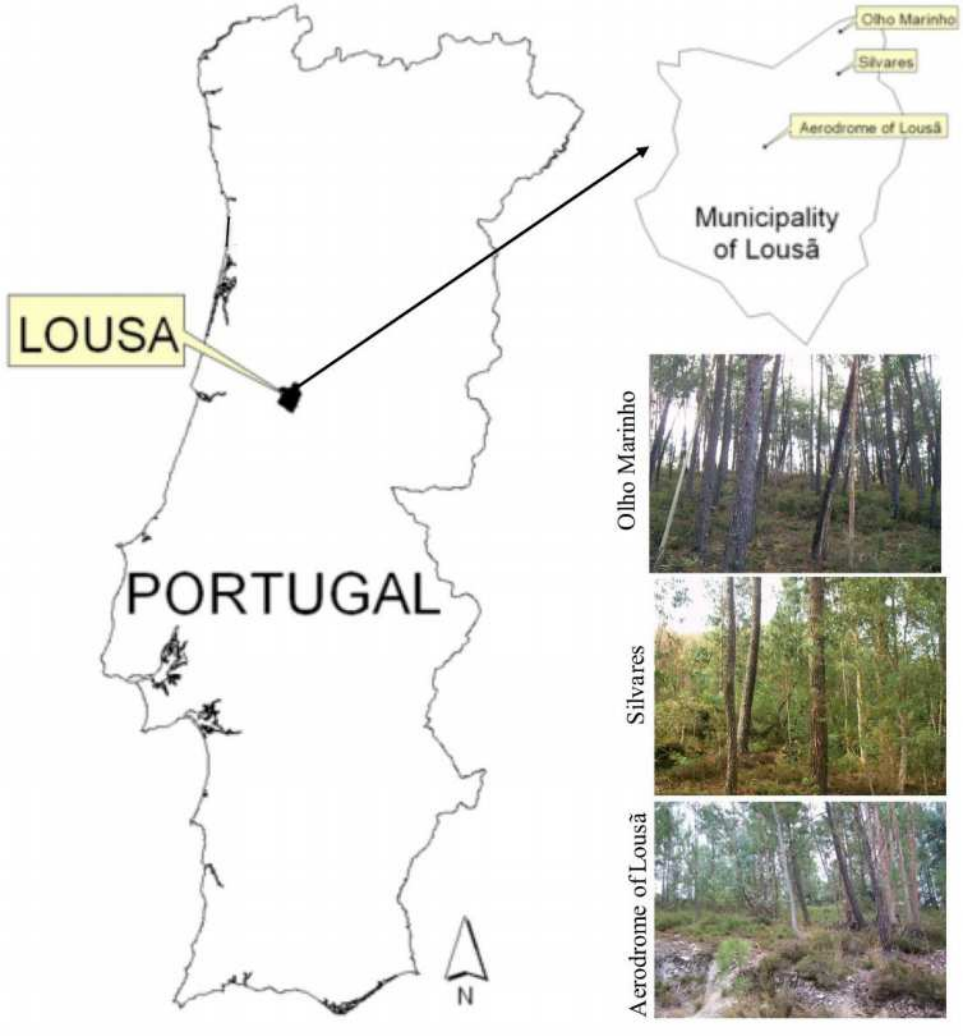

Figure 1. Geographical location of the study sites

Table 1. Main physical, climatic and vegetation characteristics of the study sites

Sampling Site	Coordinates	Altimetry (m)	Aspect	Slope (%)	Lithology	Tree height (m)	Crown closure	Vegetation
Lousã	40º8'30''N 8º14'30''W	200	South	30	Schist	10	Medium	Pinus pinaster Eucalyptus globulus Calluna vulgaris Chamaespartium tridentatum
Silvares	40º10'27''N 8º11'50''W	200	East	20	Schist	10	High	
Olho Marinho	40º11'35''N 8º11'46''W	250	East	30	Schist	10	Medium	

After the collection of approximately 50 grams of each fuel, samples were stored in a thermal bag to avoid moisture loss and immediately transported to the laboratory located in the Aerodrome of Lousã and prepared for tests. The time delay between sample collection and sample preparation was usually less than 30 minutes. If the foliage was wet with dew or rain, sampling did not occur to avoid moisture content errors.

For each fuel type, 4 samples weighing approximately 5 grams each (wet weight) were prepared and oven-dried for 24 hours at 105ºC. After the drying process, samples were weighed again in order to obtain the dry weight. The daily value of moisture content was the average of the 4 samples (*vide* Figure 2).

Figure 2. Sampling and determination procedures on the FMC research program of Lousã

3. Results

3.1. Seasonal moisture variation of the studied species

In Figure 3 the monthly FMC statistical parameters of the studied species for the period 1996–2012 is shown. As can be seen, for dead tree foliage from *Pinus pinaster* and *Eucalyptus globulus* values of moisture content between 2.6% and 182.9% were measured. For live tree foliage values of FMC between 68.8% and 225.3% were measured. The shrub foliage and extremities of *Calluna vulgaris* and *Chamaespartium tridentatum* presented values of FMC between 36.5% and 206.0%.

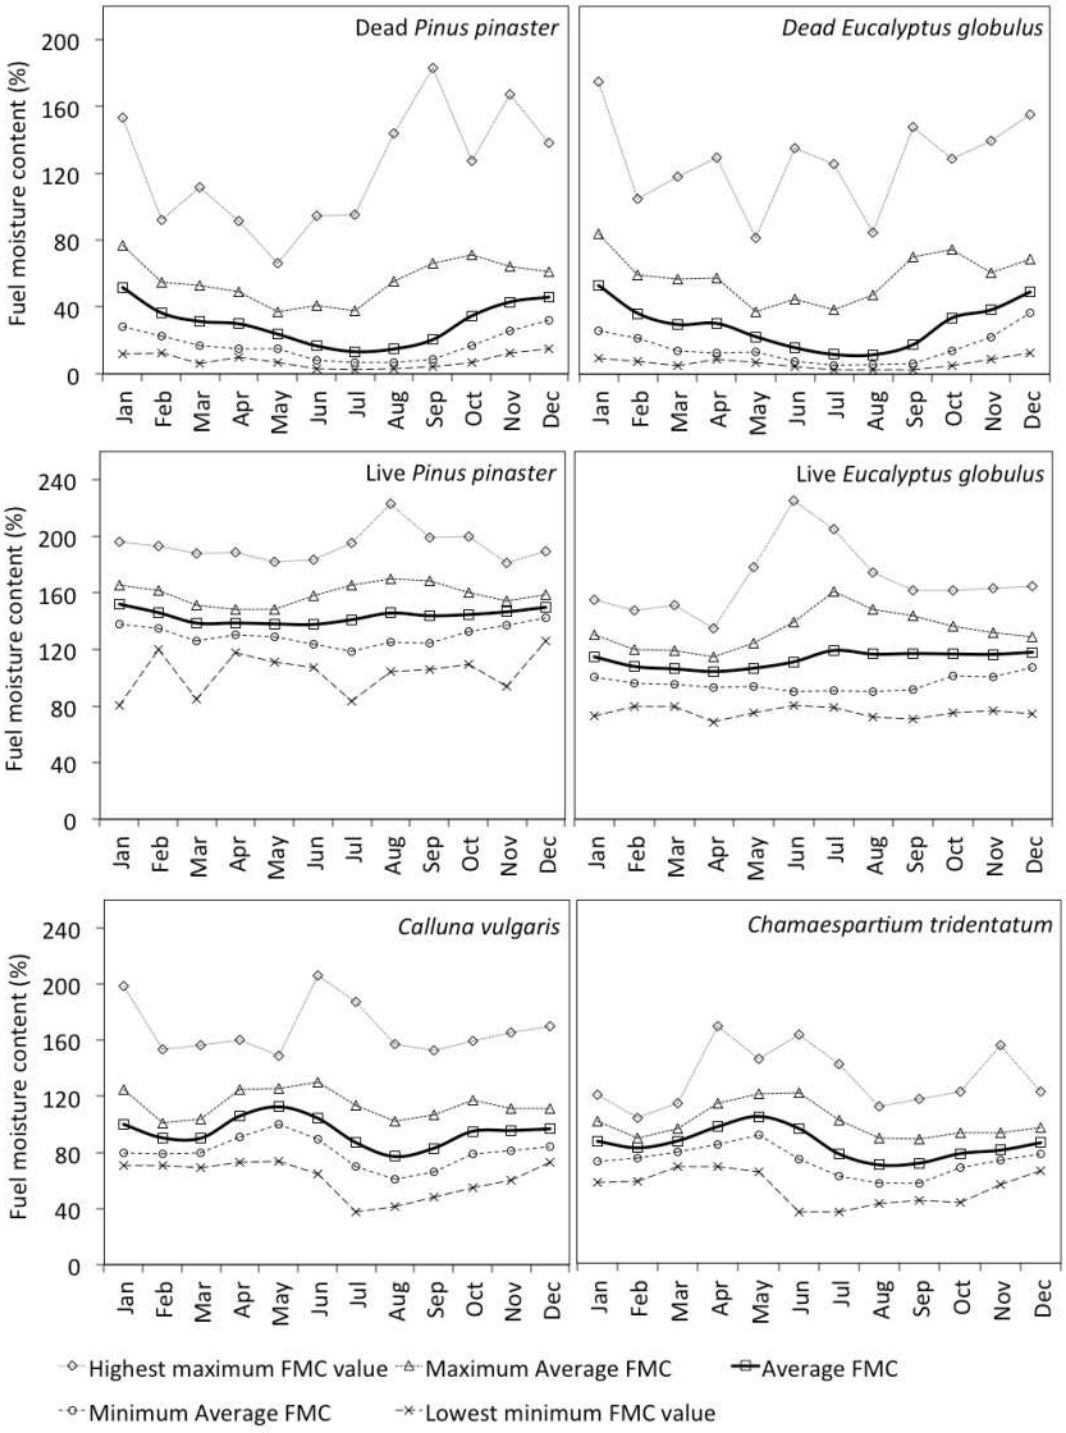

Figure 3. Monthly FMC statistical parameters of the studied species (Pinus pinaster, Eucalyptus globulus, Calluna vulgaris and Chamaespartium tridentatum) for all studied period (1996-2012)

In terms of seasonal average FMC variation, both dead tree species foliage behave in a similar way during the year. FMC is near 50% in the beginning, decreasing till a minimum of 10% in the summer months, coinciding with the forest fire period in Portugal. At the end of the year, the moisture content increases again till 50%. The average FMC of live foliage of *Pinus pinaster* is nearly constant during the year, between 140% and 150%. The same happens with live foliage of *Eucalyptus globulus* with average values of FMC between 105% and 120%. For the shrub species, in the period between August

and September, FMC decreases till 80% for *Calluna vulgaris* and till 70% for *Chamaespartium tridentatum*.

3.2. Relationship between the studied species fuel moisture content

The relationship between the FMC of the studied species are analysed through the Pearson correlation coefficients presented in Table 2. Such relationship allows the estimation of the FMC of species A through the knowledge of the FMC of species B as defined in Eqn 1. In Table 3 the model parameters estimation defined in Eqn 1 are shown. This estimation was performed using linear least squares fitting based on the field measurements. As expected, the relationship between the dead tree species and the relation between the shrub species present the best performance.

Table 2. Pearson correlation coefficients between the FMC of the studied species

3.3. Spatial representativity

In Viegas *et al* (1992) it was shown that dead fine FMC measurements in Lousã could be used as an indicator of fire occurrence of Central Portugal. Therefore, it is important to understand how representative the Lousã measurements are spatially in order to use this data as a fire risk indicator of a larger area.

As defined in Van Wagner (1987), the Canadian Forest Fire Weather Index (CFFWI), namely in its the sub-indexes Fine Fuel Moisture Code (FFMC), Duff Moisture Code (DMC) and Drought Code (DC), the moisture content indicators of litter and other cured fine fuels in a forest stand, represent respectively, loosely compacted decomposing organic matter, and deep layer of compact organic matter. In the specific case of DC it is also an indicator of live fine FMC as shown in Viegas (2001).

Thus, for the period between 1999 and 2008, fine FMC measurements of Lousã were correlated with CFFWI moisture content sub-indexes for several weather stations in the Portuguese territory shown in the map ofFigure 4, in order to verify the existence of potential relations between the measured moisture content and CFFWI predicted moisture content and to determine the spatial representativeness of the studied species FMC.

Figure 4. Geographical location of weather stations

For this purpose, Table 4 shows the Spearman non-linear correlation coefficients between the sub-index FFMC and dead needles of Pinus Pinaster moisture content measurements and the sub-index DC and live *Chamaespartium Tridentatum* moisture content measurements.
In general terms, Table 4 and Figure 5 show that dead fine FMC measurements of Lousã can be used as a fire risk indicator with a high representativeness in the central and northeast Portuguese territory and a medium representativeness in the littoral and south regions. In terms of live fine FMC, namely for shrub species, the representativeness is, in general, medium in the central and north part of the territory and low in the rest of the territory.

Table 4. Representativeness of fine FMC measurements of Lousã in terms of the Portuguese territory

All correlations are significant at the 0.01 level

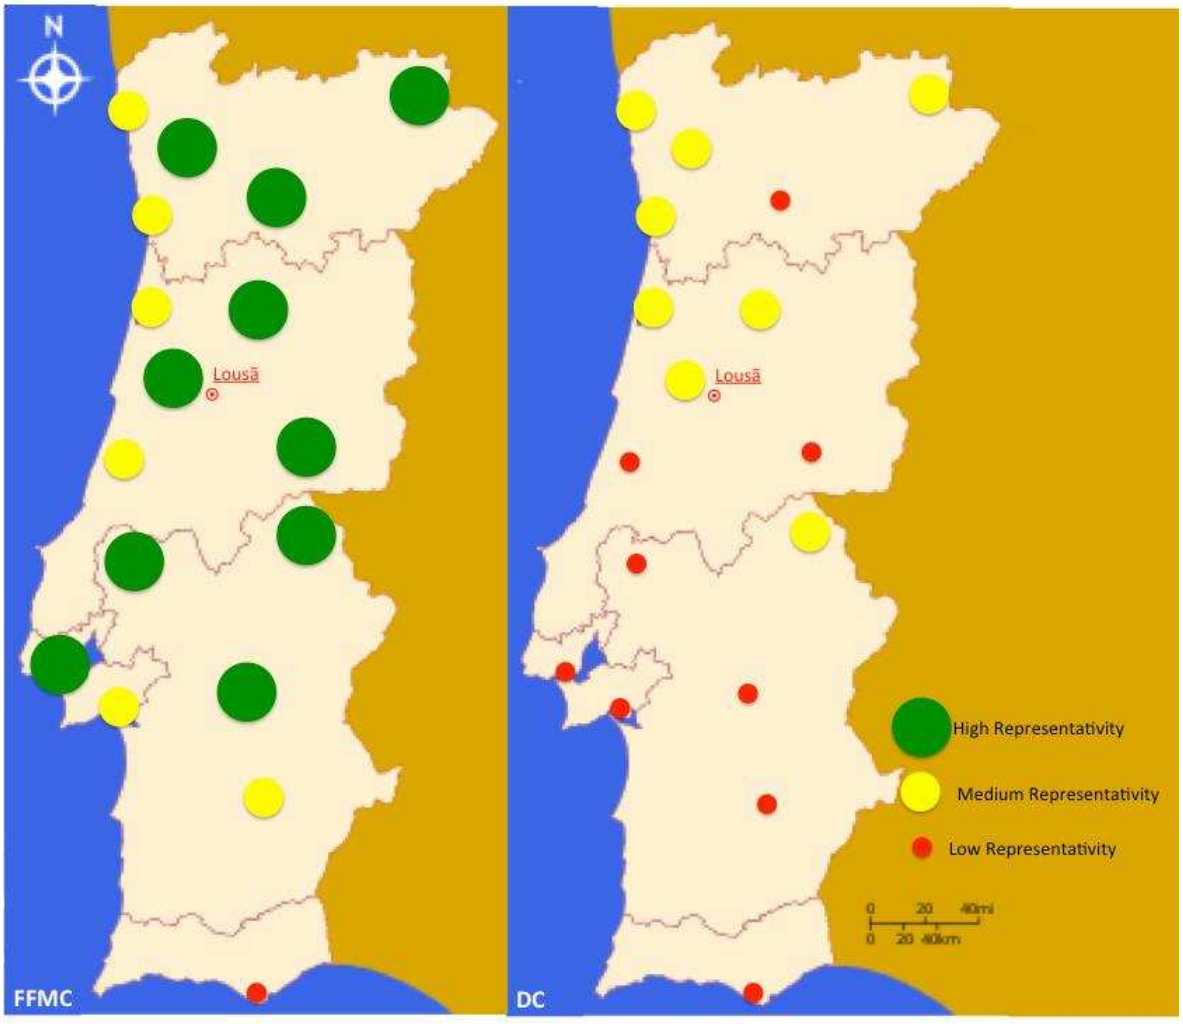

Figure 5. Representativeness of fine FMC measurements of Lousã in terms of the Portuguese territory

In order to quantify the spatial FMC patterns of the studied species (dead and live foliage of tree species, namely *Pinus pinaster* and *Eucalyptus globulus* and live shrub species, namely, *Calluna vulgaris* and *Chamaespartium tridentatum*), the data from the four sampling sites previously presented (Lousã, Silvares, Olho Marinho and Viseu) were compared. Such quantification allows the estimation

of FMC of each species, in a specific location from the knowledge of the FMC of that species in a different location.

In Table 5 the Pearson correlation coefficients between the FMC for the different species measured in Lousã and in the other two sampling sites are shown. The FMC of dead foliage of the tree species (*Pinus pinaster* and *Eucalyptus globulus*) and FMC of live shrub species (*Calluna vulgaris* and *Chamaespartium tridentatum*) show good relation between the sampling site Lousã and other three sampling sites. FMC of living foliage of the tree species shows no relation.

Due to the proximity between sites, the best relations were established between Lousã and Silvares namely for dead foliage with a Pearson correlation coefficient of 0.917 for *Eucalyptus globulus* and 0.884 for *Pinus pinaster*. As expected, the relationship between FMC measured in Lousã and FMC measured in the other three sampling sites decreases as distance increases.

The linear relation between FMC of the studied specie "*A*" at the site "*X*" and the moisture content of the same species at the site "Y" for the species that show a significant Pearson correlation coefficients were calculated using a linear equation:

$$FMC_{Specie\ A\ in\ Site\ X} = a.FMC_{Specie\ A\ in\ Site\ Y} + b \qquad (1)$$

These equations were determined using the least square method. The coefficients ***a*** and ***b*** and the respective standard error, as well as the number of data (***n***) and the adjusted determination coefficient (R^2) of the obtained equations for each species are shown in Table 6.

This analysis shows that in the lack of data, it is possible to estimate the FMC of some species in a specific location from the knowledge of the FMC of that species in a different location, using linear relationships.

Table 5. Pearson correlation coefficients between the FMC values for the different species measured in Lousã and in the other three sampling sites (Silvares and Olho Marinho)

Conclusion

The moisture content of forest fuels is very important in terms of forest fire research given its implication in many aspects of fire risk, fire spread and fire ecology. The long-term experience with direct field measurement in Lousã enables the study of several aspects related to fine fuel moisture content, being fundamental for fire risk applications or to assess the validity of existing or future FMC models.

In terms of seasonal variation, the litter moisture content of both tree species behaves in a similar way during the year, being close to 50% in the beginning, decreasing till a minimum of 10% during the summer months, coinciding with the forest fire period in Portugal. At the end of the year, the litter moisture content species increases again till 50%. Live *Pinus pinaster* average fuel moisture content is nearly constant during the year, between 140% and 150%. Live *Eucalyptus globulus* average fuel moisture content is also nearly constant during the year, between 105% and 120%. For the shrub species, in the period between August to September, fuel moisture content decreases till 80% for *Calluna vulgaris* and till 70% for *Chamaespartium tridentatum*.

The correlation between the studied species fuel moisture content was analysed. Such correlation allows the estimation of the fuel moisture content of one specie through the knowledge of the fuel moisture content of another specie. As expected, the relation between the dead tree species and the relation between the shrub species present the best performance. This representativeness allowed the establishment of linear relations between the FMC of a studied species at one site based on the FMC of that species in another site. This was performed between three sampling sites.

Dead fine FMC measurements of Lousã can be used as a fire risk indicator with a high representativeness in the central and northeast Portuguese territory and a medium representativeness in the littoral and south regions. In terms of live fine FMC, namely for shrub species, the representativeness is, in general, medium in the central and north part of the territory and low in the rest of the territory

Abstract
Dynamic global vegetation models need to be improved to accurately represent fire and land-use change in Amazonia. To this end, we are working on improving existent dynamic vegetation models to account for such strong disturbances, and aim to perform new analyses to quantify how fire, deforestation and climate change may combine to affect the distribution of major biomes and climate in the region. At present, we concentrate the development and implementation of new fire models on the simulation of fire probability and effects on vegetation dynamics, based on methods already tested in global dynamic vegetation models where fire potential is driven by the combination of presence of fuel, flammability, and sources of ignitions. To account for fire disturbance we assumed that the fraction of the vegetation affect by fires is proportional to the fire probability. Deforestation is directly interpreted as a fraction of the affected vegetation, and it is assumed to disturb tropical, temperate and conifer broadleaf, evergreen and deciduous trees. Both disturbances affect biomass, leaf area index, and total ecosystem aboveground net primary productivity, modifying the fractional cover of forest and herbaceous canopies. These implementations represent important steps towards the development and use of vegetation models that can account for major contemporary disturbances in the study region.

Keywords*: Fire, deforestation, model, Amazonia*

Introduction

Dynamic global vegetation models with improved representation of surface process are being developed to access the impacts of fire and land-use change in Amazonia. In addition to represent major features such as vegetation distribution, terrestrial carbon cycle and links between land surface and atmosphere, the models need to be improved to account for major disturbances in the region. Fires and deforestation have substantial impacts on the ecosystems of Amazonia, causing rapid shifts in surface cover, atmospheric emissions of greenhouse gases, and modifications fluxes of moisture and energy from the surface. To this end, we are working on improving existent dynamic vegetation models to account for fires and deforestation in Amazonia.

The current developments for representing fire and deforestation processes in vegetation models for Amazonia were implemented in a revised version of the IBIS model (Integrated Biosphere Simulator), which has the ability to simulate land-surface processes such as vegetation dynamics and terrestrial carbon cycle, based on dominant climate and soil properties (Foley *et al*. 1996, Kucharik *et al*. 2000). The model offered the possibility of performing global and regional simulations from common input datasets, and was tested using several experiment configurations and evaluations of model outputs. One test was the compatibility between model and observed values of evapotranspiration globally (Baumgartner and Reichel, 1975).

Our improvements of IBIS evolved into the Brazilian Integrated Land Surface Processes Model (Inland), first released on November 2012 during a workshop at INPE (http://www.ccst.inpe.br/inland). The development of the model aims global applications with emphasis on improvements and performance for ecosystems in South America and Brazil, and is part of a broad effort in Earth System modelling in Brazil [ref BESM]. From Inland 1.0, we have

implemented a new fire scheme and the ability of the model to account for deforestation disturbances, including the assimilation of deforestation scenarios for Amazonia, as summarized below.

Methods

Fire occurrence and effects

The development of the new fire model implemented in Inland was based on methods already tested in global dynamic vegetation models (Cardoso *et al*. 2013). From the methods considered, we adopt the work of Arora and Boer (2005) (AB2005) where fires are simulated as burning occurrence (probability of fire) and effects (burned area and emissions). At this initial stage, we concentrated the development and implementation of the fire model for Inland on the simulation of fire probability and effects on vegetation dynamics only. For that, we implemented the fire occurrence probability equations of AB2005, where fire potential is driven by the combination of presence of fuel, flammability, and sources of ignitions.

Presence of fuel is represented as in AB2005, which determines that a minimum of 200 gC/m2 of plant biomass is required to sustain a fire. In the Inland implementation, plant biomass was considered the sum of stem and leaf biomass from all vegetation types over land. Flammability, as described in AB2005, increases exponentially as soil moisture at the root zone approaches the wilting point. In Inland, we calculate flammability based on the moisture at the model's first soil layer, where most of roots are located. Our approach to represent ignitions sources from lightning differed from AB2005 as we assumed that lightning activity is simply random. Final fire occurrence probability is calculated by multiplying these three estimates, as in AB2005.

To account for fire disturbance, we propagated the fire occurrence probability estimation into the calculation of vegetation dynamics, following the original IBIS formulation for considering disturbances. That was done by assuming that the fraction of the vegetation affect by fires is proportional to the fire probability. As disturbances (fraction of affected vegetation) were considered in IBIS, Inland considers that fires affect biomass, leaf area index, and total ecosystem aboveground net primary productivity, which in turn modify the fractional cover of forest and herbaceous canopies.

2.2. Deforestation processes

Based on a similar approach used for fire, deforestation processes were considered in Inland also by accounting for this disturb when calculating the dynamics of the vegetation. In this case, no additional assumptions were made, and input deforestation data is assimilated by directly interpreting it as a fraction of affected vegetation. However, we assume that the grid-cell fraction of vegetation affected by deforestation only impacts tropical, temperate and conifer broadleaf, evergreen and deciduous trees. For these classes, deforestation changes plant biomass, leaf area index and net primary productivity.

In Inland, the treatment of the fire and deforestation consequences follows the original IBIS formulation, and the possibility to consider a general natural disturbance rate is also maintained. In order to avoid overly-high (greater than 100%) fractions of affected vegetation, the balance between disturbance rates is evaluated in each grid cell by assuming precedence of natural causes, than fires, and finally deforestation, and by limiting the overall annual disturbance rate for each model grid cell to a maximum of 100%.

Results

The new implementations of fire and deforestation processes in the Inland model were tested in simulations where the model was run for a total of 699 years (1400-2099), to allow for equilibrium of the slow carbon pools and to test the model stability. There was an initial spin-up period of 366 years (from 1400-1765) under constant pre-industrial atmospheric CO2 value (278 ppm). The runs were continued from 1766 to 2005 with increased prescribed atmospheric CO2 concentrations (from 278 to

378 ppm), and from 2005 to 2099 with atmospheric CO2 concentrations following the Coupled Model Intercomparison Project 5 (CMIP5) protocols. From 1400 to 2005, climate data was applied cyclically, and after 2005 from CMIP5 models. Deforestation data is based on the work of Aguiar *et al*. (2012). The results presented here represent only contemporary conditions of the study region.

Figure 1 below shows the effect of considering fires in Inland. Top panels (a, b) show the spatial distribution of evergreen trees (tropical and temperate broadleaf trees, and boreal and temperate conifers) biomass. The bottom panels (c, d) show the spatial distribution of grasses (warm and cool grass) biomass. On the left the maps show simulation results without fires, and on the right considering fires. As shown, the simulation of the transition between forests and grasslands in the Brazilian Amazonia (approximately highlighted by the dotted ellipsis) is affected by the consideration of fire in the formulation of the model. As simulated, there is an expansion of grasses over forest areas noticeable in the border between the two regions dominated by these types of vegetation.

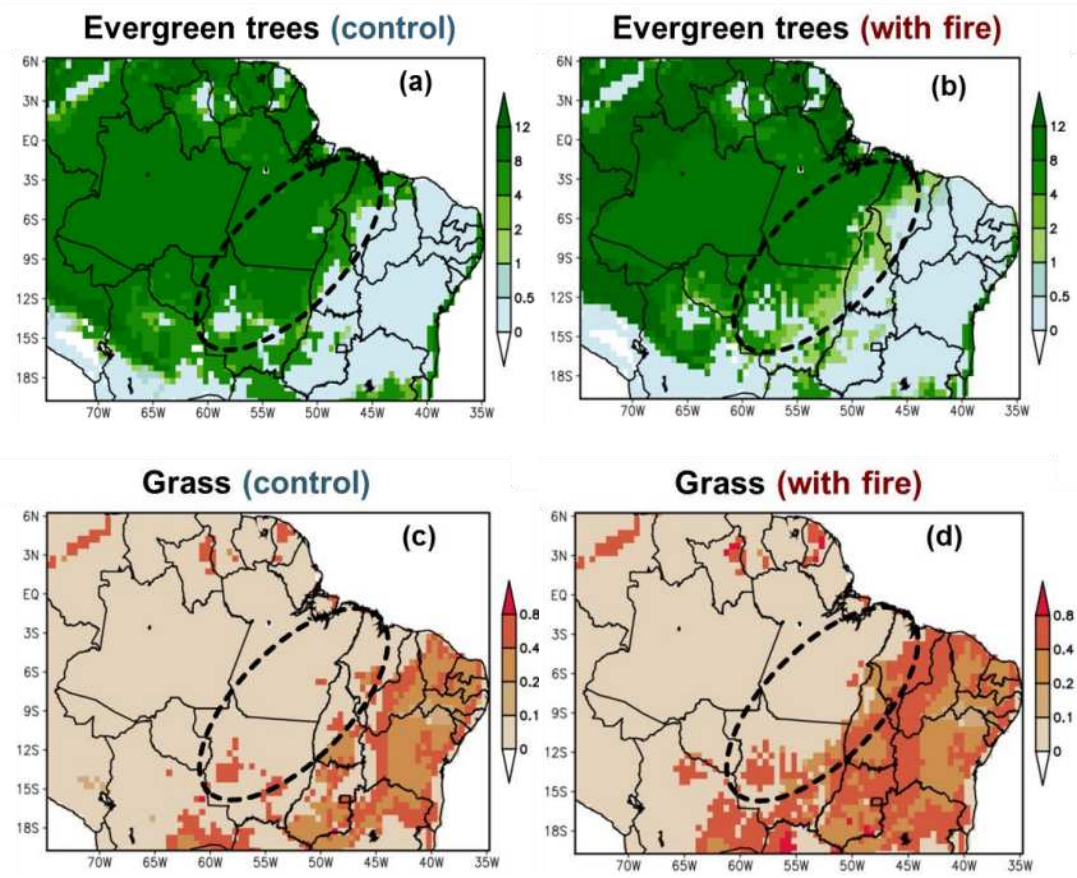

Figure 1. Contemporary distribution of evergreen trees and grasses biomass over the Brazilian Amazonia as simulated by the Inland model. Top panels (a, b) show the spatial distribution of evergreen trees (tropical and temperate broadleaf trees, and boreal and temperate conifers) biomass, and bottom panels (c, d) show the spatial distribution of grasses (warm and cool grass) biomass. On the left the maps show simulation results without fires, and on the right considering fires. The black dotted ellipsis approximately highlights the transition between forests and grasslands in the Brazilian Amazonia.

Figure 2 below shows the effect of considering deforestation on the contemporary distribution of evergreen tropical and temperate broadleaf trees biomass over the Brazilian Amazonia simulated by the Inland model. Panel (a) shows the spatial distribution of biomass without considering deforestation effects. Panel (b) shows the spatial distribution of the simulated biomass considering disturbance from deforestation based on Aguiar *et al*. (2012). As shown, the simulated biomass differs substantially by

considering deforestation. In relation to panel (a), (b) shows patterns of reduced tree biomass that resembles the observed contemporary maps of forests distribution in the study region.

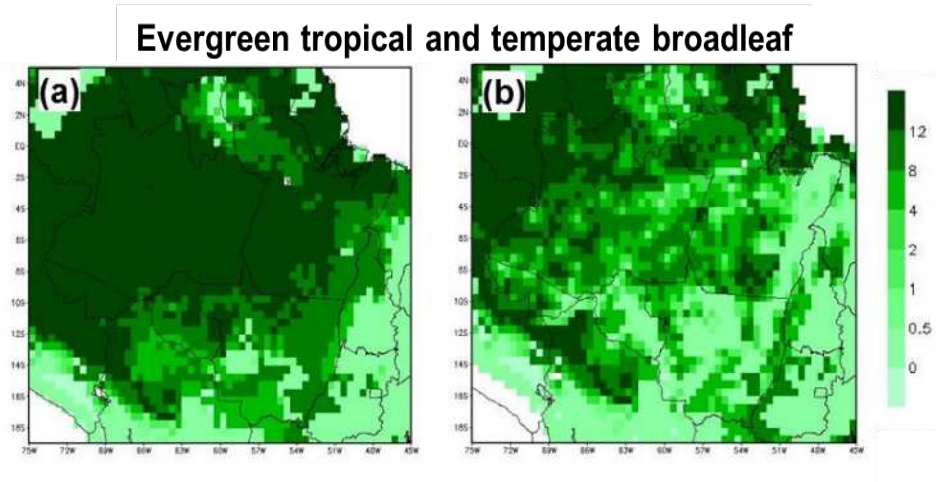

Figure 2. Effect of deforestation on the contemporary distribution of evergreen tropical and temperate broadleaf trees biomass over the Brazilian Amazonia simulated by the Inland model. Panel (a) shows the spatial distribution of the simulated biomass without considering deforestation effects. Panel (b) shows the spatial distribution of the simulated biomass considering disturbance from deforestation based on Aguiar et al. (2012).

Conclusions

At present, our implementations of major contemporary disturbances to ecosystem in Amazonia (fires and deforestation) are very simple, but they represent important steps towards the development and use of vegetation models for the study region. These new features are also important for broader analyses, where connections with prevailing environmental conditions such as climate can be considered. In specific, our preliminary results (not shown here) from offline and coupled vegetation-climate projections under current (5th Assessment Report of the Intergovernmental Panel on Climate Change) protocols of evaluations of future climate, indicate that the impacts of climate change in Amazonia will potentially intensify when combined to fires and deforestation. It is expected, for example, increase in dry season length, and reduction in the upper-canopy biomass related to an increase of the biomass in grasses from replacements of tropical forest by seasonal forest and savanna. These effects can have important implications for the distribution and stability of the vegetation in the region. Our future research activities include further model improvements and runs to understand the potential for changes and the connections between the ecosystems of the region and global environmental conditions and processes, such as carbon cycling and climate dynamics.

Acknowledgments

We thank Thiago Veloso, Luciana Soler, and Celso von Randow for earlier discussions on deforestation data assimilation in Inland. This work was developed within the scope of the research programs lead by the Brazilian National Counsel of Technological and Scientific Development (CNPq) and São Paulo Research Foundation (Fapesp) (CNPq Process 573797/2008-0, Fapesp Process 2008/57719-9), and project IRTG 1740 / TRP 2011/50151-0 funded by the DFG / Fapesp.

Abstract
The impact of bushfires in Australia can be enormous when considered in terms of loss of life, assets, infrastructure and productivity. The FireDST "proof-of-concept" system links various databases and models, including the Australian Bureau of Meteorology's new "high resolution" ACCESS (Australian Community Climate and Earth-System Simulator) numerical weather prediction system, the PHOENIX RapidFire fire behaviour model, the Commonwealth Scientific and Industrial Research Organisation's (CSIRO) smoke dispersion model as well as infrastructure and demographic databases provided by Geoscience Australia. FireDST runs multiple simulations of a bushfire utilising varying inputs (such as different ignition points, different start times, different fuel characteristics and variations in the weather) based on an understanding of what may occur. FireDST amalgamates all the simulations into a single ensemble visualisation for the fire.
This paper provides an overview of the FireDST system and examines the potential for using ensemble simulations to predict short-term (1-2 days) potential impacts from wildfires. We introduce variability in the numerical weather prediction model for three case-study fires to demonstrate the ensemble modelling system. FireDST can produce both exposure and impact statistics for the ensemble fire spread, however only exposure is covered in this paper. Such information is potentially useful in assisting in the operational management of bushfires, landscape planning (such as locating infrastructure to reduce exposed to fire) and in education and training.

Keywords*: wildfire hazard/impact simulation, ensemble modelling, integrated modelling*

Introduction

Extreme bushfires are complex physical phenomena that occur under extreme weather and environmental conditions. They are often exceedingly difficult to manage and cause sizable impacts on individuals, communities and the economy. For instance, the Victorian Black Saturday fires of February 2009 directly caused 173 deaths, over 800 admissions to emergency hospital care, destroyed 2133 houses and burned over 430,000 ha of land. It was also estimated that the fires caused a negative impact on the Australian economy of more than 4 Billion Australian dollars (VBRC 2010).
At the incident management level there have been many improvements in the ability to manage active bushfires. In particular, the last few decades have seen the development of computerised bushfire simulation models that produce a single deterministic simulation of the fire spread. These models include PHOENIX Rapidfire (Tolhurst *et al.*, 2008) in Australia, FARSITE (Finney, 1998), FlamMap (Finney, 2006) in the USA and PROMETHEUS, the Canadian wildland fire growth simulation model (Tymstra *et al*., 2009). All are able to assimilate information on the terrain, vegetation load and type and weather predictions (some also consider the built environment), to produce a single graphical output of the progress of a fire. The models, which are calibrated against how past fires have typically

progressed, consider vegetation type, terrain and topography, a fire's perimeter, air temperature, wind, and humidity. They then model where a fire will go and when it will arrive at a certain location. Incident management teams then use these predictions to help manage public warnings, evacuations and the placement of fire fighting resources.

Unfortunately there are many uncertainties in the inputs to these models (such as variations in fuel moisture, wind speed and temperature) and uncertainties in the modelling of the physics of the fire environment. These uncertainties can lead to inaccurate predictions being generated by the software. Inaccurate predictions could lead to dangerous decisions in the incident control centre and sizable effort is required to improve these simulation models. Even though accuracy is improving with new developments such as higher resolution vegetation mapping and improved fire modelling, it may never be possible to produce sufficient accuracy in every case. Recently there has been a move to incorporate uncertainty into fire modelling. Systems such as the Wildland Fire Decision Support System- Fire Spread Probability Model (WFDSS-FSPro) (USDA Forest Service, 2012) use a Monte-Carlo method to introduce uncertainty into the weather, producing a synthetic weather stream to generate a long range weather forecast. These models require an advanced understanding of the past weather and the variability in the weather that usually occurs at the time of the fire to generate this weather forecast. FSPro generates thousands of possible long range forecasts (assuming a constant weather and wind for each day) and runs a fire simulation for each. The multiple fire simulation results are then amalgamated to produce a map of fire spread probability. FSPro also places an extra level of complexity on the users of the system in understanding what the output probabilities actually mean in a physical sense. Monte-Carlo methods to generate long range weather forecasts with uncertainty, producing fire shapes which consider uncertainty, have also been used in research by Anderson *et al*. (2007), Cruz (2010) and Finney *et al*. (2011).

In 2011 the Australian Bushfire Cooperative Research Centre initiated the FireDST research project (Fire Impact and Risk Evaluation Decision Support Tool). One of the main aims of the project was to develop a "proof-of-concept" system that would allow users to easily view and assess the short-term (1-2 days) impact of various uncertainties in the information supplied to any fire spread model. The approach taken to address this aim was novel in that the FireDST system would not define the probability of an uncertainty occurring. Instead it would build an ensemble from individual fire spread simulations each with a different variation in the input condition and initially weighting each with the same probability. For example FireDST could produce an ensemble from individual fire simulations where the temperature has been varied up or down by five degrees Celsius in steps of one degree. A number of meteorological variables are varied to produce the ensemble. This paper concentrates on uncertainties in the weather however the research has also been applied to uncertainties in the vegetation and fire ignition location as well as location of synoptic frontal systems.

After producing the individual fire simulations we investigated how they could be amalgamated into a single ensemble view of the fire spread. Ensemble prediction has been applied successfully for the modelling of weather (such as the UK Met office ensemble MOGREPS[1] system) and in modelling of the paths of tropical cyclones (Zhang & Krishnamurti, 1997, Buckingham *et al*. 2010). The fire spread ensemble was then used to calculate the exposure of the ensemble footprint on people and buildings. Finally we addressed whether the smoke and combustion products from the fire could also be modelled using an ensemble.

Methodology

Concept design

We designed the FireDST system to follow the information flow defined in the Bushfire Risk Assessment Framework (Jones *et al. 2012*). The framework defines an information flow for computational analysis of bushfires from the definition of the hazard, through exposure, vulnerability and impact to calculation of the bushfire risk.

The core of the FireDST system is the Ensemble Generator (Figure 1) which controls the generation of the multiple variations for input, simulates each individual variation and creates the ensemble. Initially the supplied weather is perturbed by the Weather Ensemble Generator to provide new weather sets containing the variation in humidity, temperature, wind speed and wind direction. The supplied fuel information is also perturbed to provide variations in fuel load. Finally, the ignition information is perturbed to provide variation in the ignition location and ignition time. Once all the variations in input conditions have been created, the Ensemble Generator simulates each individual fire and amalgamates them all into an ensemble footprint of the fire.

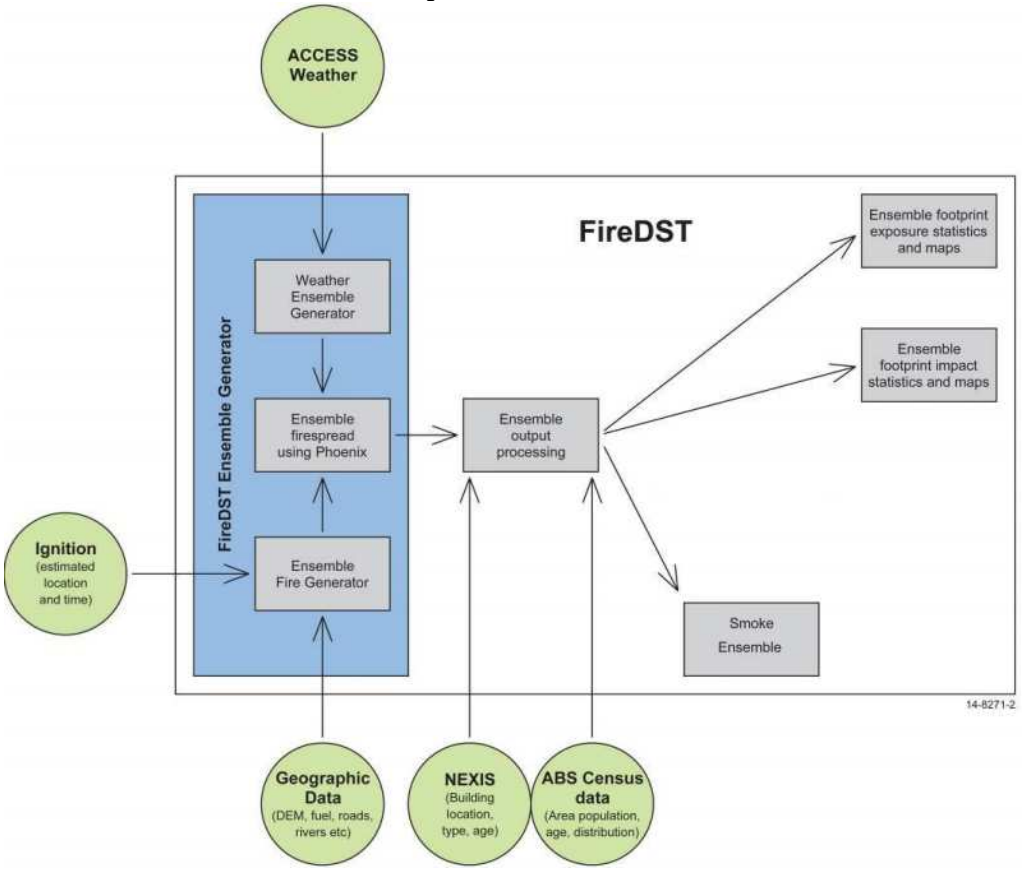

Figure 1. Information flow in FireDST

FireDST Ensemble Generator

The weather is one of the most critical inputs required for simulating bushfires. The Australian Bureau of Meteorology supplied an ACCESS (Australian Community Climate and Earth-System Simulator)(Puri, 2011) research mode numerical weather prediction for 48 hours in 5 minute time steps at horizontal grid spacing of 0.036° latitude/longitude grid spacing, which is approximately 4.0 km in the north-south direction. Each ACCESS simulation included separate grids of temperature, relative humidity, wind speed and wind direction.

The Weather Ensemble Generator allows the user to define a set of rules for creating a weather ensemble every time a new ACCESS weather forecast is produced by the Bureau of Meteorology. The Weather Ensemble Generator modifies the weather grids to produce different combinations of weather that the user considers likely to occur (i.e. takes into account some of the uncertainties in weather conditions). Simple rules were used to modify individual weather scenarios. Examples are changing the wind speed grid to increase all wind speeds by five meters per second, or changing the temperature grid to increase the temperature by two degrees. The rules also allow a more complex weather scenario by creating a profile that includes a combination of changes to humidity, temperature, wind speed or wind direction. These weather variations are stored as a weather ensemble for later use when a fire ignition location is supplied to FireDST. For this research we did not attempt localised weather change in particular areas within each weather file.

FireDST uses PHOENIX RapidFire (Tolhurst *et al*. 2008) to run each single simulation of the fire. To create a fire ensemble, FireDST uses the ignition point rules to generate other fires around the user specified ignition point (e.g. 200 meters to the North, South, East and West). 200m is the minimum distance utilised as the PHOENIX Rapidfire grid cell size is 180m in size and we wanted to ensure that each new ignition started in a new cell. Ignition time was varied from 20 minutes before to 20 minutes after the actual ignition in steps of 5 minutes. The rules can also vary the vegetation conditions (such as variations in fuel load and moisture) and their application for each weather ensemble. The FireDST Ensemble Fire Generator rules also allow the modification of wind speed based on the local terrain/topography using the Wind Ninja system (Forthofer *et al*., 2009). The user also specifies the information that is required by PHOENIX Rapidfire including the fuel type grid, a digital elevation model, road disruptions and fire history database.

The Ensemble Fire Generator then combines all of the individual PHOENIX simulations into a single ensemble view of the fire. This is achieved by taking the simulated fire area of the individual fire and converting the area inside the fire shape to "1" and everything outside to "0". An ensemble fire shape is produced by overlaying each converted fire spread simulation shape and adding the area values. For example where two fires cover the same location the ensemble fire location then contains "2", where there is no overlap the ensemble shape just contains "1". Everywhere else is "0". An example of how this is undertaken is shown in Figure 2. The overlap values are then converted to a percentage overlap in the final shape which can be displayed in discrete intervals. Typically, either half-hourly or hourly time increments are used to understand the progression of the fire.

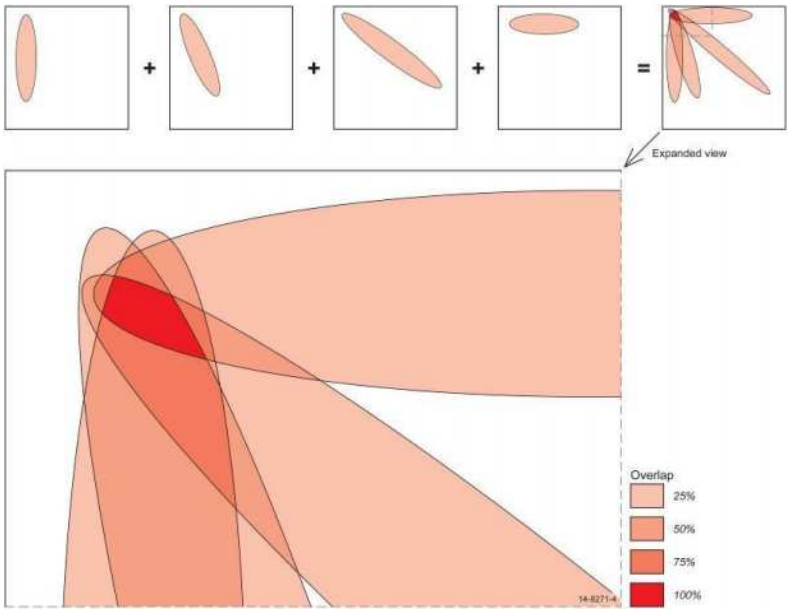

Figure 2. Example of how an ensemble likelihood shape is produced. The fire scars of the four different notional fire simulations are combined to compute the likelihood that a particular location will burn.

2.3. Ensemble Output Processing – Exposure Statistics

FireDST has been setup to display statistics and maps of residents and structures exposed to the ensemble fire spread. Geoscience Australia supplied the building database National EXposure Information System (NEXIS) (Nadimpalli *et al*. 2007; Canterford, 2011). NEXIS identifies the house location and attributes of the house (age, wall construction, roof type). NEXIS also contains quantity surveying information such as estimated building replacement cost and estimated contents value. Population statistics were extracted from the 2006 Australian Bureau of Statistics (ABS) Census at the Collection District reference level and allocated as averages to all the individual houses in that collection district. The 2006 Census information contains 14 vulnerability indicators (fields) that have been included in FireDST (Canterford 2011). The exposure statistics are produced by overlaying the ensemble fire footprint with each building location (which includes the population and vulnerability indicator statistics).

2.4. Ensemble Output Processing – Smoke Dispersion

Finally, all the individual fire simulations included in FireDST's ensemble can be passed to a new atmospheric numerical model (supplied by CSIRO Marine & Atmospheric Research) that simulates the spread of gaseous fire combustion materials such as smoke, ozone, particles smaller than 2.5 microns in size ($PM_{2.5}$), Nitrogen Monoxide (NO) and Carbon Monoxide (CO) from a single fire. Information regarding the supplied atmospheric model and smoke dispersion technique can be found in Cechet *et al.* (2014). FireDST takes the individual fire atmospheric spread results and amalgamates them into two ensemble maps of the concentration and percent overlap of the various products of bushfire combustion. The amalgamation technique is the same as described in Figure 2. These maps can be overlaid with the population statistics and building locations to display the impacted population. These maps can be useful to assist in managing public health warnings and in the movement of people and emergency service teams.

2.5. Case studies

FireDST was tested in Australia on three case studies. The Kilmore fire of 9 February 2009 was selected because the fire progressed through various terrain types and there was a high level of fire reconstruction information available. The Kilmore fire started around 11:45 and burnt 125,383 hectares, resulted in the deaths of 119 people and destroyed 1,242 homes. A comprehensive assessment of the Kilmore East fire can be found in Chapter 5 of the Victorian Bushfires Royal Commission report (VBRC, 2010). A comparison of the ACCESS weather simulation with all the Automated Weather Stations (AWS) in the region indicated a good match for temperature, humidity, wind direction and the timing of the wind change. However the 10 metre wind speed comparison found that the simulation of the wind speed was under-predicted by 5 to 7m s-1. A summary of the comparison is contained in the FireDST final report (Cechet *et al*. 2014). This deficiency in wind speed was able to be corrected by calculating wind speed bias correction factors that were then applied to the ACCESS wind speed file. This technique is fully discussed in the Kilmore Case Study report (French *et al*. 2014a). Smoke dispersion simulations were only conducted for this case study due to the excessive computer time necessary to run these simulations.

The second case study was the South Australian Wangary bushfire of 10 January 2005 which resulted in the burning of 77,964 hectares of mainly farmland, in the deaths of nine people and the destruction of 93 homes on January 11 (SA Coroner 2007). On January 10 the fire appeared to be contained, however the fire broke out at three locations during the morning of the 11th. The fire progressed through very open terrain and mainly crops, providing a contrast to the terrain and vegetation of the Kilmore fire. As with the Kilmore case study, comparison of the ACCESS weather with all the AWS observations in the region indicated a good match for temperature, humidity, wind direction and the timing of the wind change. However the 10 metre wind speed comparison found that the simulation

under predicted the actual wind speed. A summary of the comparison is contained in the FireDST final report (Cechet *et al*. 2014). The Wangary case study report (French *et al*. 2014b) contains details of the wind speed bias correction factors that were calculated and used in this case study.

The third case study was a portion of the Mt Hall fire that occurred on 24 December 2001 in New South Wales. The Mt Hall fire was ignited by lightning on the 24th of December 2001 in a rugged region of the Blue Mountains. The fire was not contained on the 24th due to excessive weather conditions and crossed Lake Burragorang at around 13:00 on the 25th of December 2001. The fire then impacted the townships of Warragamba and Silverdale destroying 30 properties. The case study covered this fire from when it jumped the lake until it impacted the townships, primarily to evaluate whether an ensemble could be used to model part of a bushfire. Comparison of the ACCESS weather with the AWS observations showed that significant aspects of the AWS meteorological observations were missing or otherwise inadequately represented. The relatively poor simulation may be due to the initial conditions, the complex topography or that the synoptic forcing was weaker. A summary of the comparison is contained in the FireDST final report (Cechet *et al*. 2014). Unfortunately due to the distance of this fire from the nearest AWS there was no ability to calculate wind speed bias correction factors.

Simulation Variability

The main uncertainty in calculating fire spread is a combination of changes in the environmental inputs particularly the meteorological parameters. This paper uses variability in the weather to demonstrate FireDST ensemble functionality. The standard perturbations initially used in each case study are outlined in Table 1. These values were chosen based on the Bureau of Meteorology's comparison of the ACCESS simulation and the observations for Kilmore and Wangary. This results in a standard set of 31 simulations including a simulation with the supplied weather.

Table 1. Standard variability initially used in all case studies

	Minimum	Maximum	Increment	Units/Comment
Temperature	-2	+2	1	Degrees Celsius
Humidity	-2	+2	1	Percent
Wind Direction	-2	+2	1	Degrees
Wind Speed	-5	+5	1	Meters/second
Ignition Time	-10	+10	5	Minutes
Ignition point				200m to the N, S, E and W of the original ignition

2.6. Ensemble Validation

Ensemble validation was conducted by comparing the ensemble shape at various time steps in the footprint with a reconstruction of each of the case studies at the same time step. Individual fire simulations were also compared with the reconstruction using the Area Difference Index (ADI) technique defined in Pugnet *et al*. (2013). This technique has the ability to also compare individual simulations that will in time assist to constrain the variability in the input parameters considered for use in the ensemble.

Results

3.1. Weather variability results

A 30 member ensemble for the Kilmore case study is displayed in Figure 3. Displayed on top of the ensemble are the blue isochrones of the reconstruction of the Kilmore fire at the same time. The reconstruction, which fitted in the ensemble footprint, indicates that the choice of ensemble members provided a wider range of variation than actually occurred in the real fire.

The Wangary fire was contained to a swamp area on 10 January 2005, but there were three outbreaks to the south-east in the morning of the 11 January. Figure 4 shows that if an ensemble was constructed on the 11th and initiated with the actual location and time of each of the breakouts, the ensemble would accurately predict the fire impacting the township of North Shields (which was impacted by the fire).

Despite many attempts it proved difficult to get a realistic ensemble using the standard perturbations for the Mt Hall fire. More variability was required in both wind direction and wind speed to achieve a realistic ensemble shape. Figure 5 is an ensemble simulation for the Mt Hall fire to 1930 EDT on 25th of December 2001. The ensemble fire spread has clearly impacted both Warragamba and Silverdale. The ensemble spread also shows the continuing path of the fire to the east. Although this ensemble simulation closely resembles the reconstruction, the choices of individual simulations in the ensemble had the largest variation from the ACCESS model output compared to the other two case studies. For example in this ensemble the minimum wind direction was increased to 25 degrees less than the ACCESS model output and the wind speed was increased to 20 $m.s^{-1}$ higher than the ACCESS model.

Table 2 displays the actual variability used to produce these ensembles. Mt Hall ensemble had the largest variation, probably due to the fact that the ACCESS weather simulation validated poorly for the available weather observations. Despite the extra variations, the ensembles still produced fire shapes that reflected the actual fire shapes.

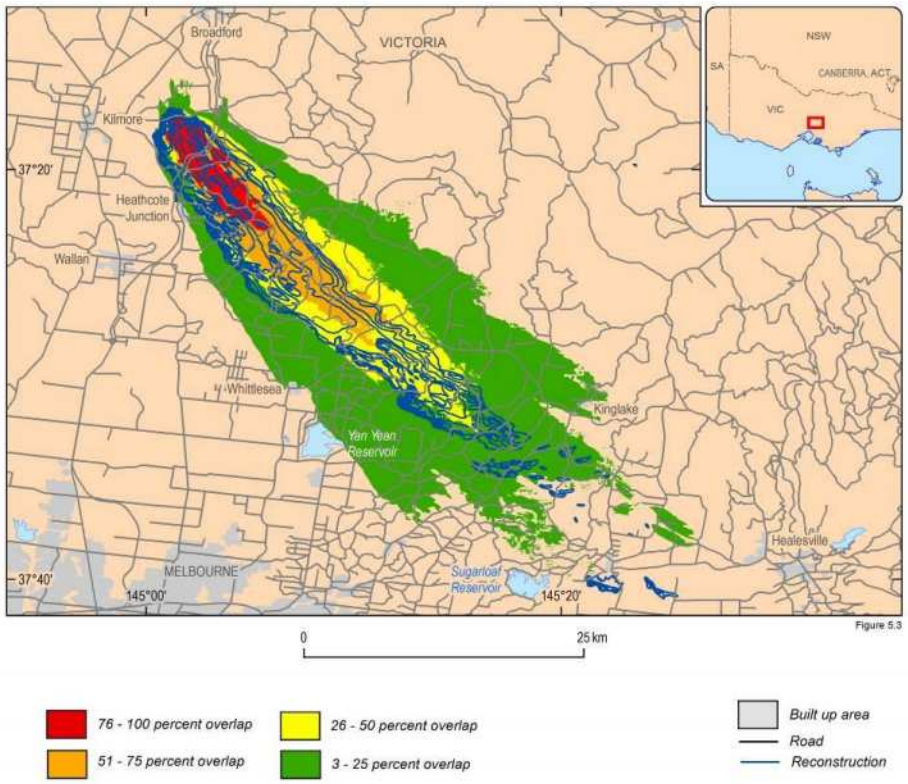

Figure 3. 30 member ensemble simulation for the Kilmore fire with the actual fire reconstruction from Gellie et.al (2012) (blue isochrones).

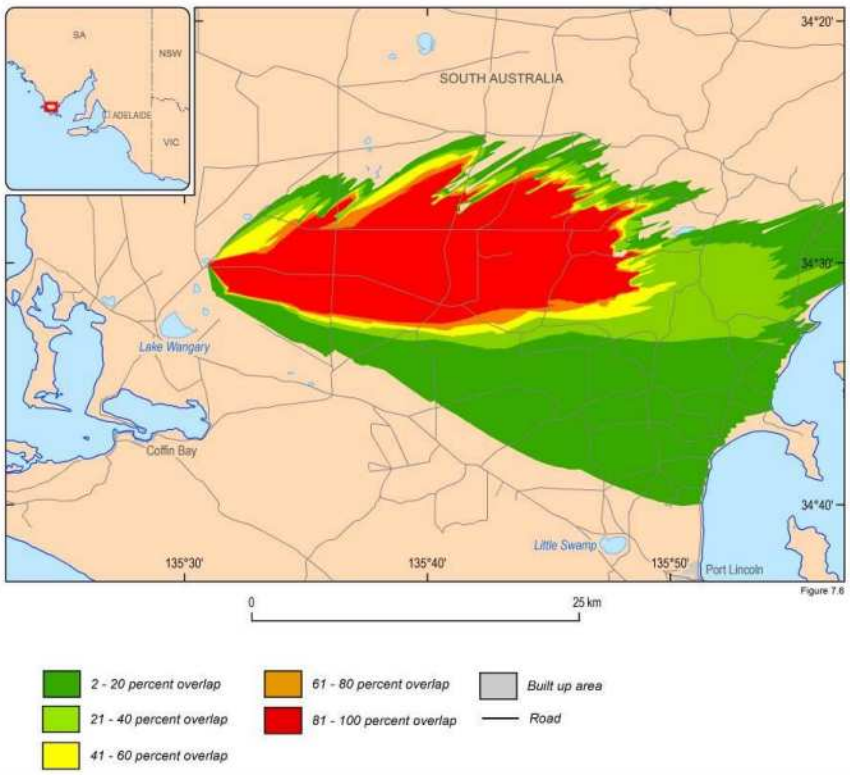

Figure 4. 39 member ensemble shape file output for Wangary to 15:50 CDT using the actual location and time of the fire breakouts on 11/1/2005.

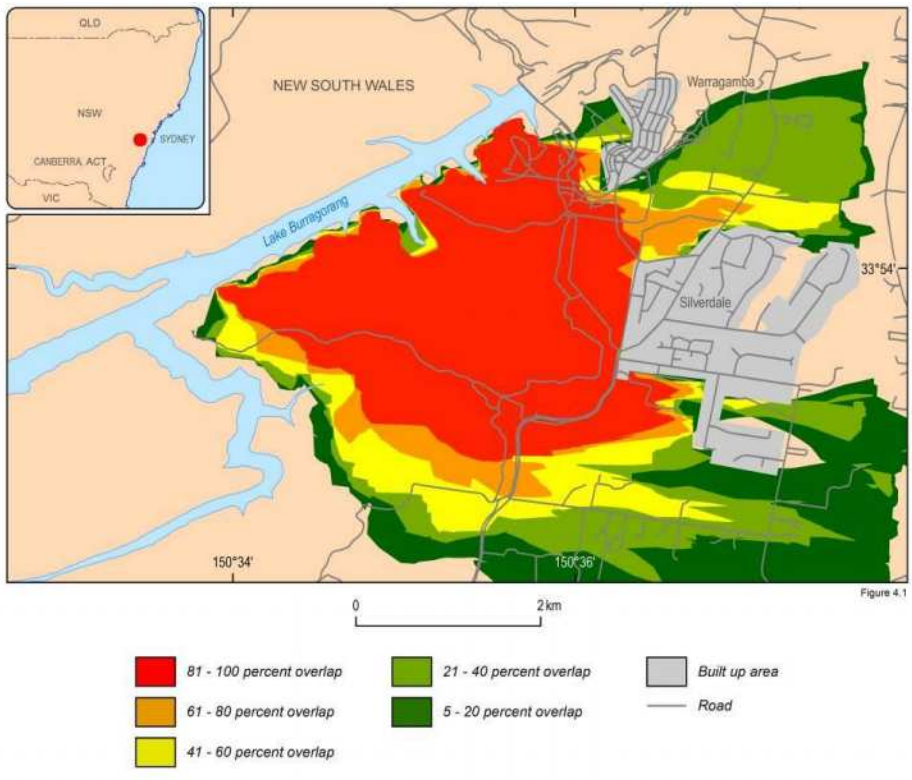

Figure 5. 25 member ensemble simulation for the Mt Hall fire to 19"30 on 25/12/2001

Table 2. Actual variability initially used in the case study examples where the letter "S" stands for the supplied information

	Kilmore		Wangary		Mt Hall		
Members	30		39		25		
	Min	Max	Min	Max	Min	Max	Units/Comment
Temperature	-2	+5	S	+10	S	+10	degrees Celsius
Humidity	-2	+5	-5	S	-5	S	percent
Wind Direction	-10	+10	-5	+25	-5	+25	degrees
Wind Speed	-5	+5	S	+10	-5	+20	meters/second
Ignition Time	S	S	S	S	S	S	minutes
Ignition point	Y		S		S		200 to the north,south,east and west

3.2. Exposure of buildings to the firespread ensembles

Figure 6 shows an example for the Kilmore case study of how the house locations can be displayed overlaid on the ensemble footprint. This overlay provides a direct visual representation of the exposure of the buildings to the ensemble footprint. FireDST can then automatically calculate from the building location the number of buildings and people that are potentially exposed to this fire.

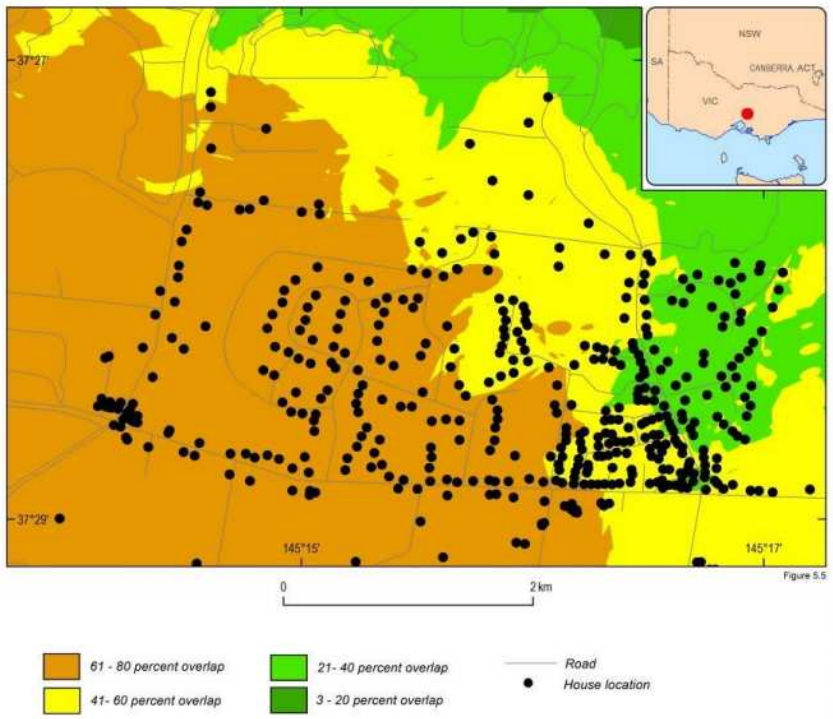

Figure 6. Kilmore fire, ensemble fire spread with house locations displayed.

3.3. Exposure of buildings/people to the bushfire smoke ensembles

FireDST is able to extend the ensemble approach to smoke and combustion element spread from a bushfire. The ensemble smoke spread was only completed for the Kilmore fire due to the computer processing time taken to produce the multiple simulations (Meyer *et.al*. 2013). Figures 7 and 8 show an example for the maximum concentration and percent overlap of Carbon Monoxide (CO) for an ensemble of 4 fire spread simulations that had different ignition points 500m to the North, South, East and West of the Kilmore ignition point. The two images are required to be considered together.

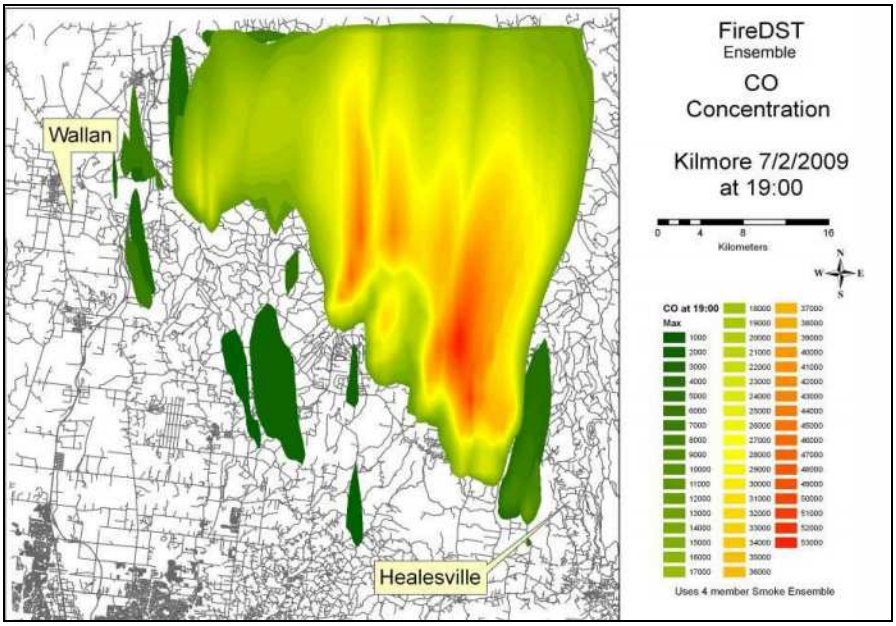

Figure 7. Map of the concentration of CO at 1900 for the 4 simulations of the Kilmore fire. This concentration map must be used in conjunction with the probability map.

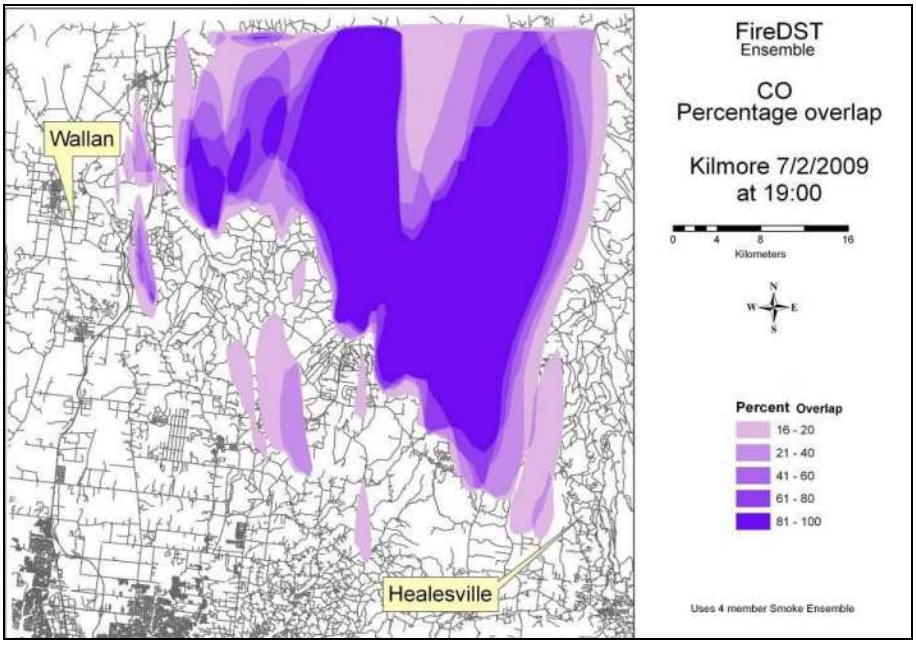

Figure 8. Ensemble map of the percentage overlap of CO at 1900 for the 4 simulations of the Kilmore fire. This probability map must be used in conjunction with the concentration map.

Discussion, Conclusions and Future Work

With the FireDST "proof-of-concept" system we have demonstrated the successful generation of short-term ensemble fire spread as well as modelling associated exposure. FireDST has shown the utility of generating multiple scenarios and generating an ensemble fire spread. FireDST has also demonstrated the ability to derive and display statistical information about people and buildings that are exposed to the ensemble footprint. Graphs and tables can be displayed showing the exposure across the ensemble footprint (e.g. an estimate of those houses and people in the 76-100% probability area for the simulations considered in the ensemble).

This research has shown the development of a simple ensemble overlap of all the individual fire simulations. However it may be possible in the future to include known probabilities for the likelihood of occurrence of each of the individual simulations. The probabilities could be supplied as part of a weather ensemble similar to the weather ensemble produced by the UK Meteorological Office. The probabilities can then be incorporated into the ensemble to produce a probabilistic fire spread which informs users of the likelihood of each ensemble area occurring (i.e. the 3-25% percent overlap area might only have a 10 % likelihood but the 76 to 100% area would have a 100% likelihood.

The next challenge is the operational implementation of this new technology. More work is needed in association with the fire agencies to define a business case for predictive models such as FireDST and a sustainable implementation plan that includes further research, training and field trial validation. A national collaborative effort among Australian fire agencies is clearly required. As a prototype, FireDST has already revolutionised fire simulation modelling. The methodologies developed in the project promise to be an invaluable asset to fire managers working under pressure to make quick decisions that affect lives and infrastructure. Operational fire decision support models could conceivably produce continually updated simulations of severe fire events which address the uncertainty in the input parameters (including the assimilation of fire ground intelligence and real-time performance statistics relating to the fire weather predictions). These simulations, developing products relating to fire spread and impacts, could provide valuable decision support for emergency management. Fire agencies face a steep learning curve in dealing with scenario information which attempts to capture the outcome sensitivity by considering the uncertainty in model inputs. The development of a national approach to fire spread and impacts, as well as standardisation and consistency with the underpinning datasets, would help enable all fire managers to become accustomed to 'what if' scenarios, and to allow transparency in utilisation, validation and learnings across state boundaries.

Abstract
Knowledge of the spatial distribution of fuel types is essential for implementation of the fire models predicting fire behaviour, severity and spread. In the present study, the most commonly used fuel classifications systems currently employed worldwide and the associated methods for generating a fuel type classification has been examined and compared. Based on a critical analysis of the state-of-the-art and on the main advances achieved in different classification systems, a simple quantitative methodology for development of a fuel type model has been developed. The results obtained showed that Austrian stands are characterized by a higher fuel load concerning both – live and dead biomass. The load of the dead material ranged from 13.3 t/ha to 47.0 t/ha and the load of the live fuel material was within the range 1.60 kg/m2 - 2.08 kg/m2. The density of the crown was also higher and equal to 0.354 kg/m2. The moisture content of the live leaves branches and dead material for Austrian pine and beech stands was relatively low in comparison with those for the other tree species.

***Keywords**: forest fuels, fuel type, fire behaviour prediction*

Introduction

Numerous forest fire studies report relationships between fire behaviour, fire suppression and their dependence on the forest fuels (Burgan and Rothermel, 1984; Fryer and Johnson, 1988; Burgan *et al*., 1998; Chuvieco *et al*., 1999; Arroyo *et al*., 2006). The rationale for using vegetation characteristics to classify fuels is that fuels are ultimately derived from vegetation. The increase in density and surface and canopy fuels has enhanced the risk of high-severity fires (Miller *et al*., 2009, 2012; Taylor *et al*., 2014). The fuel type classifications are usually based on the vegetative characteristics of a particular site or location. Fire behaviour fuel models are used as input to the Rothermel´s (Rothermel, 1972) fire spread model, which is used in a variety of fire behaviour modelling systems. Different kinds of fuel models are used in fire science (Rothermel, 1972; Albini, 1976; Anderson 1982). The variation in predicted spread rate among models is attributed to fuel load by size class (0 to 0.64 cm, 0.64 to 2.54 cm, and 2.54 cm to 7.62 cm diameter), fuel-bed depth, and fuel particle size, surface-area-to-volume (SAV) ratio by component. Later, the fuel particle heat content was included as a fuel model parameter for the BEHAVE fire behaviour prediction (Andrews, 1986; Burgan and Rothermel, 1984), FARSITE (Finney, 1998) and BehavePlus (Andrews *et al*., 2003) models. It should be mentioned that Albini's fuel models specified an extinction moisture content value for each fuel model, whereas this parameter was held constant for Rothermel's fuel models. The fuel moisture was considered for distinguishing the two major groups of fuel models: live and dead. The 1-, 10-, 100-, and 1000-h time-lag classes represent the dead fuels (Cohen and Deeming, 1982). The live fuels are further classified into herbaceous and woody shrub.
FARSITE (Fire Area Simulator) model developed by Finney (1998), includes both type of models - for crown fire behaviour as well as surface fuel models and therefore require information of crown fuel

parameters such as percentage canopy cover, canopy height, crown base height and crown bulk density. The next fuel models in the USA paid attention on the fuel beds and their classification according to the capacity to support fire and consume fuels (Sandberg *et al*., 2001; Ottmar *et al*., 2007). The fuel classification system called Prometheus has been adapted for Mediterranean conditions (Arroyo *et al*., 2006). The main criterion of classification in this system is the type and height of the propagation element divided into three major groups: grass, shrubs or ground litter and trees. The main approach of the BEHAVE system was applied for developing the other systems, such as the CARDIN system in Spain (Caballero *et al*., 1994) and for development of general fuel models for some regions in Greece (Dimitrakopoulos *et al*., 1999, Dimitrakopoulos *et al*., 2001) and photo keys (ICONA 1990) for different environments. Knowledge of the spatial distribution of fuel types is also essential for implementation of the fire models predicting fire behaviour, severity and spread.
In this paper, we examine the most commonly used fuel classifications systems currently employed worldwide and the associated methods for generating a fuel type classification. Based on the analysis of state-of-the-art and on the main advances achieved in different classification systems, a simple quantitative methodology for development of a fuel type model is presented.

Methods

Six sampling sites (SS) have been established in the western region of Bulgaria (Government Forestry Enterprises "Nevestino"), which is one of the most frequently affected by forest fires (Figure 1). The main tree species are *Fagus sylvatica L., Pinus sylvestris L., Pinus nigra Arn., Quercus cerris L., Quercus frainetto Ten.*. The main characteristics of the location and the stand's surface biomass parameters have been collected. At field conditions, the following parameters of the stands were measured: the crown cover, crown height, diameter at breast height (D.B.H.), height difference between surface and first tree branches. Information on the distribution of live and dead fuels in the pre-specified four size classes was obtained by separating all live and dead fuels in 1 m^2 plots and weighing them. The fine live biomass - leaves, twigs and branches less than 0.64 cm in diameter and thicker and live shrub biomass (if present at sampling sites) have been also collected. The dead woody fuel loading was measured collecting the material from 50 cm x 50 cm square plots in three replications at each sampling site. The material was divided into classes characterizing the drying rates of the various fuel particles, so called 1-, 10-, 100- and 1000 h time lag fuels. The fuel load values for collected size classes for live biomass and dead material were determined.
The moisture content of the various elements of the fuel complexes (live needles and leaves, woody shrub stems, ground litter, duff, etc.) was also determined by collecting samples from the sampling sites, weighing them, oven-drying them for 48 hours at 1050C, and weighing them again. This information was used to adjust all measured weights in the sample plots to oven-dry fuel loadings.

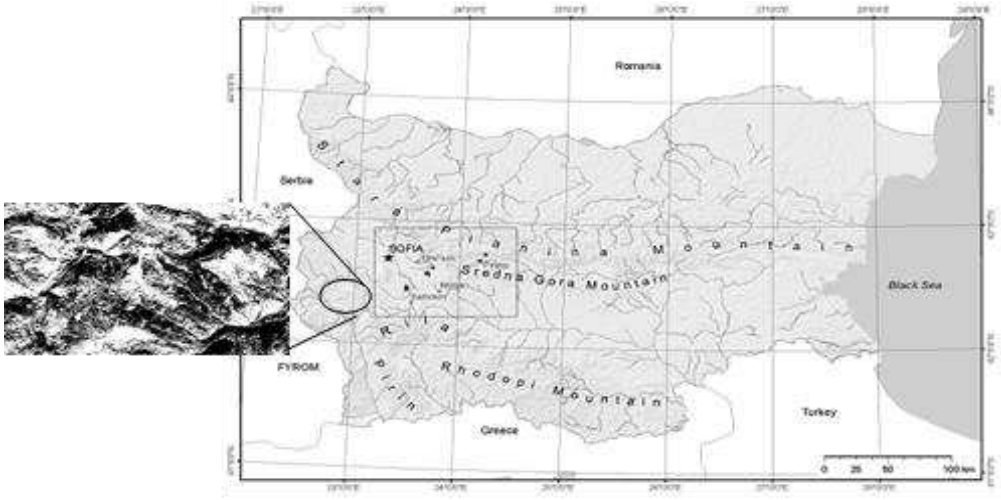

Figure 1. Legend of figure 1

Results

For the current investigation, the live fuel load (LFL) in the tree crown was determined as the weight of the lives/needles for the unit horizontal area (in kg/m2). The calculation was performed using equations 1, 2 and 3. The diameter at breast height (D.B.H.) of all trees from the sampling plot was used.

For Austrian pine: $CrFL = 1.324 - 0.13dbh + 0.025dbh^2$ (1)

for Scots pine: $CrFL = 0.023dbh^{1.802}$ (2)

where *CrFL* [kg] is the weight of crown fuel material of a tree with diameter at breast height (dbh).

$$CFL = \frac{\sum_{i=1}^{n} CrFL}{PP}\left[kg/m^2\right] \quad (3),$$

where *CFL* is the quantity of the fuel material of the continuous canopy (in kg/m^2), represented as the sum of the quantities for all separated trees on the territory of the studied sampling site, divided by its area *PP* (m^2).

The fuel load for live biomass of the deciduous forest was not determined, as its role in crown forest fires is negligible. The quantity of the fuel load of the dead material is important in case of surface fires in coniferous and deciduous forests. The highest fuel load of live biomass was found for Austrian pine stands – from 1.60 kg/m^2 to 2.08 kg/m^2 (Table 1).

Besides the fuel load, the moisture content of the various fuel materials was determined (Figures 2, 3).

Table 1. Crown fuel characteristics

SS	Main tree species	Crown fuel (leaves and twigs) (kg/m^2)	Height of crown (m)	Crown fuel density (kg/m^2)
SS1	Beech			
SS2	Scots pine	1.04	10.54	0.188
SS3	Austrian pine	2.08	12.50	0.354
SS4	Oak			
SS5	Austrian pine	1.17	11.96	0.147
SS6	Austrian pine	1.60	8.02	0.294

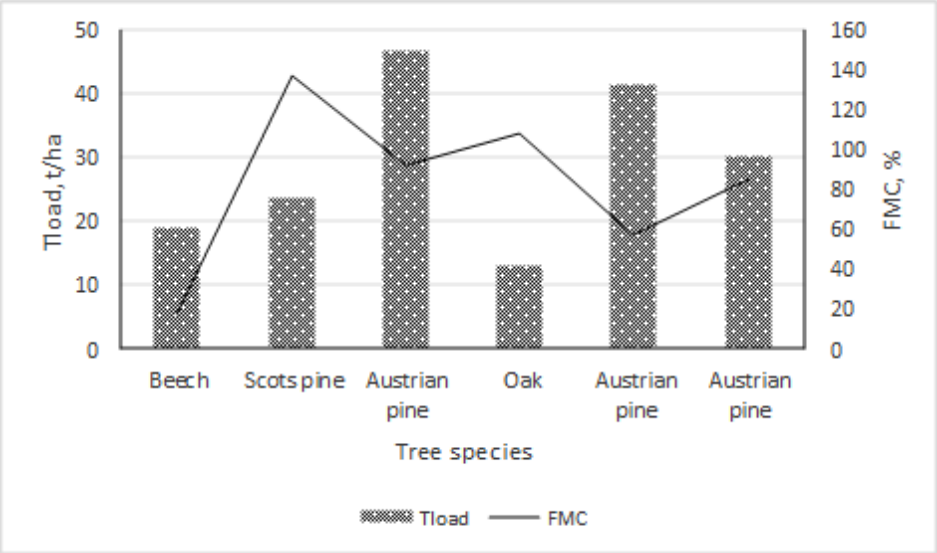

Figure 2. Fuel characteristics of sampling sites (Tload – total load; FMC – Fuel moisture content, %).

The most important variable of interest for the analysis is the total fuel loading (TLOAD), for each location. For our purpose, TLOAD represents the sum of litter load (LL), 1-hr dead woody fuel, 10-hr dead woody fuel, 100-hr dead woody fuel, cones, and bark. Similar to the load of the live biomass, the highest TLOAD was found for Austrian pine stands – from 30.0 t/ha to 47.0 t/ha (Figure 2).
Fuel moisture affects ignition by absorbing energy when being vaporized, and by diluting flammable volatiles, which increases the ignition delay time. Moist fuels reduce to less intense fires in contrast to the dry fuels that burn more fiercely (Van Wagner, 1967; Catchpole and Catchpole, 1991).

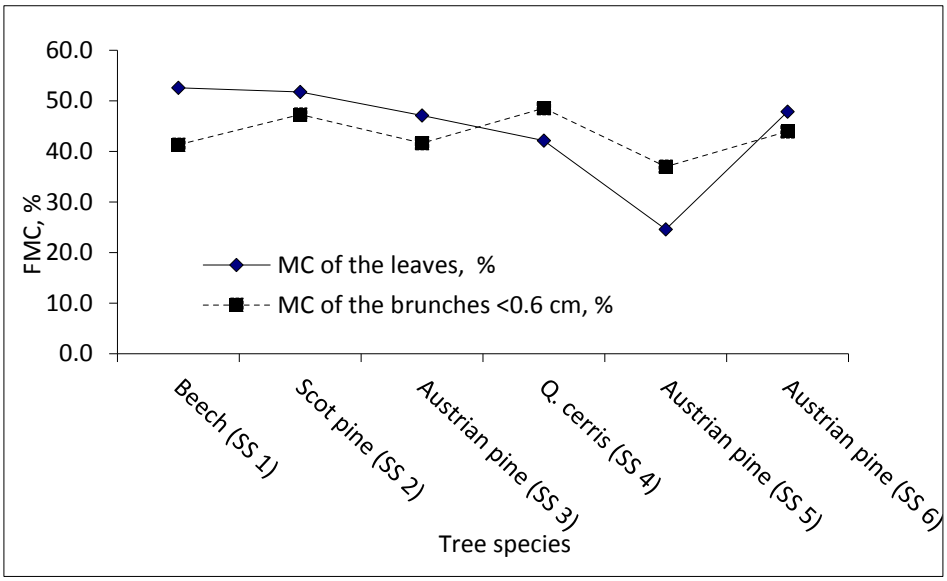

Figure 3. Moisture content (MC) of the live fuel load.

The experimental results show that the FMC of the live leaves/needles and brunches varies from 24. 6% to 52,6 %. Based on the definition of the moisture of extinction (ME) (32% of plant fresh weight), in could be noted that very flammable is the plantation of the Austrian pine from SS 5, as its moisture content was less than 25% (Figure 3). The MC of the brunches changes within narrower limits.

Conclusions

The results obtained clearly show that Black Pine stands are characterised by a higher fuel load concerning both – live and dead biomass. The load of the dead material ranged from 13.3 t/ha to 47.0 t/ha and the load of the live fuel material was in the range 1.60 kg/m2 - 2.08 kg/m2. The density of the crown was also higher and equal to 0.354 kg/m2. The moisture content of the live leaves branches and dead material for Black pine and beech stands was relatively low in comparison with those for the other tree species.

Abstract
The spatial distribution, structure, and environmental conditions of the fuels are key variables in wildland fire behavior and effects. This study developed environmental scenarios, based on global weather information and topography, in order to calculate surface fire behaviour parameters using the Fuel Characteristic Classification System and a global fuel map previously developed.
The results show the geographic variation in monthly mean wind speeds and fuel moisture content for the months of January and July and for the period 1981-2010. Also, the worst monthly conditions were evaluated, corresponding to the maximum monthly wind speeds and minimum fuel moisture content. From these environmental scenarios, the rate of spread for the global fuels was mapped, obtaining more realistic results than in the past.

Keywords*: Fire risk, FCCS, global fuel map, fire behavior, ECMWF*

Introduction

Surface fire behaviour is dependent on the available fuels and also on the environmental conditions when the fire occurs. Specifically, fuel moisture, slope and wind speed affect the speed in which fire spreads, and the energy released by it (Rothermel 1983). The different fire behaviour systems that are currently widely used, such as BehavePlus (Andrews *et al.* 2008), the National Fire Danger Rating System (Cohen and Deeming 1985), the Canadian Fire behaviour prediction (Stocks *et al.* 1989), the Fuel Characteristic Classification System (Ottmar *et al.* 2007), etc., include these environmental conditions in the calculation of the surface fire parameters.

The Fuel Characteristic Classification System (FCCS) (Ottmar *et al.* 2007) was designed to represent the structural and geographic diversity in wildland fuels, and combines the fuel properties into "fuelbeds", which include the physical and chemical variables used to model fire behavior and fuel consumption, and predict emissions (Riccardi *et al.* 2007). FCCS uses fuel characteristics (e.g. percentage cover, loading, depth) to calculate and report nine fire potentials, organised into three categories: surface fire behaviour potential, crown fire potential and available fuel potential (Sandberg *et al.* 2007a). Also, based on input environmental variables, the FCCS also predicts surface fire behaviour parameters using a reformulation of the Rothermel (1972) fire behaviour model (Sandberg *et al.* 2007b).

During previous work developing fuel maps using FCCS (Pettinari *et al.* 2013a; Pettinari *et al.* 2013b), default environmental parameters were used to estimate fire potentials and surface fire behaviour such as rate of spread, flame length, and reaction intensity. The use of a defined set of environmental conditions allowed the comparison of the different fuelbeds based solely on their intrinsic characteristics, but they did not reflect the variations of weather conditions around the world, which influence fire behaviour. In this study we focused on improving the fire behavior results by means of applying more realistic environmental conditions to the different regions of the world.

Methods

To run FCCS, it is necessary to select the fuelbeds that will be included in the calculations, and also the environmental variables that affect fire behaviour. These environmental conditions are: fuel moisture content (FMC) for different fuel classes, wind speed and slope. The required FMCs are: 1-, 10- and 100-h dead fuel moisture, and live-herb, live-shrub and live-crown moistures. The FMCs can be input as individual FMCs, or a Fuel Moisture Scenario (FMS) can be used. The 16 combinations of the Scott and Burgan (2005) dead and live FMSs are already input as selectable FMSs. Terrain slope is input in units of % slope, and wind speed is input in units of miles per hour (mph).
For the purpose of this study, we selected FMSs from the existing ones in FCCS according to their dead 10-h FMC, and we created slope and wind scenarios to reflect the influence of these variables in surface fire behaviour. All the calculations were done using FCCS version 3.0 module inside the Fuel and Fire Tools (http://www.fs.fed.us/pnw/fera/fft/index.shtml, accessed June 2014) version 3.03.203.
The climatic data was extracted from the European Centre for Medium-Range Weather Forecast (ECMWF). We used the ERA-Interim Global Reanalysis (Dee *et al.* 2011) because it includes all the climatic variables required to calculate the environmental variables for the FCCS run, and it is the latest release of the ECMWF reanalyses. The data covers a 30-year period, from 1981 until 2010, and was rescaled from the original 0.75º grid to a 0.50º grid covering the whole globe directly at the ECMWF Data Server. ERA-Interim provides daily forecast information for 8 hours UTC (time steps): 0, 3, 6, 9, 12, 15, 18 and 21 hr. Since the lowest fuel moisture content usually occurs at early afternoon, the globe was divided in 8 strips of 45º longitude, each one including information of local solar time (LST) between 12 hr. (in the western part of the strip) and 15 hr. (in the eastern part of the strip). For example, the data of UTC 15:00 was used for the strip extending between 45º and 90º, and that information represents weather conditions at 12 hr for the longitude 45º, 13 hr. for latitude 60º, 14 hr. for latitude 75º and 15 hr. for latitude 90º. Table 1 summarises the climatic variables used for this study and their characteristics.

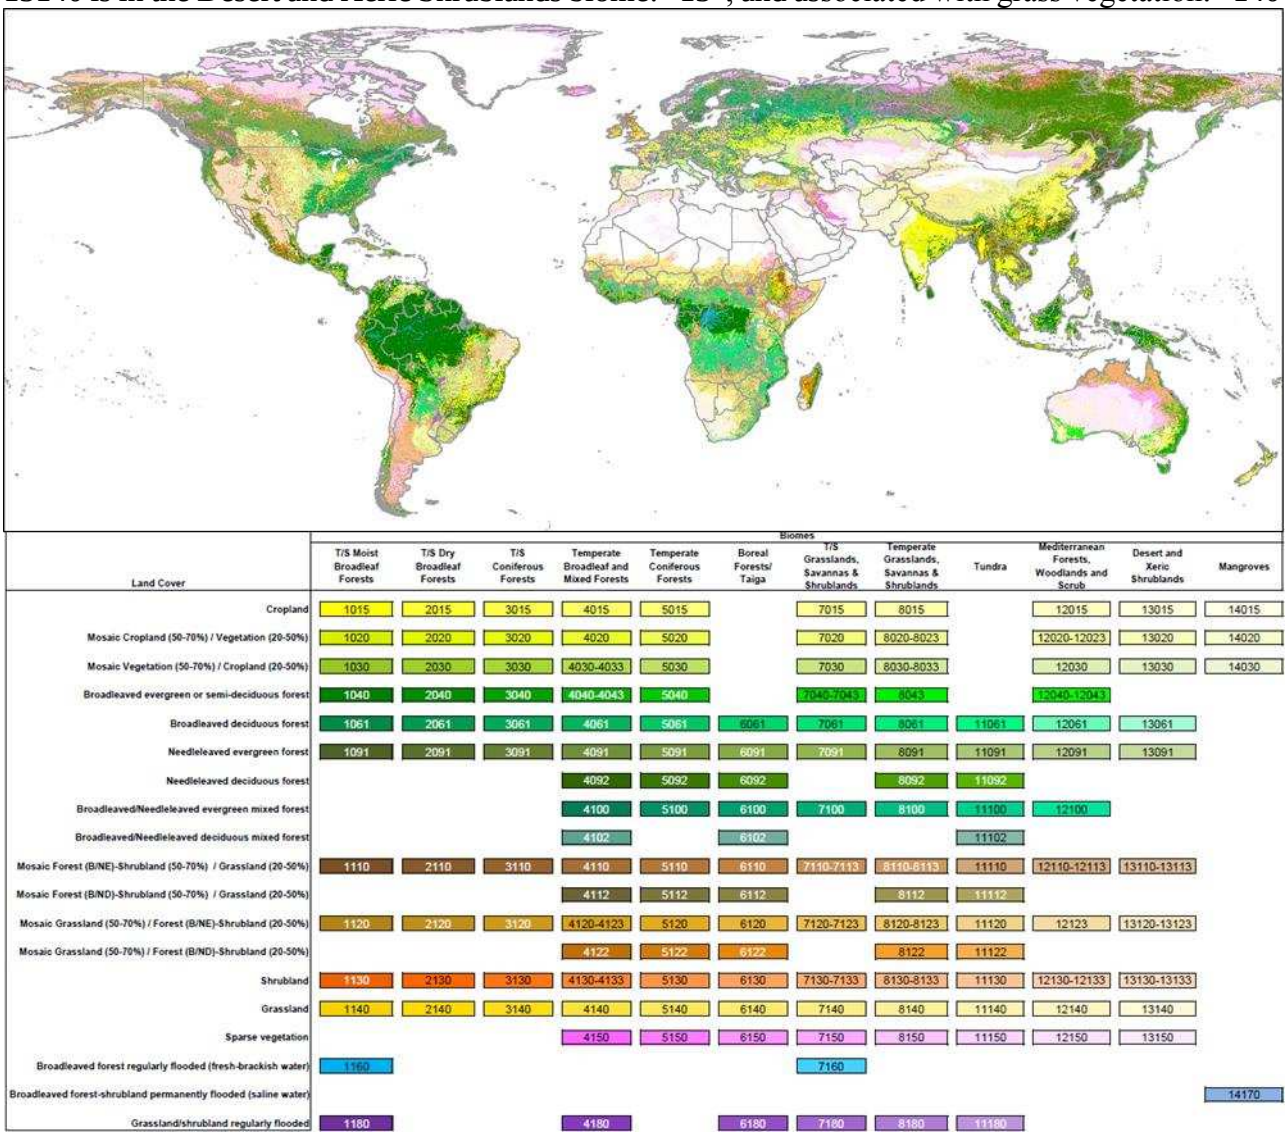
Table 1. Climatic variables from the ERA-Interim Reanalysis used for this study

Variable Name	Variable Code	Units	Type of Level	Stream	Other information
10 m Wind Speed	207	m s^{-1}	Surface	Synoptic Monthly Mean	Produced by forecast. Monthly average at time step.
Total Cloud Cover	164	Fraction of cover (0-1)	Surface	Daily	Produced by forecast. Instantaneous at time step.
Snow Depth	141	m of water equivalent	Surface	Daily	Produced by forecast. Instantaneous at time step.
Total Precipitation	228	m of water	Surface	Daily	Produced by forecast. Accumulated from the previous 24 hr.
2 meter Dew Point	168	ºK	Surface	Daily	Produced by forecast. Instantaneous at time step.
2 meter Temperature	167	ºK	Surface	Daily	Produced by forecast. Instantaneous at time step.

2.1. Fuel map

The fuel distribution and their physical and chemical variables related to fire behaviour were extracted from the Global Fuelbed Map developed by Pettinari and Chuvieco (2013a). This map is based on vegetation data provided by the GlobCover V2.2 product (Bicheron *et al.* 2008), and has a spatial resolution of 10 arc seconds (~300 m at the Equator). Its legend was defined using the Land Cover Classification System (Di Gregorio 2005). The land cover information was sub-divided using the biomes described in the Map of Terrestrial Ecoregions (Olson *et al.* 2001), in order to account for differences in vegetation characteristics due to the influence of climate. This map (see Fig 1) has a total of 166 Fuelbeds, some of them subdivided according to their percentage of canopy cover. Each

fuelbed is identified by a number, where the thousands value corresponds to the biome, and the following three values identify the land cover type associated with each pixel. For example, fuelbed 13140 is in the Desert and Xeric Shrublands biome: "13", and associated with grass vegetation: "140".



Land Cover	T/S Moist Broadleaf Forests	T/S Dry Broadleaf Forests	T/S Coniferous Forests	Temperate Broadleaf and Mixed Forests	Temperate Coniferous Forests	Boreal Forests/ Taiga	T/S Grasslands, Savannas & Shrublands	Temperate Grasslands, Savannas & Shrublands	Tundra	Mediterranean Forests, Woodlands and Scrub	Desert and Xeric Shrublands	Mangroves

Figure 1. Global fuel map. The table legend lists the 166 fuelbeds developed. B: Broadleaf, NE: Needleleaf Evergreen, ND: Needleleaf Deciduous.

Each fuelbed has several structural, physical and chemical parameters, necessary to run FCCS. These parameters were extracted from global products based on remote sensing when possible, or from existing databases. The percentage of tree cover was extracted from the MODIS Vegetation Continuous Field, Collection 5, product (Carroll *et al.* 2011), and canopy height was derived from the map developed by Simard *et al*. (2011). For each fuelbed, the mean value of these variables was used. Representative tree, shrub and grass species were assigned based on the description of the ecoregions of the World Wildlife Fund Ecoregions' database (http://worldwildlife.org/science/wildfinder/, accessed June 2014). The remaining variables for each fuelbed (canopy height to live crown (HLC), tree density, diameter at breast height (DBH), the presence or absence of ladder fuels, shrub height, grass height and load, dead woody fuels cover and depth, fuel loads by size class of dead woody fuels, and litter and duff cover and depth) were assigned selecting the most similar fuelbeds from the ones in the FCCS database or from the Natural Fuels Photo Series from Mexico and Brazil (Ottmar *et al.* 2001; Morfín-Ríos *et al.* 2008).

Slope

Percentage slope was calculated using the GTOPO30 product, which is a global digital elevation model with a horizontal grid spacing of 30 arc seconds (approximately 1 kilometre at the Equator), developed by the United States Geological Survey (USGS) - EROS Data Center (https://lta.cr.usgs.gov/GTOPO30, accessed June 2014).

Three slope classes were established with the following criteria (see Figure 2):

- Slope class 1: 0% slope (for slope ranges between 0 - 5%)
- Slope class 2: 30% slope (for slope ranges between 5 - 45%)
- Slope class 3: 70% slope (for slopes higher than 45%)

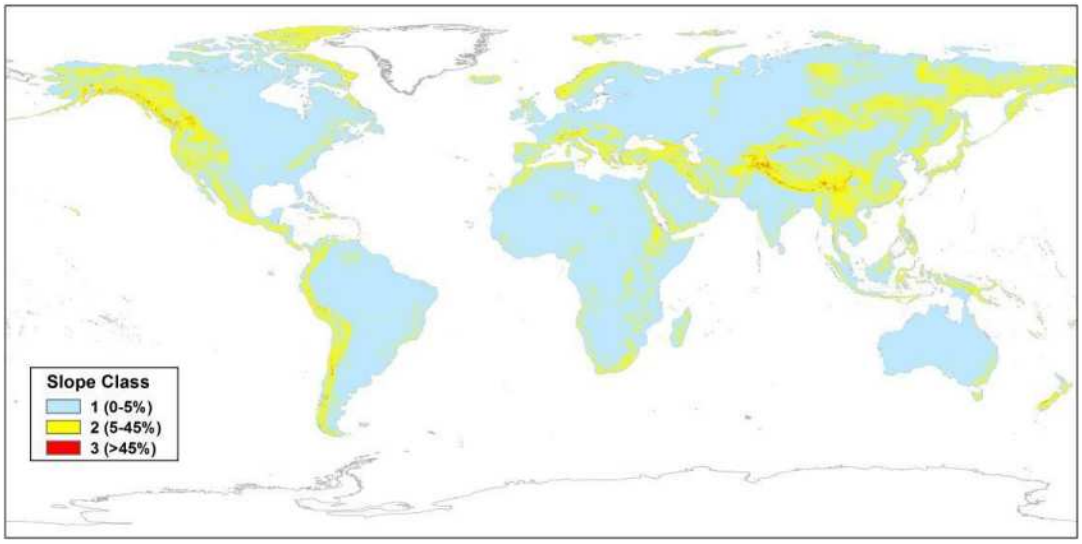

Figure 2. Slope classes derived from GTOPO30.

Wind Speed

The wind speed data was downloaded from the ECMWF Data Server directly as a monthly mean wind speed for each time step. The mean value of wind speed for each month within the 30-year period was calculated, and also the maximum monthly wind speed was identified.

The wind data correspond to 10 m winds, but the FCCS input requires the midflame wind speed, which is the average wind velocity that affects surface fire spread, and is usually referred as to the velocity of the wind taken at the mid-height of the flames. To convert from 10 m to midflame wind speed, a wind adjustment factor (WAF) is used. This WAF is dependent on the sheltering from overstory vegetation above the fire, and take values from 0.6 (for unsheltered fuels) to 0.1 (for sheltered fuels), based on 6.01 m (20-ft) wind speeds (Andrews 2012). For this study, a general intermediate WAF of 0.4 for 20-ft winds was used, which corresponds to 0.348 for 10-m winds (Turner and Lawson 1978).

As with the slope, three wind speed classes were established, to account for the contribution of wind speeds to fire spread:

- Class 1: 0 – 1.0 m/seg (0 – 2.24 mph). Assigned to 1.0 mph in FCCS.
- Class 2: 1.0 – 2.5 m/seg (2.24 – 5.59 mph). Assigned to 4 mph in FCCS.
- Class 3: 2.5 – 5 m/seg (5.59 – 11.18 mph). Assigned to 7 mph in FCCS.

2.4. Fuel Moisture Content

Four FMSs were selected to represent different moisture conditions, based on their 10-hr fuel moisture content. They combine Scott and Burgan's Dead Fuel Moisture Scenario (DFMS) and Live Fuel Moisture Scenario (LFMS). Their FMCs are described in Table 2.

Table 2. FMCs of different fuel classed assigned to each FMS. Extracted from the FMS table inside FFT

FMS Code	FMS description	Herb	Shrub	Crown	1-hr	10-hr	100-hr
D1L1	Very low dead, fully cured herb	30	60	60	3	4	5
D2L2	Low dead, 2/3 cured herb	60	90	60	6	7	8
D3L3	Moderate dead, 1/3 cured herb	90	120	120	9	10	11
D4L4	High dead, fully green herb	120	150	150	12	13	14

The 10-hr FMC was calculated using the equations formulated for the National Fire-Danger Rating System (Cohen and Deeming 1985). Relative humidity was calculated from temperature and dew point using the formulas described in Wanielista *et al*. (1997), because there were not data for relative humidity in ERA-Interim for the 8 time steps. Cloud cover data was converted to the State of Weather code (SoW), which was in turn used to adjust the temperature and humidity values. The 10-hr FMC was calculated daily for each month and for the 30-year period. Wet fuel conditions were assigned for a day when the snow depth was higher than 0 m of water equivalent, or if the total precipitation in the previous 24 hr was higher than 0.01 m. In that case, the 10-hr FMC was assigned to 35%.

From the daily 10-hr FMC, monthly mean values were computed, and from those, the monthly mean value for the 30-year period was obtained, and also the minimum monthly mean value was identified. 10-hr FMC was converted to FMS according to the following classification:

- D1L1: 10-hr FMC < 5.5%.
- D2L2: 5.5% < 10-hr FMC < 8.5%.
- D3L3: 8.5% < 10-hr FMC < 11.5%.
- D4L4: 10-hr FMC > 11.5%.

Results and discussion

Figure 3 shows the wind speed classes for January and July, for both the mean monthly conditions and the worst monthly conditions, corresponding to the maximum monthly wind speeds in the 30-year period. The highest mean monthly wind speed values during July are found in the Horn of Africa, where the maximum value is 4.6 m/seg for the mean monthly values, and 5.6 m/seg for the worst year. During January, the highest mean monthly wind values are found in the coast of southern Argentina and Chile, the Great Lakes, the coasts of the United Kingdom, a region in northern Siberia and the Borkou region in Chad. The maximum mean monthly value is 4.15 m/seg, and during the worst monthly conditions the maximum value is 5.18 m/seg.

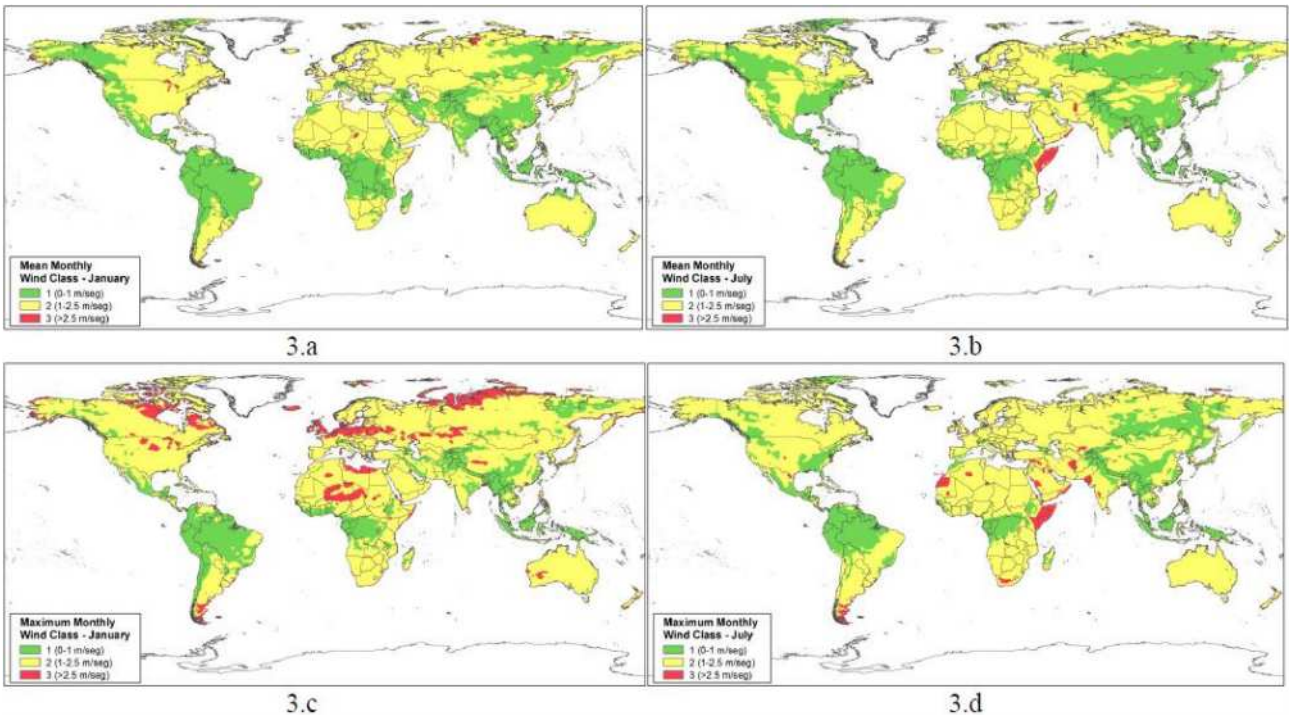

Figure 3. Wind classes calculated for the 1981-2010 period. 3.a: Mean January wind class; 3.b: Mean July wind class; 3.c: Maximum January wind class; 3.d: Maximum July wind class.

Wind speed varies greatly, even at very short time scales (seconds to minutes), and is also influenced by topography, vegetative sheltering, local heating or cooling, and surface friction (Rothermel 1983). The use of different wind classes does not intend to predict wind conditions for a particular moment or point in space, but to identify general regions and time periods where and when faster winds could occur compared with other parts of the world or seasons, and hence more severe surface fire behaviour could be expected.

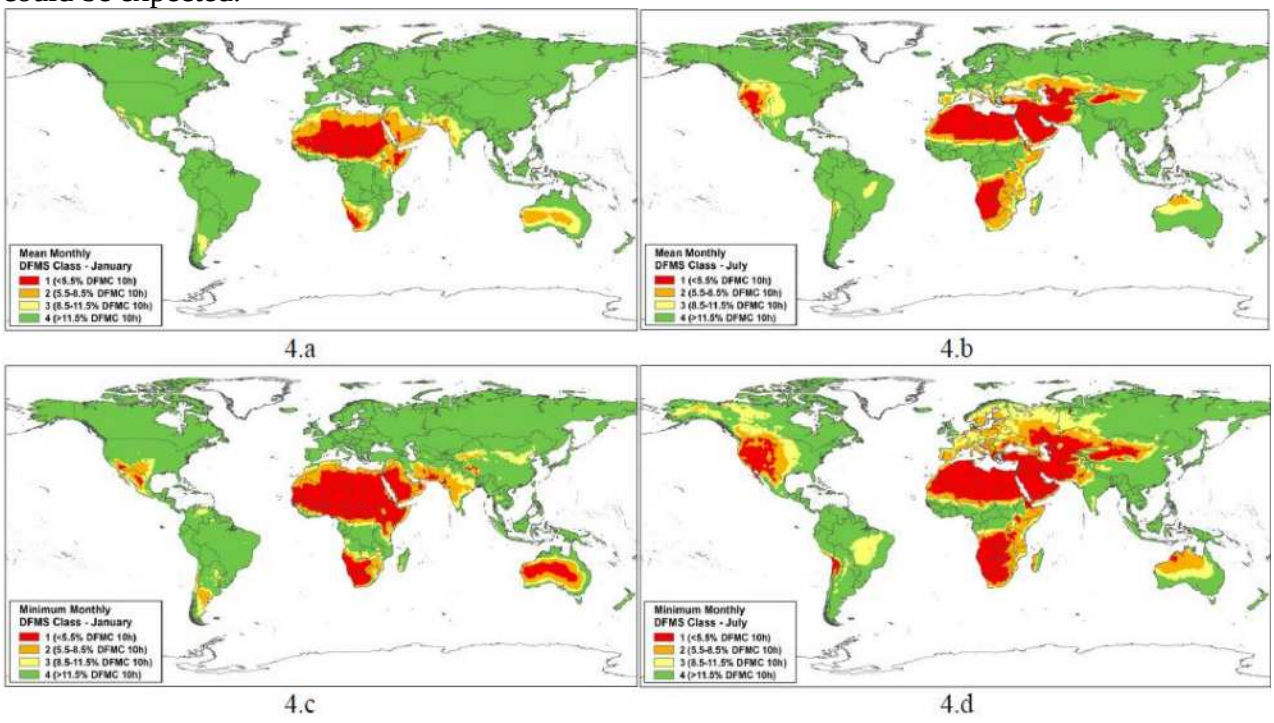

Figure 4. Dead Fuel Moisture Scenario calculated for the 1981-2010 period. 4.a: Mean January DFMS; 4.b: Mean July DFMS; 4.c: Minimum January DFMS; 4.d: Minimum July DFMS.

The result of the calculation of the 10-hr FMC, which determined the assignation of a Dead Fuel Moisture Scenario (DFMS), is shown in Figure 4. This figure includes the DFMS for January and July, for both the mean monthly conditions and the worst monthly conditions, corresponding to the minimum monthly FMC found in the 30-year period. During January, the highest latitudes of the northern hemisphere are covered in snow, and hence are considered to have wet fuels, and a FMS of D4L4. On the other hand, January means summer for the southern hemisphere, and higher temperatures determine lower FMCs in regions such as Australia and Patagonia. During July, the tropical rain belt is located in the northern hemisphere, and the tropics below the Equator have a dry season, which causes the fuel moisture content to be lower compared to January. This process is particularly noticeable in the southern African savannahs and in the Brazilian cerrados. On the contrary, during January the savannahs above the Equator are drier than during July, due to the shift of the tropical rain belt to the southern hemisphere.

The use of longitude strips derived in brusque changes in weather conditions along the borders of the strips, where at the west of the border the weather data corresponds to 15 hr. LST, while at the east it corresponds to 12 hr. LST. Although in most of the borders that situation did not produce differences in the wind or DFMS classes, it did in some cases, most prominently at longitude 0º in Northern Africa. But since that region is mostly desert, and has few vegetation, it did not cause an important effect in the resulting fire behaviour results.

The combination of the 4 possible FMSs, the 3 wind classes, and the 3 slope classes, produced a total of 36 different environmental conditions, which were used to run FCCS with the exiting fuelbeds. The environmental scenarios are classified as D(a)L(a)W(b)S(c), being a the FMS, b the wind class, and c the slope class. As an example, an environmental scenario of D2L2W1S3 would mean a FMS of 2, a wind class of 1 and a slope class of 3.

For the purpose of showing the differences in fire behaviour due to changing environmental conditions, Figure 5 show the rate of spread values obtained for January and July, during the mean and worst monthly conditions.

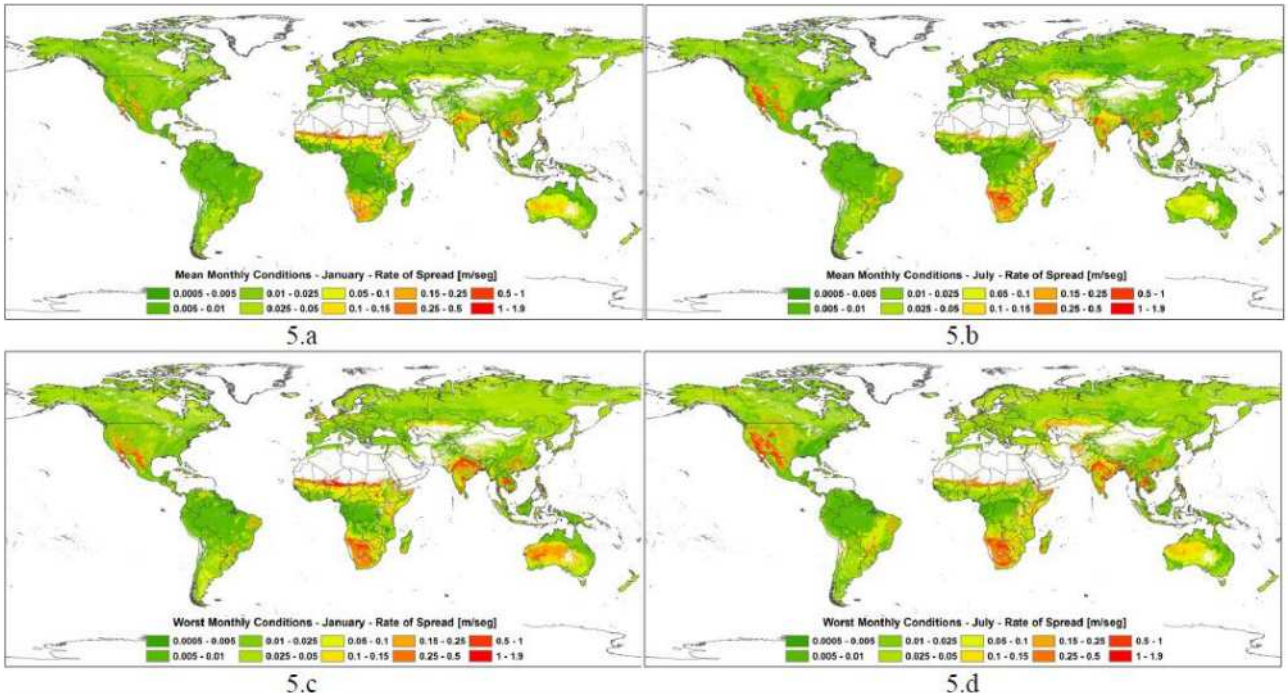

Figure 5. Rate of spread calculated for the global fuelbeds using the environmental conditions detailed in the legend of the maps.

The highest ROS values in Figure 5 (higher than 1 m/seg) belong to fuelbeds associated with grasslands (fuelbed numbers finishing in 140 or 180) and croplands (fuelbeds finishing in 015). The highest ROS correspond to rice croplands in tropical regions (fuelbeds 1015, 2015 and 14015), and vary in their value depending on the environmental conditions. The highest mean value for January is 1.63 m/seg, obtained for an environmental scenario D4L4W3S3. For the mean conditions in July, as well as the worst conditions in January, the highest value is 1.83 m/seg, for an environmental scenario D1L1W2S3. In the worst July conditions, the highest ROS value is 1.88 m/seg, but with an environmental scenario D2L2W3S2. These results indicate the prominent influence of wind on the rate of spread, as specified by the Rothermel's (1972) equations used in FCCS and in other fire behaviour systems such as BehavePlus (Andrews *et al.* 2008) or FARSITE (Finney 2004).
The results of the rate of spread show the variation with the different environmental conditions in different seasons, as exemplified for January and July. This is particularly evident in the North American and Australian deserts, as well as in the African savannahs. The comparisons between the mean and worst monthly conditions also reflect the inter-year variability of the weather conditions, and should be taken into account when evaluating possible fire behaviour results. The existence of extreme weather seasons can significantly increase the surface fire behaviour, as shown in Figs 5.b and 5.d regarding the Brazilian Cerrado, or Figs. 5.a and 5.c in Africa.

Conclusion

This study developed environmental scenarios, based on global weather information and topography, in order to calculate the surface rate of spread using the Fuel Characteristic Classification System and a global fuel map previously developed. The results shown correspond to the months of January and July, in order to illustrate the temporal variability of the environmental conditions in different geographic regions. These results allowed obtaining more realistic results than in the past, where only one set of environmental conditions had been used for the whole globe.
Still, these are preliminary results, and further refinement is needed. Future research will focus on improving the weather data to eliminate brusque changes in weather conditions along some longitudes, incorporating live fuel moisture scenarios to increase the environmental variability, and calculating other fire behaviour parameters.

Abstract
It is known that the weather conditions can greatly affect the frequency of forest fires and their behaviour and thus the size of the burned area. Besides the wind, the instability of the atmosphere also affects the fire behaviour and that kind of fires are called "plume dominated". In the dry and unstable atmospheric environment fires are intensified and may behave abnormally. As a quantitative measure of the instability in the dry atmosphere and potential for large fire growth Haines Index is used. Higher value of Haines Index (or the class) means higher potential for fire growth. In this work performance of Haines Index was tested for the Adriatic area, part of Croatia with Mediterranean climate where forest fires are the most common and severe. The distribution of the low-elevation Haines Index calculated from upper air soundings was analyzed as well as relationship between Haines Index and forest fire number and burned area. Analysis was done particularly for Zadar region in summer fire seasons of 2011, 2012 and 2013. In all seasons the smallest percentage of high class of Haines Index was noticed, proportion which was desirable and expected. Surprise was a large proportion of moderate class, which stands out in comparison to the other classes. This result disagreed to the Haines Index statistics found in the literature. However, results showed an obvious connection between Haines Index and forest fires in Adriatic region, particularly Zadar area. In the majority of days of fire seasons the increase of class of Haines Index was related to the increase of number of fires and larger burned area. On average the largest number of fires and largest burned area were associated with the high class. The impact of high class of Haines Index to fire behaviour was pointed out the most when the three-day moving sums/averages were applied. Conclusion is that Haines Index can be used also in the Adriatic region of Croatia as an additional tool for issuing warnings on severe fire weather related to instability. However, there is some place for improvements and further research.

Keywords*: Adriatic, atmospheric instability, forest fire, Haines Index*

Introduction

It is known that the weather conditions can greatly affect the frequency of forest fires, their behaviour and thus the size of the burned area.
The instability of the atmosphere, besides the wind, also strongly affects the fire behaviour by generating covective plumes (columns). Forest fires are then denoted "plume dominated". In dry and very unstable atmosphere this kind of fires are intense due to development of stong indrafts with more oxygen entraining from the surrounding environment. Also they may behave abnormally showing high rates of spread, extensive spotting, crowning etc. As a quantitative measure of the instability of the dry atmosphere Haines Index is used.
In this work the performance of Haines Index was tested for the Adriatic area, part of Croatia with Mediterranean climate where forest fires are the most common and severe. Haines Index in Croatia has been used operationally since 2011.
The distribution of the Haines Index calculated from upper air soundings data at Zadar station was analyzed as well as its relationship with the forest fires in the surrounding area during the summer fire seasons.

Methods

The summer forest fire season in Croatia typically lasts from the beginning of June to the end of September. Fire seasons in 2011, 2012 and 2013 were considered and during this period all available forest fire data in the Zadar area were collected and analyzed. Also Haines Index data from the Zadar upper air soundings were calculated for the same period.

Haines Index

Haines Index is a simple index that is based on the vertical lapse rate in some layer of air as well as on moisture content in that layer as described by Haines (1988).
Haines Index is calculated from empirical relation:

$$\mathbf{HI=A(}T_p\mathbf{-}T_{p1}\mathbf{)+B(}T_p\mathbf{-}Td_p\mathbf{)},$$

where A is a function of temperature difference (lapse rate) between the levels of the atmospheric pressure *p* and *p1* and B is a function of a dewpoint depression at the level of pressure *p*. Haines Index is, therefore, the simple sum of stability term (A) and moisture term (B).
Because of the difference in altitudes of certain areas, three elevation variants of Haines Index are calculated: low variant (elevations below 500 m.a.s.l.), middle variant (elevations from 500 to 1500 m.a.s.l.) and high variant (elevations above 1500 m.a.s.l.). The layers *p* and *p1* are chosen considering ground elevation and also high enough above the ground to ignore the daily variability of surface temperature and surface temperature inversions. Depending on the upper level atmospheric conditions terms A and B may get values 1, 2, or 3 for each of the variants (Table 1), so Haines Index values between 2 and 6. Lower values are in thermally stable and more humid air and higher values in thermally unstable and drier air.

Table 1. Three elevation variants of Haines Index depending on the terrain elevation and upper level atmospheric conditions, i.e. lapse rate and dewpoint depression.

Lapse rate T_p-T_{p1}			
A	Low 950 - 850 hPa	Middle 850 - 700 hPa	High 700 - 500 hPa
1 2 3	<4 4 to 8 >=8	<6 6 to 11 >=11	<18 17 to 22 >=22
Dewpoint depression T_p-Td_p			
B	Low 850 hPa	Middle 850 hPa	High 700 hPa
1 2 3	<6 6 to 10 >=10	<6 6 to 13 >=13	<15 15 to 21 >=21

The relationship between Haines Index and potential for large forest fires growth or unpredictable behaviour is shown in Table 2.

Table 2. Classes of Haines Index. Values 2 and 3 of Haines Index are combined together in one class (very low).

Haines Index	Class (potential for large fire growth)
2 or 3	very low
4	low
5	moderate
6	high

Generally, Haines Index is designed in the way that low classes are expected most often and accompanied by low potential for large fire growth, while high class is expected rarely but accompanied by high potential for large fire growth. Some additional research on Haines Index can be found in Werth and Ochoa (1993).

In a preliminary analysis conducted in this work the low-elevation variant Haines Index was used because Zadar area has elevation mostly lower than 500 m.a.s.l. (higher mountains occupy smaller part in the north of the region). At this stage possibility of using a middle-elevation variant Haines Index for Zadar area was left for further examination.

Distribution of Haines Index, i.e. percentage of days of the fire season with different Haines Index values, and missing data were calculated for a whole range of soundings and separately for those at 00 and 12 UTC. Analysis is made for all three fire seasons and 122 days per season were taken into account. Also the analysis of stability and moisture terms was performed in the same way to investigate how the values of A and B were distributed and which of them contributed the most.

Forest fires and Haines Index

The available data on forest fires contained information about the location, date, starting time and duration of the fire and the size of burned area. Fire locations were chosen to be less than 100 km away from the station in Zadar. In that case upper air soundings were supposed to be valid for all chosen locations. The proximity condition was satisfied by the total of 930 forest fire cases in 244 days corresponding 21489 hectares of burned area (356 fires in 91days of the fire season 2011 wasted 6369 ha of vegetation, 402 fires in 88 days of fire season 2012 wasted 13206 ha and 172 fires in 65 days of fire season 2013 wasted 1914 ha). In the whole analyzed period there was no significant wind over the area of interest, so all forest fires cases were taken into consideration. It was considered also that a large number of this fires were "plume dominated", i.e. under the strong influence of the atmospheric instability. For fires lasting more than 2 days burned area was reduced by linear interpolation to the size which might burn in the first 36 hours. This time period was chosen arbitrarily but reasonably so that the reduced burned area could be associated with the Haines Index on the day of the occurrence of fire. Also different truncation times were tested but results showed no significant differences. However, it should be noted that there were just 16 long-lasting forest fires but the idea was not to exclude them.

The relationship between the number of fires in one day and the associated Haines Index at 00 and 12 UTC of the same day was analyzed using box plot statistical method, as well as relationship between total area burned in those fires and Haines Index. Days with missing Haines Index data were omitted. Identical procedure was done with moving sums of number and burned area of fires and the associated moving averages of Haines Index. The idea was not just to test the impact of atmospheric instability on forest fires in one day, but also to see how longer periods with unstable dry weather conditions impact forest fires. Different time (day) windows were used, but three-day forward oriented window seemed to be appropriate for moving sums and averages.

Results and conclusions

In all three forest fire seasons the smallest percentage of high class (value 6) of low-elevation Haines Index was noticed. Such a small proportion of high class was desirable and expected. Surprise was a large proportion of moderate class (value 5), which stands out in comparison to the other classes (Figure 1). This was the case for a whole data set and separately for sets at 00 and 12 UTC.

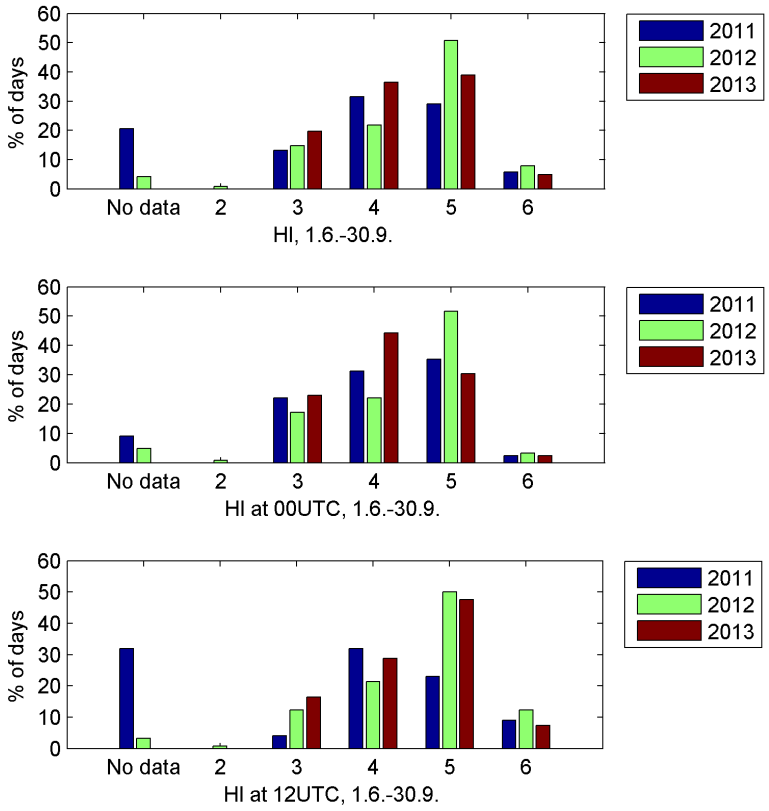

Figure 1. Distribution of Haines Index calculated from upper air soundings at Zadar station for three forest fire seasons. 12 UTC data set is shown in the lower plot, 00 UTC in the middle and a whole data set is in the upper plot. Missing data were also taken into account.

The resulting distribution of Haines Index did not match distributions found in the literature. The possible issue was strange distribution of the stability term A with too large proportion of value 3 (not shown). With a given distribution the performance of low-elevation variant Haines Index as a marker of severe fire weather conditions in the Zadar/Adriatic area may be reduced. But as already mentioned, the further plan is to test the middle-elevation variant in the calculation of Haines Index, in other words taking into account the effects of higher topography. Also a calibration of the original set up of Haines Index to the Mediterranean climate of the Adriatic can be carried out (particularly through tuning the thresholds of the stability term A) but this procedure requests for longer and more detailed data series of forest fires in the Adriatic region.

In any case there was an obvious relationship between Haines Index and forest fires in Adriatic region, particularly Zadar area. Haines Index at 12 UTC showed similar connection to the forest fires behaviour as Haines Index at 00 UTC but with a little bit better correlation, probably because daylight heating of land surface still had some small effect on instability in the upper levels.

In the majority of days of fire seasons the increase of the class of Haines Index was related to the increase of number of fires (Figure 2) and larger burned area (Figure 3).

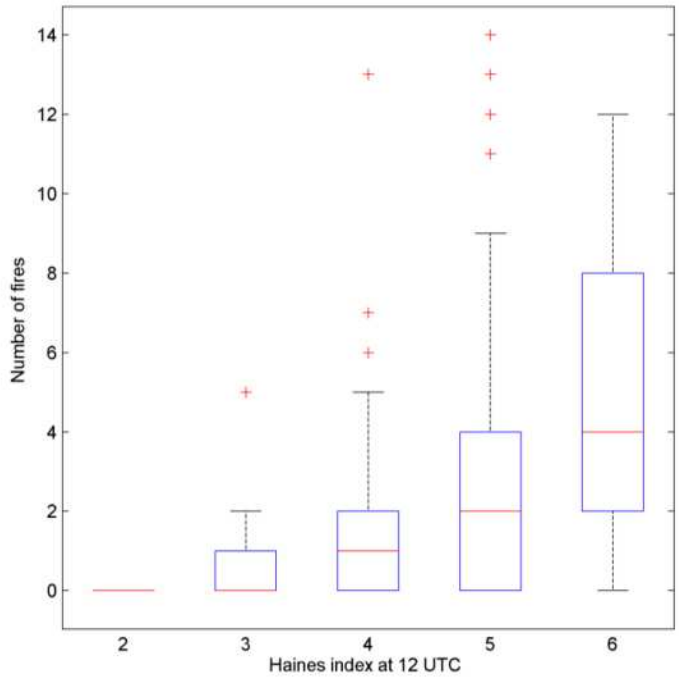

Figure 2. Box and whisker plot of the number of forest fires in one day against Haines Index class at 12 UTC same day. Red lines are medians, blue boxes represent interquartile range, black lines at the top of the whiskers are extremes and red pluses indicate outliers, i.e. cases not belonging to the set.

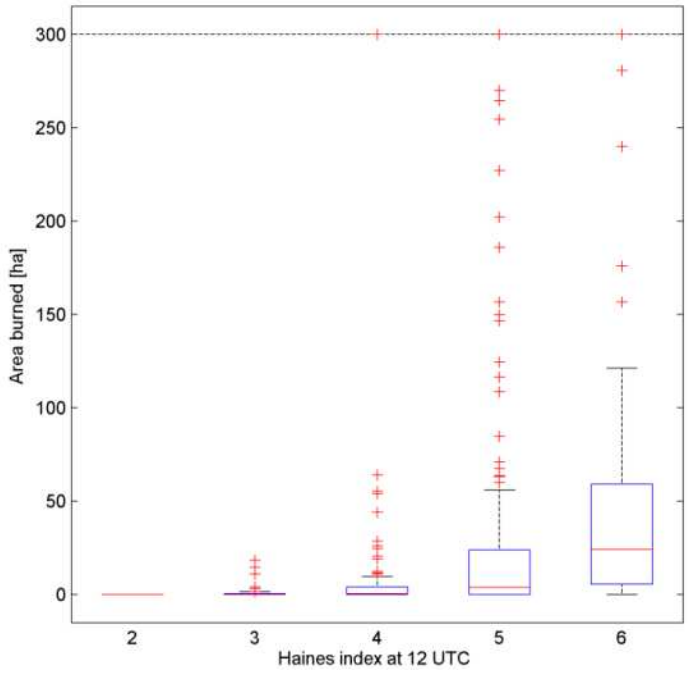

Figure 3. Same as Figure 2, but for an area burned in one day.

According to the results of box plot statistics the largest number of fires and the largest burned area were associated with the high class of Haines Index as seen in higher values of both median and upper quartile in comparison to moderate class and especially low classes. Despite the procedure of reducing size of long-lasting fires, there was still large number of outliers, especially for burned area. This could be explained by the fact the forest fires are not affected just by weather conditions but also by other factors, e.g. fuel availability, topographic characteristics, fire suppression efficiency and others.

The positive correlation of forest fires behaviour with the unstable dry air mass was even stronger when the three-day moving sums/averages were applied to the number of fires, burned area and associated Haines Index. Then the high class of Haines Index was pointed out the most as seen in Figures 4 and 5. Longer periods, in this case three consecutive days with unstable dry weather conditions had obviously strong impact on forest fire behaviour.

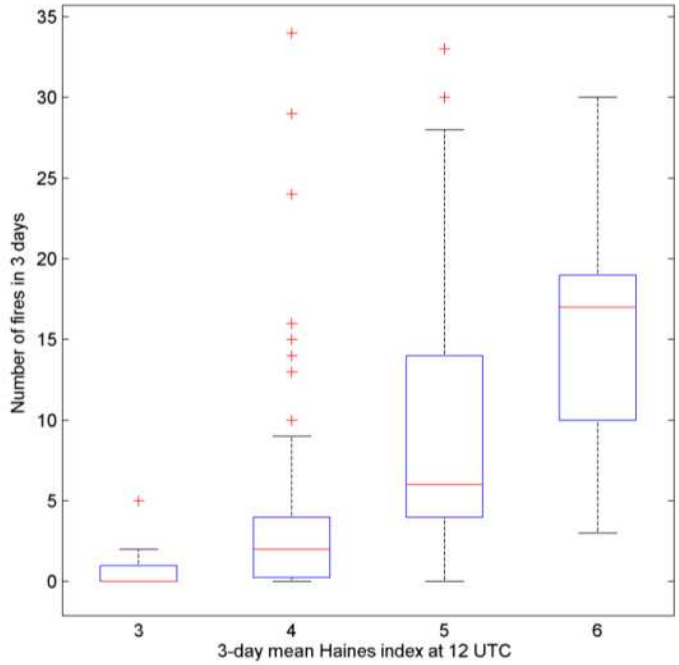

Figure 4. Box and whisker plot of a total number of forest fires in three days against three-day average of Haines Index classes at 12 UTC. Red lines are medians, blue boxes represent interquartile range, black lines at the top of the whiskers are extremes and red pluses indicate outliers, i.e. cases not belonging to the set.

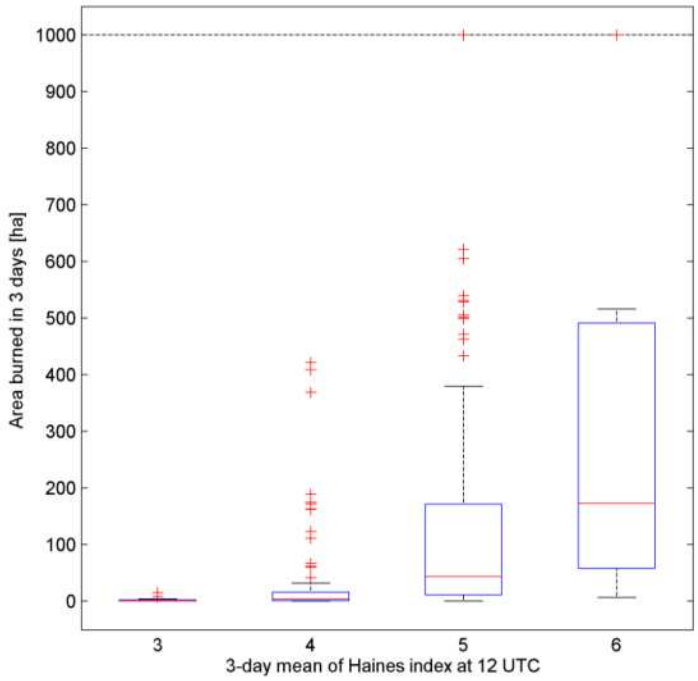

Figure 5. Same as Figure 4, but for a total area burned in three days.

Final conclusion is that the original set up of Haines Index can still be used in the Adriatic region of Croatia as an additional tool for issuing warnings on severe fire weather related to atmospheric instability. At least high class of Haines Index can be used what is currently the case in Croatia. However, as shown in this work, there is place for improvements and further research.

Acknowledgments

Authors thank to Robert Rozic from the National Protection and Rescue Directorate of Croatia (Fire Fighting Sector) on providing the data on forest fires, and to Lovro Kalin from Meteorological and Hydrological Service of Croatia on constructive comments.

Abstract
Forest fires are a global phenomenon due to the interaction between climate, fuels and human activities. Fires are also a critical component in the dynamics of planet earth and atmosphere. Recent advances in remote sensing products gathered via sensors on board satellites, have demonstrated the possibility of fire identification and monitoring on a global scale. The weather and climate are the major factors directly affecting fire and are being modified due to climate change caused mainly by man. There is an expectation of most researchers that changes in climate over the next 100 years will cause a major impact on forest ecosystems. The aim of this study was to determine, by decade, forest fire risk zoning for the State of Paraná, Brazil, based upon the scenarios predicted by the Intergovernmental Panel on Climate Change (IPCC) in 2007. Vegetation maps, fuel moisture, Monte Alegre Formula (FMA) for forest fire risk, slope, population density and road network, were used. These information, after being classified according to the risk of fire hazard, were weighted in a mathematical model. The determined values were then used to compose the Forest Fires Zoning Risk (ZRIF) per decade for the State of Paraná. Results showed that for the best scenario, which considers an increase of 1.8 ºC in the average temperature of the Earth by year 2100, there will be an increase in class extreme risk of forest fires, rising from 1.80% of the area of the State in 2020 to 8.49% in 2100. The same applies to the class of very high risk, which rises from 10.43% (2020) to 32.38% (2100). For the worst scenario, which considers an increase of 4.0 ºC in the average temperature of the Earth by 2100, the class of extreme risk rises from 2.18% (2020) to 22.72% (2100). The higher risk class rises from 13.93% (2020) to 55.95% (2100). It was concluded that, if the IPCC predictions were confirmed, there will be an increase in the number of occurrences and area affected by forest fires in the State of Paraná, which will require integrated actions to prevent and suppress forest fires to minimize environmental, social and economic damages.

Keywords*: forest fire risk, climate change, forest fire zoning risk, FMA fire risk*

Introduction

The effects of fire on the forests affect not only vegetation but also soil, fauna and atmosphere characteristics, and can be highly destructive when it is a forest fire. A fire occurs in the simultaneous presence of oxygen, fuel and heat source (Marques *et al*., 2011). According to the terminology of wildfires proposed by the Food and Agriculture Organization (FAO), "fire hazard" is defined as the probability of starting a fire due to the presence and activity of active causal agents. Also, "fire hazard" is used to express the degree of involvement of fixed and variables factors that determine the ease of ignition, rate of spread, difficulty of control and impact of fires, usually expressed as an index (FAO, 2007).
The assessment of the risk of forest fires is a critical part in fire prevention, since for pre-suppression planning and fire-fighting tools are needed to monitor when and where a fire can occur or when its effects will be more negative (Chuvieco *et al*., 2010).
Several factors may explain the ignition and spread of forest fires, such as: the characteristics of fuels, weather conditions, sources of ignition and topography. Fuel characteristics depend on the structure

and composition of vegetation, allied to anthropogenic factors (Marques *et al*., 2011). Another important ignition factor is the influence of human activities, which increase the risk of fire in the vicinity of road networks and urban areas (Cardille *et al*., 2001).

The risk of fires has been assessed by means of fixed and variable environment factors (e.g. fuels, weather and topography), that determine the ease of ignition, rate of spread, the difficulty of control, and the impact of forest fires (Vadrevu *et al*., 2010).

The importance of drawing up forest fire risk maps is evident for a long time (Show; Clarke, 1953). A very simple way to achieve a forest fire risk map is through the use of fire reports of previous years and plotting on a map the areas affected by fires. When there are multiple-year records, one can define a pattern for the areas of greatest occurrence and draw boundaries that define areas of risk (Brown; Davis, 1973; Chandler *et al*., 1983).

Several researchers have developed forest fires risk zones, using methods that allow to associate environmental factors with forest fires, allowing in this way to map the potential risk of fires according to the sensitivity of the factors related to fire. The main factors used in these studies, in order to establish different levels of forest fires risk, were: type of vegetation, characteristics of forest fuels, weather variables (temperature, air humidity, speed and direction of winds and precipitation), topography and ignition human activities (roads, demographics and usage type and occupation of land) (Salas; Chuvieco, 1994; Ferraz; Vettorazzi, 1998; Verde, 2008; Chuvieco *et al*., 2010; Marques *et al*., 2011; Oliveira *et al*., 2012).

Climate change can affect the number of fires that occur annually, the duration of the fire season and the area burned by fires. It also can increase the intensity of fire. Changes in these properties result in a direct influence of fire, increasing their frequency and intensity, and therefore, greater potential of fire (IPCC, 2007).

Several studies have demonstrated the impact of climate change on the behaviour of forest fires in various parts of the world, such as the research of Liu *et al*. (2012), on spatial patterns of fire occurrence and its future trend in Northeast China; Liu *et al*. (2010), on global trends of forest fire potential in the light of climate change, and the research conducted by Westerling and Bryant (2008), about climate change and California wildfires.

Flannigan *et al*. (2009a) reviewed the current understanding of what the future can bring with respect to forest fires. Research conducted in China by Tian *et al*. (2011), indicated a general increase in burned areas and in cases of fires, but with a considerable spatial variation, with some areas without alteration or even decrease in burned areas and the number of occurrences of fires.

Recent studies conducted by Flannigan *et al*. (2009b), suggest a doubling of burned areas, and an increase of 50% of the occurrences in several parts of the boreal forests by the end of this century. Fire seasons are expanding in the temperate and boreal regions and this trend should continue in the hottest regions of the world.

The Paraná is a State with a long tradition in the use and management of forest resources, mainly due to the exploration of extensive areas of forest with Araucaria covering almost the entire territory of Paraná in 20 mid-century (Maack, 2012). It is also the State in which occurred one of the biggest forest fires in the world, which in 1963 burned an area of 2 million hectares (20,000 hectares of plantations, 500,000 hectares of primary forests and 1,480,000 hectares of fields, secondary forests and brushlands) (Soares; Batista, 2007). And since that time the State of Parana has been a pioneer in research on control of forest fires in Brazil (Soares *et al*., 2009).

In view of the importance of forest fire risk zones and considering the hypothesis that the frequency and intensity of forest fires will increase in the light of global warming, the objective of this work was to evaluate the risk of forest fires for the State of Paraná, considering the scenarios predicted by the Intergovernmental Panel on climate change (IPCC) in 2007.

Methods

Study Area

The study area comprises the whole territory of the State of Paraná, located between the Parallels 22º 58' 30'' and 26º 43' 00'' South latitude and the Meridians 48º 05' 37''and 54º 37' 08'' West longitude. The territory comprises an area of 199,281 km^2, which corresponds to 2.34% of the total area of Brazil and 34.61% of the area of the southern region. In 2010, the State had 399 municipalities, 10,444,526 inhabitants and a population density of average 52.40 inhab/km^2, and much of this population live in urban area (85.30%). In the State of Paraná the altitudes range from sea level to 1,922 m at Peak of Paraná, located at Serra do Mar, highest elevation in the State and also in the southern region (IBGE, 2000, 2010).

Due to geographical location and topography, Paraná State has two dominant types of climate, having a third covering small land area between the coastline and the Valley of Ribeira (IAPAR, 1994). According to the Köppen classification (Trewartha; Horn, 1980), based on temperature and rainfall, Paraná State has the following climatic types: Cfa, Cfb and Af.

The less rainy months of June, July and August, shows that South and Southeast regions have rainfall between 350 and 450 mm, followed by Central and West regions, between 250 to 350 mm. The North region near the edge of the Paranapanema River, bordered by the State of São Paulo, rainfall is between 150 and 250 mm). The combination of low temperatures with occurrence of frosts and the decrease of precipitation make this quarter (June, July and August), most favourable to dry, making it susceptible to forest fires (Grodzki *et al*., 1996).

Collection and analysis of data

To obtain the necessary information to carry out the research, the following data set was used: historical series of temperature, relative humidity and precipitation of 28 weather stations operated by IAPAR from a period of 40 years (1970 to 2010); slope, aspect and elevation (INPE, 2008); demographic density (IBGE, 2010); map of State of Paraná with states and county boundary in 1:250,000 scale (IBGE, 2007); vegetation types map (Probio, 2005); road network map (DER, 2010). The method consisted in the elaboration of preliminary risk maps for each variable under study: vegetation type, moisture of forest fuel, fire danger index (FMA), slope, elevation, aspect, population density and road network. These maps were integrated by means of a weighted sum of the characteristics of fuels, weather and ignition sources, according to the equation:

RIF=0.33*((MC+UMC)/2)+0.33*((FMA+DE-Hipso+Orient)/4)+0.33*((DD+SV)/2)

Where:
RIF = risk of wildfire computed in each unit of analysis;
MC = forest fuel;
UMC = forest fuel moisture;
FMA = fire danger index;
DE = slope;
Hipso = elevation;
Orient = aspect;
DD = population density;
SV = road network.

The risk map depending upon vegetation type (forest fuel), was prepared based on a map of vegetation type of PROBIO (2005). This variable was considered static for the period under examination. The 55 vegetation types found in this survey were grouped into the following classes: agriculture, pasture/fields, forest cover, forest cultivation and no information.

The forest fuel moisture was estimated by the equation proposed by Simard (1968):

$$E = 21.06 – 0.4944*H + 0.005565*H^2 – 0.000638*H*T \ (H > 50)$$

Where:
E = forest fuel moisture, in percentage;
H = relative humidity, in percentage;
T = air temperature in °C.

Two scenarios were generated according to the IPCC report of 2007: (i) The best scenario, considering 1.8 °C increase in the average temperature of the Earth by 2100, (ii) The worst scenario, considering 4.0 °C increase in the average temperature of the Earth until 2100.
For the estimation of the necessary weather variables, stochastic simulations were carried out with the program PGECLIMA_R (Das Virgens Filho *et al*., 2011), for the period of 2010 to 2100.
The cumulative index of fire danger was calculated for the period of 2010 to 2100 and for both scenarios, using the fire risk index called Monte Alegre Formula (FMA). After generating the indexes, the values were classified into 5 classes through the method of Quantile and interpolated using Kriging method.
The variables slope, aspect and elevation were considered static variables for the analysis, and were generated using TOPODATA data set (INPE, 2008). Ratings were established on the basis of Soares and Batista (2007), Salas and Chuvieco (1994) and Fernandez and Vettorazzi (1998), respectively.
To generate the variable population density (dynamic variable), data were used from Brazilian Institute of Geography and Statistics (IBGE) related to 1991, 2000 and 2010 census for each municipality in the State of Paraná, as well as population estimates from 2000 to 2009. Initially it was necessary to estimate the population every decade for further calculation of the density. For this the method of Von Sperling (2005) was used. Population projections were generated using descending rate of growth. The observed values for the population density by municipality were distributed into five classes adapted from Guillhermo Julio (1992).
Considering that distance from the road system is inversely proportional to the risk of forest fire, buffers were established from the roads and railway network (DER, 2010). This was adapted from Salas and Chuvieco (1994) method. This variable was considered static for the analyzed period.
The final risk map was obtained applying GIS algebra operations between the preliminary risk maps (Salas; Chuvieco, 1994, Souza *et al*., 1996, Ferraz; Vettorazzi, 1998). After that, the risk map was classified into five classes of risk (low, moderate, high, very high, extreme), using the Quantile method. Finally, maps were generated for both, best and worst scenarios.

Results and discussion

The forest fire risk map depending on the vegetation cover featured a 4,263,177 ha (21.53% of the area of the State) in the extreme risk class, while the area for the very high class indicated 6,187,629 ha (31.25%). These areas where concentrated in the East and Northwest of the State.
In the eastern region are the most extensive forest fragments in the State, while the Northwest region is dominated by extensive grazing areas. These higher-risk areas reflect the largest vegetation flammability when compared with other types of vegetation found in the State of Paraná.
Considering the fuel moisture variable, in the best case scenario simulation, classes were not observed with very high and extreme risk in 2020. While in 2100 these classes have covered more than half of the State area (56.08%). The extreme class concentrated in the northern region with 11.97% of the State area. The worst case scenario simulation also failed to provide the most extreme classes (very high and extreme) in 2020, when compared to the best case scenario. However, in 2100 much of the State was ranked in the extreme risk of forest fire, reaching 91.33%. The moisture content is the most

important property that controls the flammability of living and dead fuels (Soares; Batista, 2007). Therefore, it has great influence on the risk of fire (ADAB *et al*., 2013). The moisture of forest fuels is the result of climate and atmospheric conditions. The results showed that as climate becomes drier over the years, according to the IPCC scenarios, there were more extensive areas with drier forest fuels and therefore, more dangerous and more flammable.

Regarding the simulation to the best case scenario of the FMA, it was observed a discrete spatial variation in the behaviour of the index, with little variation in terms of area in the State. In 2020 the high, very high and extreme classes resulted in 62.58% of the State area, keeping this extension in 2100. For the worst case scenario, it was noticed a significant spatial variation in the analysis period, with very high and extreme classes with more than half of the State at the end of the period. In this scenario the high and very high classes resulted in 56.82% in 2020, reaching 96.89% of the area in 2100.

For the slope variable, the State presented largely in low and moderate risk classes. The low risk class totalled 12,802,087 ha (64.41% of the area of the State) and the moderate class 3,845,465 ha (19.35%). The extreme risk concentrated in the Serra do Mar and Ribeira Valley and corresponded to 3.00% of the total area. According to Adab *et al*. (2013), the slope is one of the parameters that influence the rate of spread of fire. The fire runs faster uphill than downhill. In addition, the rate of spread of fire can increase on the steepest slopes, because the flames are tilted closest to the surface of the soil, and the process of heat convection may be increased by the wind.

The risk of fire in terms of elevation showed that much of the State was ranked in high risk and very high, totalling 98.23% of area (altitude less than 1,200 m above sea level). As Hernandez-Leal *et al*. (2006), the altitude is a physiographic variable that is associated with the temperature, moisture and wind. Therefore, it plays an important role in fire propagation. The altitude influences the structure of the vegetation, air moisture and fuel. It was observed that the humidity and temperature have greater influence over fire in areas with higher altitude. It has also been reported that the fire behaviour trends are less severe on higher places due to higher rainfall (Chuvieco; Congalton .1989).

The classes of fire risk due to the aspect of the slopes were low, with 36.59% of the area, followed by a very low, with 25.20% and high, with 12.93 %. The aspect of the slopes is correlated with the amount of solar energy that an area receives (Soares; Batista, 2007). The north-facing slopes receive more sunlight and high temperatures, high winds, low humidity and low fuel moisture in the southern hemisphere. Therefore, the vegetation is typically drier and less dense in the northern slopes (Vadrevu *et al*., 2010; Soares; Batista, 2007). Because of this, the driest fuels are more exposed to ignition (Adab *et al*., 2013).

The simulation of population density and its classification in terms of risk of forest fire showed a continuation of higher risk in the North, East and West of the State. The State had, in 2010, 76.41% of its area in the low risk class, which fell in the period under examination, passing to 69.70% of the area. The extreme risk class increased from 7.83 % to 12.72%, which represented an increase of 62.4%. Humans are the cause of the vast majority of fires and therefore, the population density is a factor which expresses the omnipresent effect of population on the ignition and spread of fire. In this sense, Marques *et al*., 2011, claim that the population density has been singled out as the main source of ignitions of fires in Portugal.

The road network has an area of influence of 831,534 ha (4.38% of the State area). This area is divided into 170,692 ha with low risk, 167,645 ha with moderate risk, 166,028 ha with high risk, 164,268 ha on the degree of risk too high and 162,900 ha in degree of extreme risk. The road network showed no influence on 95.62% of the area of the State. It is necessary to emphasize that human activities are one of the basic factors that affect fire occurrences (Xu Dong *et al*., 2005). Due to more intensive human activities, the fire risk is larger and offers plenty of opportunity for the unexpected fire ignition (Alencar *et al*., 2004). Proximity of roads and road density are potentially important parameters once the roads facilitate access of people in areas of forest and pasture and this can cause fires (Jaiswal *et al*., 2005).

In figures 1 and 2 are presented forest fires risk zones in the years 2020 and 2100, for the best scenario. In the first decade (2020) the risk was concentrated in the moderate and high classes, with 33.04% and 54.64%, respectively. Areas located in the North region of the State and in the surrounding areas of the metropolitan region of Curitiba, concentrated much of the extreme risk of forest fires, which totalled 1.80% of the total area. This value increased in the following decade, passing to 2.51%. The same behaviour is observed for the very high class, ranging from 10.43 % to 13.82 %.
This behaviour has remained throughout the period under examination. In 2100, the area corresponding to the low risk class was 0.01 %, while the moderate class corresponded to 7.66 %, the high class 51.47%, very high class to 32.38% and extreme class to 8.49%.

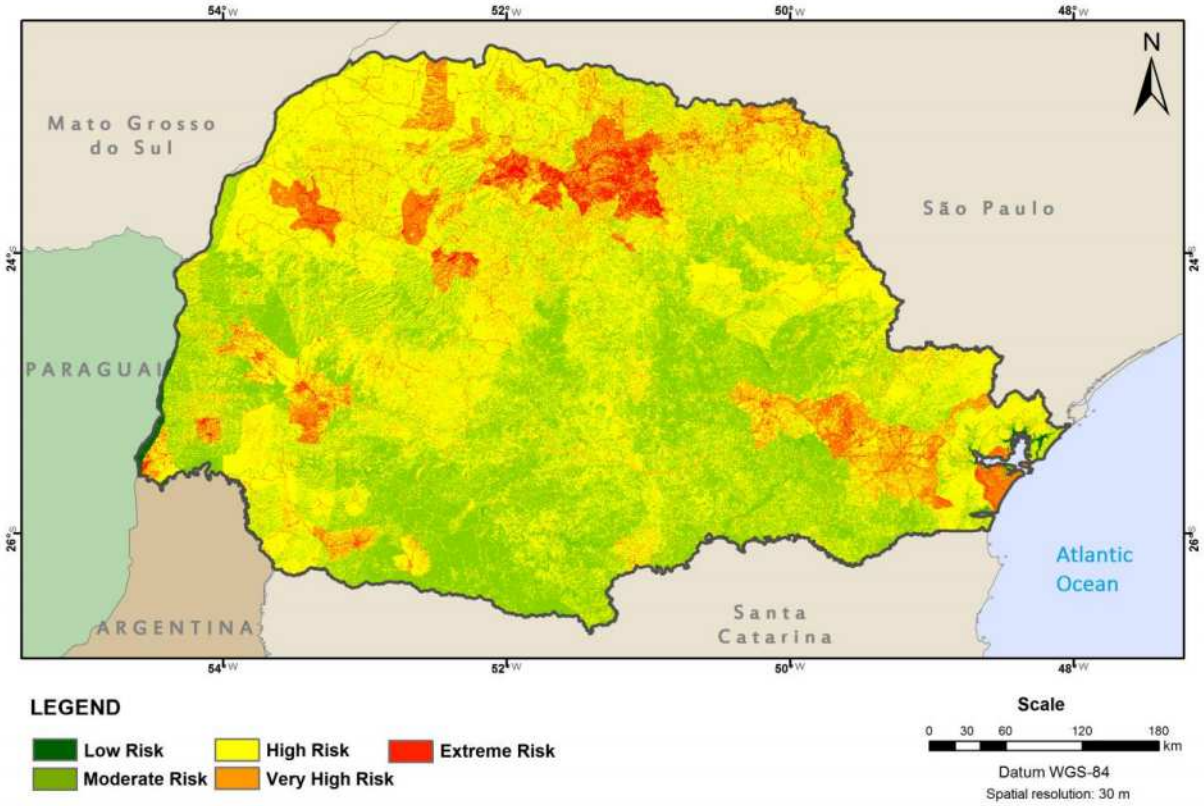

Figure 1. Risk of wildfire in 2020 (best case scenario).

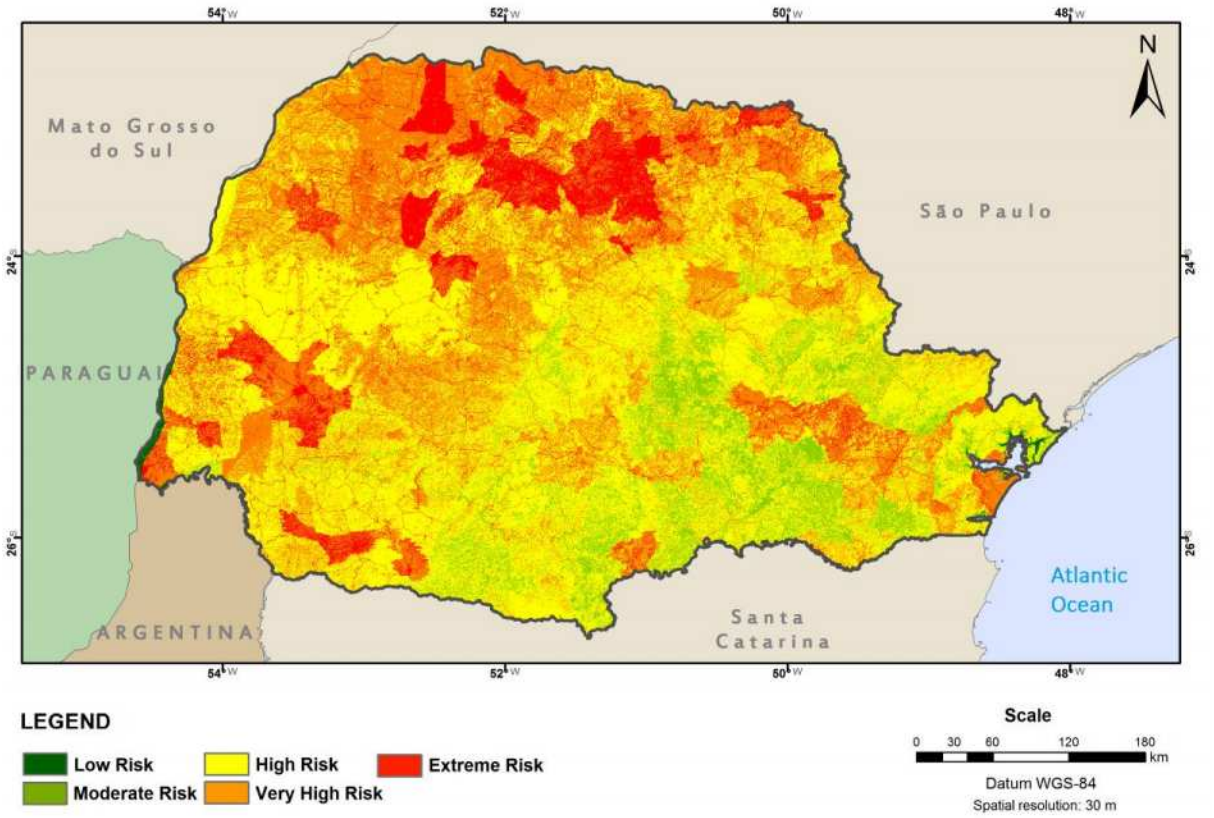

Figure 2. Risk of wildfire in 2100 (best case scenario)

In figures 3 and 4 are presented the forest fires risk zones, in the years 2020 and 2100, for the worst case scenario. In the 2020 decade, much of the State performed at high-hazard class (51.74% of the area), followed by the moderate (32.08%) and very high (13.93%). The class of extreme danger, with 2.18% of the area, passed the decades following the 3.54% and 5.98%, respectively.

At 2100 the State failed to provide more area in the low risk class and the moderate risk class corresponded to 0.07% of the State. The high class, that in 2020 was 51.74%, showed 21.27%. The classes very high and extreme, both with significant increment, represented 55.95% and 22.72% of the total area.

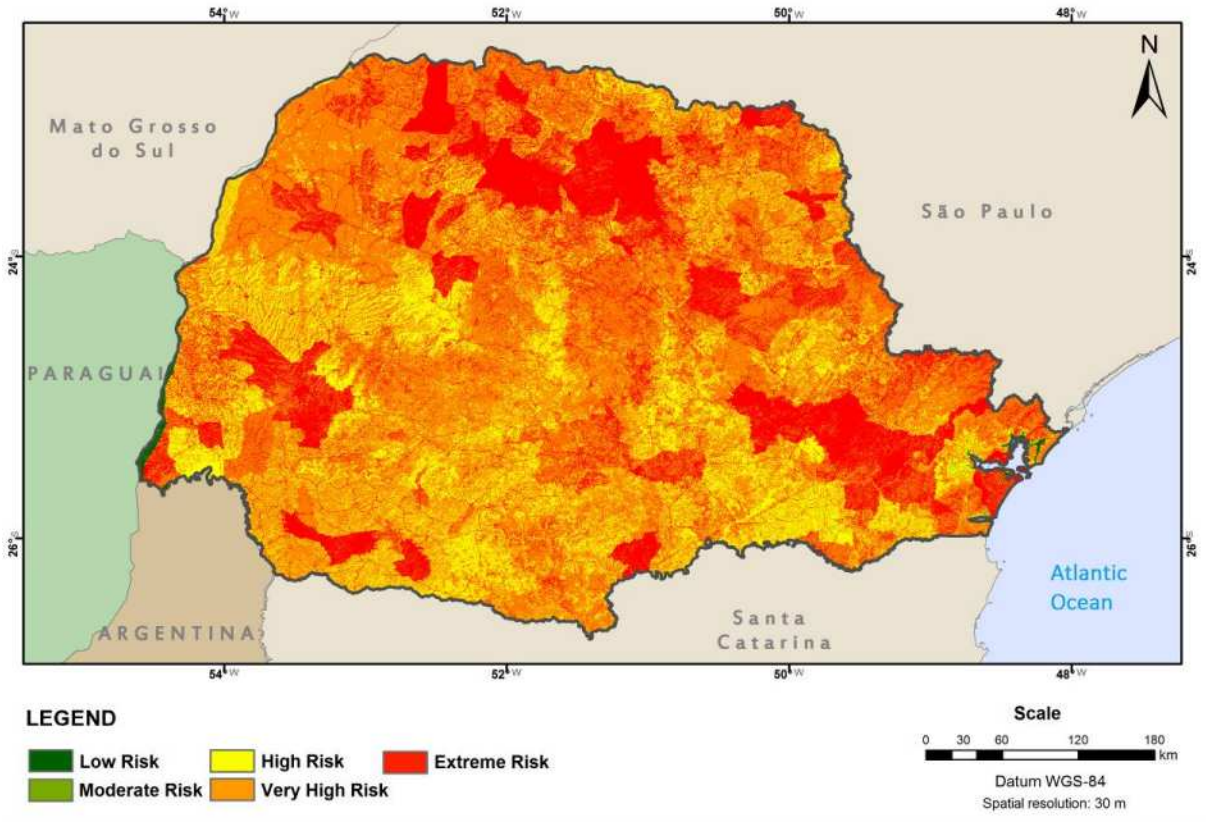

Figure 4. Risk of wildfire in 2100 (worst case scenario)

Conclusions

The dynamic variables (demographic density, fuel moisture, fire danger index (FMA) and forest fire risk zoning), showed an increase in higher classes of danger from fires over time. This behaviour was observed for both the best and the worst scenarios of temperature increase (in accordance with the IPCC).
The data integration model used showed generate consistent results, considering that the mapping of the exposure classes obeyed an evolution according to the decades.
The hypothesis that there will be an increase in the risk of forest fires in the event of an increase in the average temperature of the Earth, was accepted. It is concluded that, if the IPCC predictions are confirmed, there will be an increase in the number of fire events in the State of Paraná, which will require integrated actions for preventing and fighting forest fires to minimize possible environmental, social and economic damages.

Aknowledgments

To FINEP for enabling the accomplishment of this work.
To professionals of IAPAR and SIMEPAR: Paulo Henrique Caramori, Luciane Christina Pinheiro, Roberto Oliveira Santos, Fábio Sato and Livia Maria Pereira for all the support.
To the students of the forest fire Laboratory of the Federal University of Paraná (UFPR), SIMEPAR and IAPAR: Igor K. Takashina, Regiane Kock de Sousa, Luciana Pereira Lauthert, Rafaela de Asunção, Chaiane Cristina Rech Leiva and João Jankowski Saboia.

Abstract
Wildfires in Portugal are a major problem, with about 18 500 fires and 110 000 ha burnt every year and an increasing trend of the large fires (>100 ha) during the 1980 – 2011 period. In previous studies, climate and weather conditions were identified as the most important drivers of annual total burnt area in the country which inspire assessing potential changes in the statistical distribution of the areas burnt by fires in the expected warmer and drier conditions of future climate. The aim of the study is therefore to project area burnt by vegetation fires in Portugal for different future climate scenarios using an appropriate Burnt Area Model (BAM). The BAM is a multiple regression model that shown to be able to simulate the burnt areas in July and August with just two predictors: the Daily Severe Rating (DSR) in the pre-fire season (May and June) and during the fire season (July and August). Then, the regression model is fed with simulated data by a Global Climate Model (GCM) respecting to present climate and to future IPCC emission scenarios B1 and A1B. It is shown that samples of observed and simulated logarithms of burnt areas follow normal distributions. Changes in measures of location and dispersion (mean and variance), from recent past to future climates, are analysed after statistically removing the effects due to the limitations of the GCM and the BAM. When comparing present climate with future climate scenario B1 (A1B), maximum increases in the averages of the decimal logarithm of July and August burnt area are of 11% (28%) while the standard deviation remaining almost unchanged for scenario B1 and presenting an increase of 25% for A1B. Obtained estimates need to be looked at with due care but the developed approach consistently points towards an increasing risk of fire under future climate conditions, inter-annual variability and likelihood of having much larger fire events.

Keywords*: Forest fire; Climate change; GCM; Fire risk/danger*

Introduction

Assessing the potential impacts of climate change on the fire regime is especially relevant in Portugal, where according to the Portuguese National Forest Authority (*Instituto de Conservação da Natureza e das Florestas*, ICNF) and the European Forest Fire Information System (EFFIS), more 610 000 fires and 3,5 million ha have burnt between 1980 and 2012, almost 1 million ha of which between 2003 and 2005 (Calado and Dacamara 2008). Besides, the number of large fires (with more than 100 ha), amount of burnt area (hereafter, BA) and fire severity have lately increased in Portugal (Pereira *et al.* 2011). Weather and climate are considered the most important drivers of fire activity, even more important than fuel pattern and topography in determining BA in simulated landscapes due to the direct and indirect profound influence they have on wild land fire ignition potential, fire behaviour and severity (Cary and Banks 2000; Benson *et al.* 2008). The climatic conditions determine the existence, type and life cycle of the vegetation which helps explaining the strong resemblance between the spatial patterns of the global pyrogeography (Krawchuk *et al.* 2009) and the updated world map of the Köppen-Geiger climate classification (Peel *et al.* 2007). On the other hand, weather conditions such as lightning promotes fire ignition, while air temperature, wind, atmospheric stability and air relative humidity determine the fuel moisture content and fire spread and, on the contrary, precipitation, even in small amounts, contributes to fire extinction (Pereira *et al.* 2013).

Climate and weather play a particularly important role in the fire regime in Portugal, where long-term climatic pre-conditions (e.g. temperature and precipitation in winter and spring before the summer fire peak season) and short-term synoptic forcing (e.g. extreme synoptic weather patterns and weather types from classifications schemes) are able to explain about two thirds of the variance in the annual, seasonal and monthly total BA (Pereira *et al.* 2005; Pereira *et al.* 2013; Trigo *et al.* 2013). Extreme fire activity as recorded in 2003 and 2005 tends to occur under (also) extreme and consistent weather conditions from the surface to high levels of the atmosphere (Trigo *et al.* 2006) and is related to the evolution of the synoptic- and meso-scale wind, temperature and humidity patterns associated to the appearance of the Iberian thermal low (Hoinka *et al.* 2009).

These factors are continuously changing due to natural climate variability and human-caused climate change (Stocker *et al.* 2013) which may contribute to the high inter-annual variability and increasing trends observed in the last decades (Pereira *et al.* 2005; Pereira *et al.* 2011) and legitimizes the ambition to try to estimate future fire activity.

Many of the most recent studies on the impacts of climate change on some aspect of the fire regime and wildfires has focus on North (Johnstone *et al.* 2010; Wotton *et al.* 2010; Westerling *et al.* 2011; Rocca *et al.* 2014) and South America (Silvestrini *et al.* 2011), Australia (Pitman *et al.* 2007; Murphy and Timbal 2008; Clarke *et al.* 2011) Lynch *et al.*, 2007), in boreal forests of North America and Eurasia (Kilpeläinen *et al.* 2010; Liu *et al.* 2012; De Groot *et al.* 2013), in Europe (Moriondo *et al.* 2006; Batllori *et al.* 2013; Cane *et al.* 2013; Bedia *et al.* 2014; Karali *et al.* 2014) and even at global scale (Moritz *et al.* 2012). However, and despite the magnitude of the problem in Portugal, a very short list of studies have dealt with the impact of climate change on wildfire risk in Portugal (Durão and Corte-Real 2006; Carvalho *et al.* 2008; Carvalho *et al.* 2010; Pereira *et al.* 2013).

The projection of future fire activity requires the development of robust and resistant fire-vegetation-weather/climate relationships to be used in future climate conditions and the availability of sufficiently long and reliable datasets of observed and simulated values of meteorological and fire variables (Pereira *et al.* 2013). Portugal holds one of the largest (in terms of total number of recorded fires) and most comprehensive rural fire databases, not only in European context but also in comparison to many other countries worldwide (Pereira *et al.* 2011).

Currently, a large set of long and reliable meteorological datasets of analysis and reanalysis are available for climate research studies which includes the European Centre for Medium-Range Weather Forecasts (ECMWF) ECMWF 40-year Reanalysis (ERA-40), the ECMWF Interim Reanalysis (ERA-Interim), the Japanese 25-year (JRA-25) and 55-year Reanalysis (JRA-55), the NASA Modern Era Reanalysis for Research and Applications (MERRA) and (MERRA2), the National Centers for Environmental Prediction (NCEP) Climate Forecast System Reanalysis (CFSR) and NCEP/DOE Reanalysis II and the NOAA-CIRES 20th Century Reanalysis V2.

On the other hand, General Circulation Models (GCMs) are nowadays recognized as suitable tools for climate modelling because they are based on well-established physical principles, able to simulate global- and many regional-scale observed features of contemporary climate, past climate changes and there is significant confidence that GCM provide credible quantitative estimates of future climate change (Randall and Fichefet 2007). In this sense, most climate models are able to derive fire danger and thereby characterize a probable fire regime (Lynch *et al.* 2007). In addition, climate change data, which may include climate estimates from observations, socio-economic data and scenarios, global climate model data simulated by different GCM and for different future climate scenarios may be easily obtained from many different data providers such as the Data Distribution Centre (DDC) of the Intergovernmental Panel on Climate Change (IPCC) or the Program for Climate Model Diagnosis and Intercomparison which provides the World Climate Research Programme Coupled Model Intercomparison Project, WCRP CMIP datasets (Meehl *et al.* 2007). Recently, a Burnt Area Model (BAM) was developed for Portugal based on multiple regression analysis of meteorological parameters with the aim to model the BA during the summer months and be used as a BA generator (Pereira *et al.*

2013). Therefore, the aim of this study is to produce and compare projections of future BA in Portugal by means of the BAM for different future climate change scenarios.

Materials and Methods

This study is based on a fire database and on daily meteorological data of both analysed and simulated fields. Indices of fire risk that integrate the Canadian Forest Fire Danger Rating System (CFFDRS) are then computed using the appropriate meteorological data.

Data

The fire database was provided by the Institute for the Conservation of Nature and Forestry (*Instituto da Conservação da Natureza e das Florestas*, ICNF) and consist of detailed information (e.g., fire ignition location, in terms of administrative division of Portugal, fire ignition and extinction date and time, fire area in forest, shrublands and agricultural land cover type) obtained from ground measurements for each fire occurred in Continental Portugal between 1980 and 2011. This dataset is an extension of the Portuguese Rural Fire Database (Pereira *et al.* 2011) and after correcting the additional data for inconsistencies and errors using the same procedures, monthly cumulated values were computed for the considered 32 – year period.

The observed meteorological database consist of analysed fields from the ERA-Interim which is the latest global atmospheric reanalysis produced by the ECMWF to replace the ERA-40 with a new atmospheric reanalysis which will extend back to the early part of the twentieth century and able to provide a better representation the hydrological cycle, improve the quality of the stratospheric circulation and the consistency in time of the reanalysed fields (Dee *et al.* 2011). The ERA-Interim data server surface archive has a mixture of analysis fields, forecast fields and fields available from both the analysis and forecast which is determined by the step variable: 0 for analysis (which are available for 0000, 0600, 1200 and 1800 UTC); 3, 6, 9 or 12 for forecast fields which are produced from forecasts beginning at 0000 and 1200 UTC). The other daily archives have only analysis data.

The selected meteorological fields are: 2 meter air temperature, 2 meter dew point temperature, 10 meter zonal and meridional components of wind speed and 24 hour cumulated precipitation (all at 12 UTC). The air relative humidity was computed with the Magnus formula (using 2 meter air temperature, 2 meter dew point temperature) and corrected according to the altitude. All meteorological fields are defined on a 0.75°×0.75° latitude/longitude grid over Continental Portugal. Spatial means were then computed over the selected grid points and monthly means were finally derived for all meteorological data.

The simulated meteorological database consist of outputs from the Model for Interdisciplinary Research on Climate (MIROC), which is a coupled Atmosphere-Ocean GCM that comprises five components, namely atmosphere, land, river, sea ice and ocean. Developers of MIROC are at the Centre for Climate System Research (CCSR), the University of Tokyo, the National Institute for Environmental Studies (NIES) and the Frontier Research Centre for Global Change (FRCGC). Several different model comparison studies identify MIROC as one of the best models (Lucarini *et al.* 2007; Scherrer 2011; Watanabe *et al.* 2011; Watanabe *et al.* 2011; Mochizuki *et al.* 2012; Chikamoto *et al.* 2013) with especial good performance over the Iberian Peninsula (Nieto and Rodríguez-Puebla 2006; Errasti *et al.* 2011).

For comparison purposes, data for three grid points were selected from MIROC 3.2 medres grid, all approximately at the same longitude but at different latitudes: two of them located over Portugal (one in the south and another in the centre) and one at north of Portugal, in Spanish region of Galicia. Daily grid values of 10 m wind speed, 24h cumulated precipitation, surface air temperature and relative humidity were extracted for 1951 – 2000 period respecting to the recent past conditions (20th century) model simulations (20C3M), and for the 2051 – 2100 respecting to IPCC Special Report on Emissions Scenarios (SRES) B1 and A1B (Nakicenovic and Swart 2000). The B1 scenario corresponds to a high

level of environmental and social consciousness accompanied by rapid changes in economic structures and the introduction of cleaning technologies. On the other hand, the A1B scenario reflects a future world of very fast economic growth, low population growth, with a rapid introduction of new and more efficient technology, and a balanced mix of technologies and supply sources.

The Canadian Forest Fire Weather System

In this study, the indices of the Canadian Forest Fire Weather Index (FWI) were used to account for the effect of weather on fuels and fire behaviour. The FWI System (Figure 1) comprises six components: the first three components, the Fine Fuel Moisture Code (FFMC), the Duff Moisture Code (DMC) and the Drought Code (DC), are fuel moisture codes which aim respectively to rate the moisture content of litter and other fine fuels, the average moisture content of loosely compacted organic layers of moderate depth, and the average moisture content of deep, compact organic layers; the remaining three components, the Initial Spread Index (ISI), the Build Up Index (BUI) and the Fire Weather Index (FWI), are fire behavior indices, which characterize the rate of fire spread, the fuel available for combustion, and the frontal fire intensity (Van Wagner and Pickett 1985; Van Wagner 1987). Finally, the Daily Severity Rating (DSR) is simply a power function of FWI ($DSR = 0.0272 \times FWI^{1.77}$), with the aim to rate the difficulty of controlling fires and specifically designed for averaging either in time or in space in opposition to FWI that is suitable as a single day value. All these indices are computed solely with the values of four meteorological variables and their values increase with the rise of fire danger (Van Wagner and Pickett 1985). The FWI System was developed for Canada but has been successfully used all over the world (Amiro *et al.* 2005; Wotton 2009) and shown to be especially useful in Portugal to assess the fire behaviour potential in maritime pine stands (Palheiro *et al.* 2006) and to rate fire risk in Portugal during the summer season (Rainha *et al.* 2002; Viegas *et al.* 2004; Carvalho *et al.* 2008; Carvalho *et al.* 2010). Since 1998, the System has been operationally used by the Portuguese Weather Service.

Values of the FWI and DSR derived on selected grid points based on daily values of the above-listed meteorological values (analysed and simulated) and then, spatial averages were computed over grid points and monthly means were finally computed.

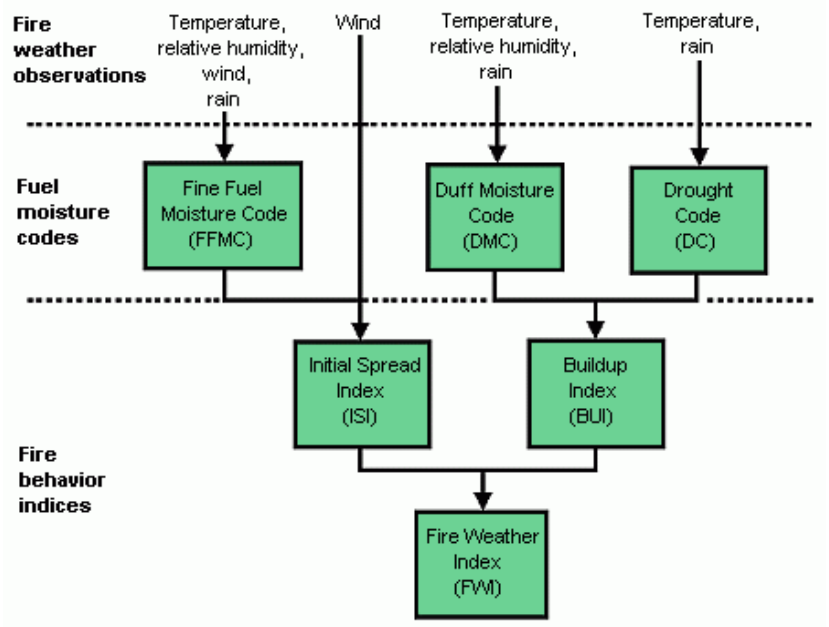

Figure 1. The Structure of the FWI System. The components of the FWI System are computed with consecutive daily observations of air temperature, relative humidity, wind speed, and 24-hour rainfall. The six standard components provide numeric ratings of relative potential for wildland fire. Adapted from Natural Resources Canada (http://cwfis.cfs.nrcan.gc.ca/background/summary/fwi).

Results

The observed summer burnt areas

The annual cycle of monthly BA for Continental Portugal during the considered 32 – year period is shown in Table 1. It is well apparent that the vast majority of area burnt by forest (71% of the total BA) take place during the summer months of July and August. The close agreement between the time series of annual and July plus August BA and the very large inter-annual variability dominated by the outstanding values registered in the years of 2003 and 2005 (Figure 2) suggest that the annual fire regime is dominated by the events that take place in July and August and to restrict the study to those two summer months.

Table 1. Annual cycle of monthly burnt area in Portugal for the period 1980 − 2011. Values of simple and robust and resistant statistics including the maximum, upper quartile (Q3) median, lower quartil (Q1), minimum, interquartile range (IQR), range and total.

This behaviour is expected in Mediterranean regions since vegetation presents elevated levels of water stress as induced by periods of dry conditions and relatively high temperatures that often characterise the late spring and the beginning of summer (Viegas *et al.* 2001; Pereira *et al.* 2005; Trigo *et al.* 2006). The inter-annual variability (as measured by the inter-quartile range) is also clearly larger during the summer months and it is worth noting that the variability of July and August is about twice the one of September.

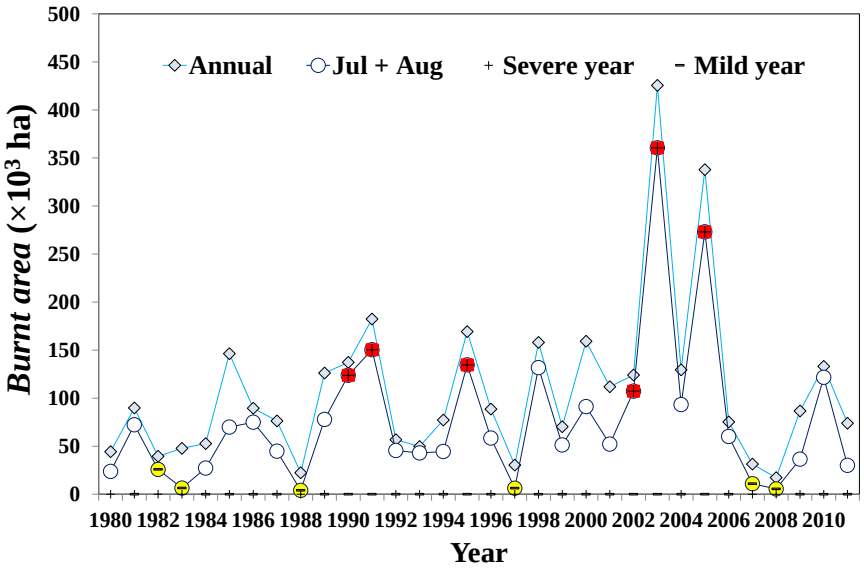

Figure 2. Inter-annual variability of burnt area amounts in Continental Portugal for the whole year (Annual) and just for July + August (Jul + Aug), for the period 1980−2011. Severe (+) and mild (–) years signs inside respective red and yellow circles.

It is also important to underline some of the results of correlation analysis during the period 1980 – 2011, namely: (*i*) the existence of a positive and statistical significant (p-value<0.0001) value of the Pearson Product-Moment correlation coefficient (r = 0.66) between the areas burned in July and in August; (*ii*) the very low (r =0.22) and statistically not significant correlation between the DSR monthly means of July and August; (*iii*) despite the significant (p-value<0.0001) high value of the correlation coefficient between DSR and the decimal logarithm of monthly BA for the months of July and August, (r = 0.76 and r = 0.59, respectively). These results underline the usefulness of the DSR to rate the meteorological fire danger and suggests the existence of a pre-summer season climatological background that would condition the fire regimes of both July and August.

The Burnt Area Model

With the aim of identifying the most promising predictors of BA in July and August and characterizing the climatological background, a composite analysis (Pereira *et al.* 2005; Trigo *et al.* 2006) of all the analysed meteorological fields was performed for two classes of extreme summer fire seasons, respectively severe and mild (Figure 2), defined depending on the monthly BA of July and August are both greater/lesser than the upper/lower tercile of the respective month (i.e. greater than 40,000 ha for July and 46,000 ha for August).

Results reveal that, from the meteorological standpoint, major differences between mild and severe years may be found during the months preceding and during the summer fire season (Figure 3). In the pre fire season, severe years are associated to positive anomalies of precipitation in the early spring (March), which favours the growth of vegetation, followed by significant negative anomalies of precipitation and air relative humidity and positive air temperature anomalies in May and June. This climatic pattern is consistent with the atmospheric circulation from NE, over Portugal during this period and, as expected, the increasing trend of positive DSR anomalies from April to June reflect the above-described cumulative behaviour of temperature, relative humidity, wind and precipitation. During the fire season, major statistically significant differences between severe and mild fire seasons are naturally found in all meteorological variables and, consequently, in DSR. Severe fire seasons are characterised by extreme negative precipitation and humidity anomalies and positive temperature anomalies associated to south-eastern winds leading to utmost DSR anomalies. In the case of mild years, the opposite behaviour is observed.

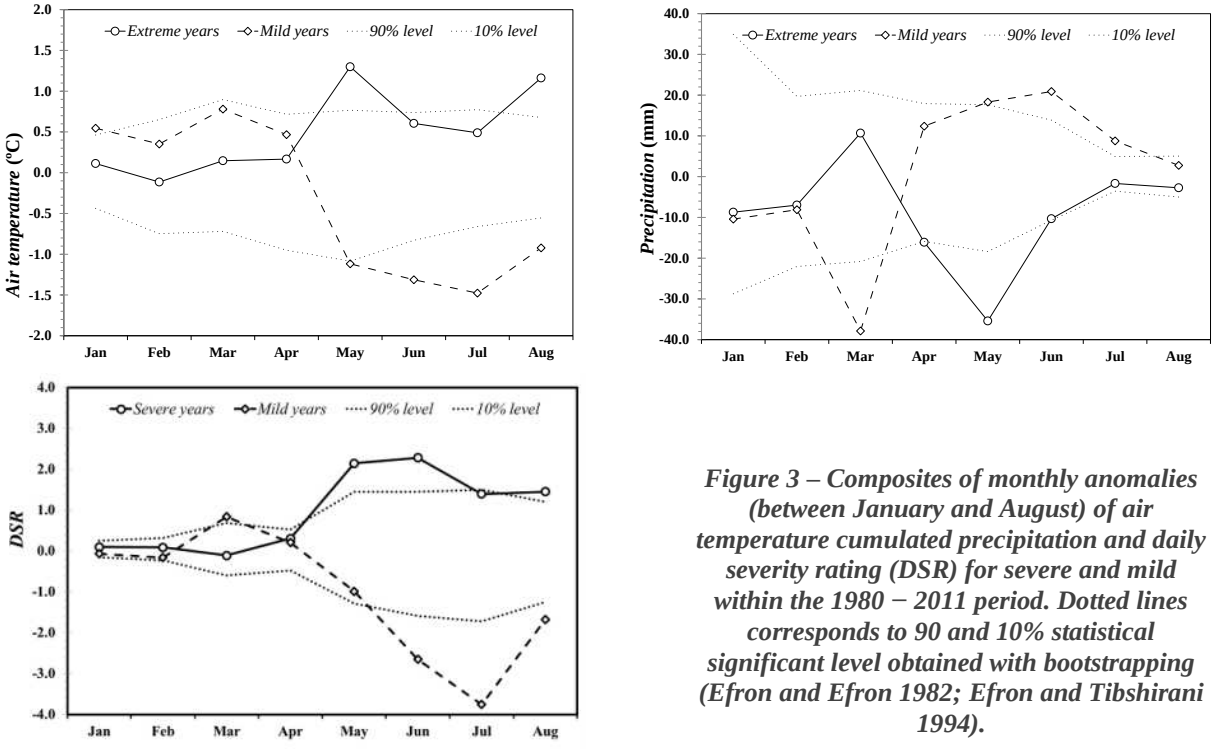

Figure 3 – Composites of monthly anomalies (between January and August) of air temperature cumulated precipitation and daily severity rating (DSR) for severe and mild within the 1980 − 2011 period. Dotted lines corresponds to 90 and 10% statistical significant level obtained with bootstrapping (Efron and Efron 1982; Efron and Tibshirani 1994).

These results suggest the development of a multiple linear regression BAM for decimal logarithm of monthly BA (due to the highly asymmetrical character of monthly BA) in summer months using, as predictors, meteorological variables and/or fire risk indices respecting to the pre-fire and/or fire seasons. In order to mitigate the effects of over fitting, the performance of the experiments was evaluated using a leave-one-out-cross validation scheme (Wilks 2011). Several selection methods (e.g., stepwise, forward, backward and explained variance) using different criteria were tested to select the best and parsimonious BAM for BA time series in July, August and July + August for the 32-year period using the equation presented in Table 2 where the $Log_{10}BA_{J/A}$ is the decimal logarithm of monthly BA in July or in August; DSR_{PF} is the monthly mean of DSR during the pre-fire period (PF), defined as May and June when the predictand is the decimal logarithm of monthly BA in July ($Log_{10}BA_J$) and May, June and July when the predictant is the decimal logarithm of monthly BA in August ($Log_{10}BA_A$); $Log_{10}BA_{J/A}$ is the monthly mean of DSR in July or in August depending if the predictand is the monthly BA in July or August, respectively.

	Total		63	18.5533			

Results of the regression analysis and analysis of variance (ANOVA) obtained independently for July and August (Table 2) are very similar for both months not only in what respects to regressions statistics (R^2 = 0.59 – 0.61, R^2_{adj} = 0.56 and standard error of 0.32 (August) – 0.36 (July), respectively), regression coefficients (A, B and C), statistical significance (Student's *t* distribution statistic and significance of *F-statistic*). Results for BA in July and August (jointly) are even slightly better (R^2 = 0.64, R^2_{adj} = 0.62) but regression coefficients are very similar to those obtained independently for July and August.

The two predictors are statistically significant and were selected in the same order they appear in the equation, with increasing R^2 value from 0.44, when $Log_{10}BA_{J/A}$ is the only predictor, to 0.630 when the model has both predictors. Several other aspects are worth being noted namely: the overall good agreement between observed and modelled values of the decimal logarithm of BA; the relatively high value of the coefficient of determination R^2 = 0.64 (p-value<0.001) for July and August BA; which means that the BAM is able to explain, in cross-validation mode, almost 3/5 of the total variance. Finally, the normality of the values of the logarithm of the values of BA observed, modelled and residuals from the use of the BAM was confirmed by the Kolmogorov-Smirnov test. All these features are especially important and will be exploited in the next subsection when the BAM will be used as a generator of monthly BA scenarios in recent past and future climate conditions.

3.3. The simulated summer burnt areas

Simulated time series of BA in July and August were generated by feeding the BAM with DSR values computed for the pre-fire period and for the fire season with GCM outputs respecting to present (20C3M) and to future B1 and A1B climate scenarios. The Kolmogorov-Smirnov (K-S) test was used to check that the simulated BA for all cases are normally distributed at the 5% significant level (Table 3). Values of the mean and standard deviations of $Log_{10}BA_{J/A}$ reveal that, as expected, the use of the multiple linear models with observed DSR leads to a simulated BA samples with the same mean as the one of the observed sample but with smaller variance. However, when feeding the BAM with

Table 3 – Mean, standard deviation (SD) and p-value of the one-sample Kolmogorov-Smirnov test for normality of burnt area time series for July and August observed and simulated by the BAM when fed with ERA-Interim (Modelled) and with GCM outputs (BAM+MIROC) for different periods of scenario B1 and A1B.

Model	Scenario	Period	Mean	SD	p
BAM	Observed	1980 - 2011	4.31	0.54	0.41
	Modelled	1980 - 2011	4.31	0.43	0.85
BAM + MIROC	20C3M	1971 - 2000	5.06	1.06	0.42
	B1	2051 - 2080	5.63	0.72	0.38
		2071 - 2100	6.03	1.07	0.68
	A1B	2051 - 2080	6.72	0.97	0.68
		2071 - 2100	7.48	1.36	0.29

simulated data by a GCM for future climate scenarios there is an increase in both the mean and the variance, even for the recent past conditions (20C3M). The latter case is an expected consequence of the GCM's characteristics, namely the known fact that the simulated meteorological fields by MIROC, or by other climate models, are biased and have too much variability. Accordingly, changes in the mean and in the standard deviation are due to climate change (signal) and to the limitations of BAM and GCM (noise) to properly reproduce the observed reality. With the aim of, at least reduce the model bias, the $Log_{10}BA_{J/A}$ obtained for the recent past conditions (20C3M scenario) were corrected to have mean and standard deviation equal to the observed values. Then, time series of $Log_{10}BA_{J/A}$ for the future scenarios were transformed with exactly the same correction factors.

Comparison between future projections of the normal distributions may be performed on the basis of the descriptive statistics of the decimal logarithm of BA (Table 4). When compared with the present climate scenario (20C3M), there are increases in the means of $Log_{10}BA$ for both future climate scenarios periods, respectively of 7% and 11% (20% and 29%) from the 20C3M to the 2051 – 2080 and 2071 – 2100 periods of the B1 (A1B) scenario. The standard deviation remains almost unchanged from the 20C3M to the last (first) period of B1 (A1B) scenario, but presents a decrease (increase) of about 32% (28%) from the 20C3M to the first 30-year of B1 (A1B) scenario. It is also worth noting that differences in percentiles changes with increasing percentiles, e.g. from 0.39 (0.36) in P5 to 0.48 (0.57) in P50 and to -0.28 (0.38) in P95 when going from present climate to first (last) 30-year period of B1 scenario while the correspondent differences for A1B scenario are even higher (about the double). This is an important aspect, since it reveals that in the B1 scenario conditions, for the 2051 – 2080 period major increases in burnt area are only expected for values below P75 and the larger increases should be expected for P10 (0.58) values of burnt area while for the 2071 – 2100 period the increases are therefore to be expected for all values of burnt area nonetheless larger increases are found between P10 (0.55) and P75 (0.47). A similar changing pattern is expected for A1B scenario during the first period but increasing changes may be expected from P5 (0.85) to P95 (1.47). As expected, differences are even more impressive when analysing changes in BA (and not in the logarithm) from present to future climate scenarios. The median may change from 16,000 ha in 20C3M scenario to 49,000 ha (158,000 ha) and 61,000 ha (294,000 ha), respectively in the first and second 30-year period of B1 (A1B) scenario. On the other hand, the mean remains unchanged from recent past climate scenario to 2051 – 2080 period of B1 but increase to 158,000 ha in the 2071 – 2100 period of future scenario. Values of the mean BA for A1B scenario are even higher (270,000 and 1,500,000 ha).

Conclusions

This study shown that the annual total BA in Continental Portugal is dominated by the fire events taking place in July and August which accounts for almost 3/4 of the total burnt area. The influence of weather conditions on the BA in these summer months was disclosed by the results of composite analysis of relevant meteorological variables performed for severe and mild years, defined as those where both the monthly BA of July and August are higher or lower than the respective upper or lower terciles, respectively. Results indicated that severe years are related to averaged anomalies of precipitation in March followed by positive anomalies of temperature and negative anomalies of precipitation and relative humidity in pre fire season. These climatic patterns are consistent with the atmospheric circulation over Portugal and with the anomalies of DSR becoming increasingly positive and statistically significant from May to June for severe years. Differences were also obtained during the fire season (July and August), where extreme meaningful positive anomalies of temperature and DSR (i.e., above the 90% significant level) were found for severe and negative for mild year composites.

These differences in the meteorological parameters have a profound impact on the life cycle and the thermal and hydric stress of the vegetation. In fact, during severe years a higher averaged precipitation and relative humidity in March increases the likelihood of a healthy growth of vegetation while the lower values of precipitation that follow in May and June, together with the higher values of temperature, increase the stress in a more abundant vegetation contributing to a larger amount of available fuels and burnt area. This process is particularly highlighted if, during the fire season, Portugal is affected by atmospheric circulation patterns that induce extreme hot and dry spells (heat waves) over the territory.

A Burnt Area Model (BAM) was developed to simulate the decimal logarithm of monthly burnt areas in July and August using, as predictors, the DSR during the pre-fire and the fire season. This model is able to explain almost 2/3 of the total observed variance and is almost unaffected by over fitting which increase the confidence in their use in practice with future unknown validation dataset. The BAM was then fed with simulated data by the MIROC climate model respecting to present climate conditions (20C3M) and to future climate IPCC emission scenario B1 and A1B and the bias of the BAM and GCM was corrected before proper comparison between projections of future BA.

When compared with the recent past climate scenario (20C3M) with the two periods (2051 – 2080 and 2071 – 2100) of future climate scenarios B1 and A1B, increases in the means of the logarithm of July and August BA ranges, respectively between 7% and 11% for B1 and between 20% and 29% for A1B whereas the standard deviation remained almost unchanged in the latter case of scenario B1, presented a decrease of about 30% and 9% in the case of the former period of both B1 and A1B and an increase of 28% in the last period of A1B scenario. Differences in percentiles (between present and future climate scenarios) increased with increasing percentiles indicating that the larger increases in burnt area are to be expected for all fire events at the end of the XXI century.

It is very likely that the simulated BA are overestimated due, at least to three orders of reasons: (*i*) the use of global (GCM) or regional (RCM) circulation models (which are just limited representations of the observed reality); (*ii*) the use of a linear BAM (which prevents the existence of feedback mechanisms that might reduce the amounts of burnt area); and, (*iii*) not taking into account other important factors for fire occurrence and size such as those related to changes in fuel structure (Pausas and Paula 2012; Gibson *et al.* 2014); climate-vegetation dynamics and conservation planning (Krawchuk *et al.* 2009); patterns of lightning strikes (Wotton *et al.* 2010; Wendler *et al.* 2011; Liu *et al.* 2012); and anthropogenic activities and drivers of fire, such as control over ignition, fire management, suppression activities, land use/land cover changes (Krawchuk *et al.* 2009; Le Page *et al.* 2010; Aldersley *et al.* 2011; Costa *et al.* 2011; Kloster *et al.* 2012). Nevertheless, obtained results are of the same order of magnitude of other similar studies (Le Goff *et al.* 2009; Carvalho *et al.* 2010; Westerling *et al.* 2011; Nitschke and Innes 2013).

Finally, despite all the identified limitations, the developed approach consistently points towards an increasing of: (*i*) the meteorological fire danger; (*ii*) having much larger fire events; (*iii*) inter-annual variability of the fire regime under future climate, which together with the positive bias will have dramatic consequences at the social, economic and environmental levels. These conclusions could be even more dramatic as an increase of the fire season length is very likely to be expected in boreal and temperate climates (Flannigan *et al.* 2009; Wotton *et al.* 2010; Carvalho *et al.* 2011; Westerling *et al.* 2011; Kloster *et al.* 2012).

Abstract
Large forest fires are of great concern in all fire prone countries. Understanding them and predicting the possibility for their occurrence can be very helpful for forest fire management. They usually occur under very adverse fire weather conditions so any investigation about them is sure to take this into consideration. The Fire Weather Index (FWI) of the Canadian Forest Fire Danger Rating System which enjoys very broad use not only in the vast forests of Canada but also in other parts of the world, is a composite index that represents fire weather conditions quite well. The study presented here is an investigation of the possibility to associate fire weather conditions, as captured by FWI, with the occurrence of large forest fires in the broader area around Athens, the capital of Greece. It is based on forest fire data from the Greek Fire Service for the 2003-2011 period, matched to FWI values for this period, calculated using gridded observation data from the ERA Interim data sets, that were interpolated using the Thin Plate Spline Technique in order to obtain high resolution (1 km) spatial analysis data. Correlations between FWI and burned area per fire proved to be very poor, precluding regression modelling, so an alternative analysis method was used in order to determine, according to the data for the study period, the minimum FWI above which it is possible for fires to exceed certain burned area thresholds.

Keywords*: Fire Weather Index (FWI), large forest fires, Athens, Attica, Greece*

Introduction

In the world of forest fire management the need for understanding and prediction of fire ignition probabilities and difficulty of control is the main reason for collecting fire statistics and for the development and use of fire danger rating systems. A significant number of such systems have been developed around the world, some having more global characteristics and use than others. Among them the Canadian Forest Fire Danger Rating System (CFFDRS) (Stocks *et al*. 1989, Forestry Canada Fire Danger Group, 1992) enjoys very broad use not only in the vast forests of Canada but also in other parts of the world including Europe where the System's Fire Weather Index (FWI) was evaluated favourably, among others, by Viegas *et al*. (1999) in comparison with four other methods of fire danger evaluation, and was adopted since 2007 at the EU level by the European Forest Fire Information System (EFFIS) of the Joint Research Centre of the European Commission (http://forest.jrc.ec.europa.eu/effis). The FWI was also evaluated favourably by Dimitrakopoulos *et al*. (2011) and by Karali *et al*. (2014) in Greece. Both these studies proposed FWI value classes for association with fire danger.
Although the FWI, according to most evaluation studies produces good predictions, its use can become much more meaningful for use in operational fire management if it is further investigated and calibrated to the specific fire conditions in the region where it is to be applied (e.g. Fogarty *et al*. 1998, Rainha and Fernandes 2002). Furthermore, it makes sense to examine if its predictions and utility can be improved by introducing additional information to the one already required for FWI calculation.

The study presented here is an investigation of the fire weather conditions leading to large forest fires in the broader area around Athens, the capital of Greece. It was prompted by the operational need to tie the potential for such fires to FWI, in conjunction with the finding of studies like the one by Dimitrakopoulos *et al*. (2011) that the Fire Weather Index (FWI) while highly correlated to fire occurrence is only moderately correlated to burned area.

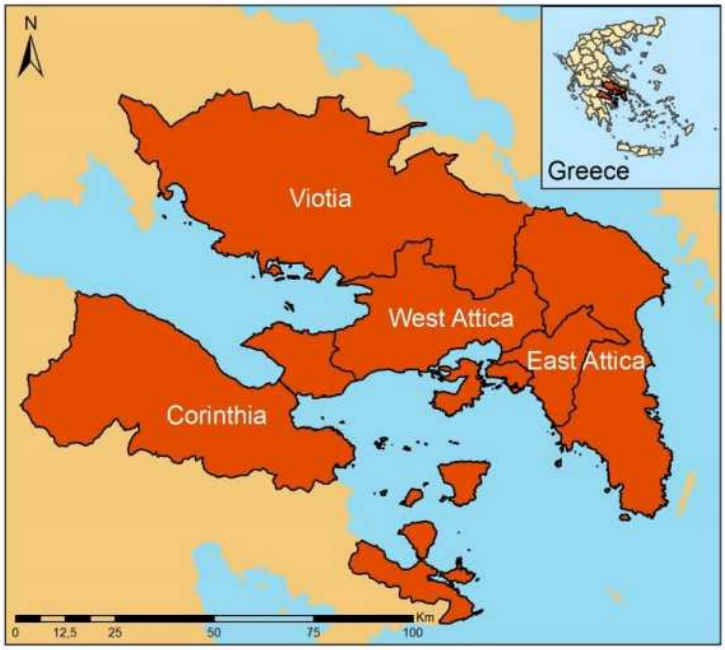

Figure 1. Map of the study area in Greece.

Methods

The study area covered the prefectures of East Attica, West Attica, Corinthia and Viotia (Figure 1). For this area forest fire data (dates, number of fires, burned area) for the 2003-2011 period, were obtained from the Greek Fire Service. Meteorological data were obtained from the ERA Interim data set (Dee *et al*. 2011) at a horizontal resolution of 0.75° (approximately 82km). The gridded meteorological data were firstly interpolated from the 82 km grid to a high spatial resolution 1-km grid using the 3D Thin Plate Spline technique (Hutchinson 1998). Subsequently, the interpolated meteorological data were used to calculate FWI values for a particular representative site on Mount Hymettus near Athens. Forest fire data were then matched to the calculated FWI values. Further to this, each fire was associated with representative predawn water potential (WP) measurements for roughly the same day, collected during the 2003-2011 period on the same site on Mount Hymettus (Xanthopoulos *et al*. 2006). These WP measurements were carried out for three representative Mediterranean species: *Pinus halepensis*, *Quercus coccifera and Cistus creticus.* This trial aimed to examine if the drought experienced by the living forest plants can play an important role in the occurrence of large fires in addition to the influence of the current weather condition captured by the FWI.

Analysis and results

The total number of fires reported in the four prefectures in the period of interest reached 6,860. They had burned a total area of 43,569 ha, roughly 5% of the study area. Some of them were identified as

non forest fires (e.g. agricultural residue burning) and were dropped from the database. The rest of the fires were analyzed putting emphasis on the large fires that occurred in this time period.
The FWI for all days with fire, varied between 0.0001 and 102.92. On the day of the highest FWI (August 22, 2010) six fires were reported. Their burned area ranged between 0.05 and 7 ha. The maximum burned area for one fire was 17,500 ha. This historic fire started on August 21, 2009, under an FWI of 71.845.
Focusing on large fires, a sub-sample of the data set was created with all fires having a burned area equal to or larger than 10 ha. The number of observations was 175. This smaller data set was examined in regard to the correlation of burned area with FWI. The Pearson correlation proved to be very low (0.133) and non-significant. The existence of the large 17,500 ha fire of August 2009 in the dataset was considered as a probable reason for this low correlation. However, even when this data point was removed (N=174), the correlation reached only 0.183 and became significant at the 0.05 level (2-tailed). Obviously, these low correlations preclude any effort for predictive regression modelling. Figure 2 is a plot of the 174 point data set, after omission of the 17,500 ha fire.

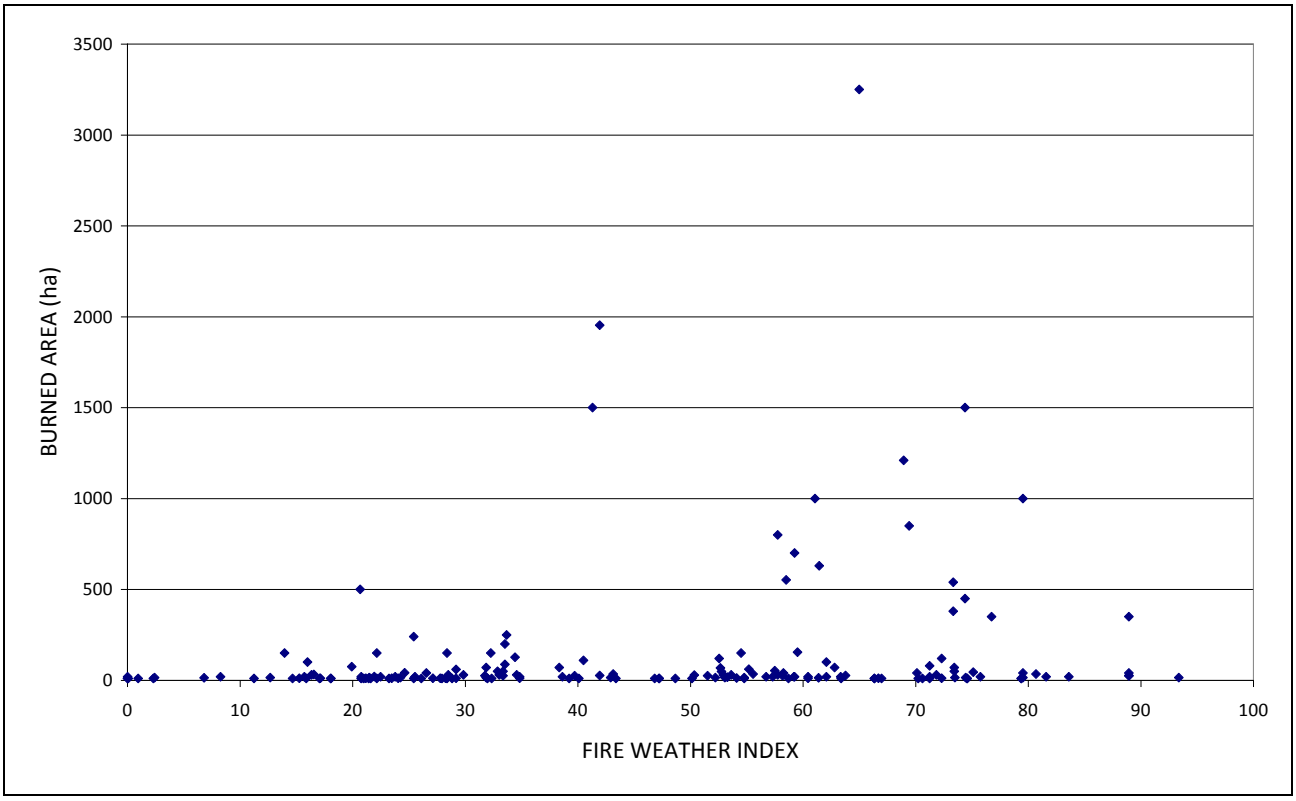

Figure 3. Plot of the Fire Weather Index versus the burned area of the 174 largest fires in the study region in the 2003-2011 period, omitting for scaling purposes the largest fire of 17,500 ha that occurred under a FWI of 71.845

The water potential data for the three species examined also had poor correlation with burned area. The same was true when the product of FWI with water potential was examined for correlation with burned area, so at this stage the WP data were not examined further.
These results illustrated the problem of the potential discrepancies between FWI and burned area and called for a different ad-hoc approach for analysing the data set in regard to large fires. This approach was as follows: selecting sub-samples of the database that included only the fires that burned an area larger than a specific threshold (ha), the minimum FWI and maximum FWI for each sub-sample were entered in a table (Table 1) and were also plotted against that threshold.

Table 1. Number of fires, Minimum FWI, and Maximum FWI for subsets of the complete dataset that each included only the fires above a selected burned area threshold (ha).

Burned Area Threshold (ha)	Number of fires	FWI Min	FWI Max
10	175	0,00705	93,37405
20	100	0,01265	88,93933
30	69	13,95373	88,93933
40	56	13,95373	88,93933
50	48	13,95373	88,93933
60	44	13,95373	88,93933
70	41	13,95373	88,93933
80	36	13,95373	88,93933
90	34	13,95373	88,93933
100	34	13,95373	88,93933
110	32	13,95373	88,93933
120	31	13,95373	88,93933
130	28	13,95373	88,93933
150	28	13,95373	88,93933
170	22	20,67158	88,93933
200	22	20,67158	88,93933
250	20	20,67158	88,93933
300	19	20,67158	88,93933
350	19	20,67158	88,93933
400	16	20,67158	79,54018
500	15	20,67158	79,54018
600	12	41,3183	79,54018
700	11	41,3183	79,54018
800	10	41,3183	79,54018
900	8	41,3183	79,54018
1000	8	41,3183	79,54018
1200	6	41,3183	74,38725
1400	5	41,3183	74,38725
1600	3	41,3183	74,38725
1800	3	41,3183	74,38725
2000	2	64,99238	71,84505
3300	1	71,84505	71,84505

As shown in table 1, 175 fires had each burned an area equal to or exceeding 10 ha (N_{10}=175). The minimum FWI value among these fires was 0.007 and the maximum FWI was 93.374. This means that a fire may reach or exceed 10 ha even at an FWI=0.007.

When setting the threshold at 20 ha the number of fires dropped to N_{20}=100, the minimum FWI was 0.012 and the maximum FWI was 88.894. This means that even at this minimum FWI value a fire may exceed 20 ha. The smaller maximum FWI value in this subset means that a fire that occurred with an FWI of 93.374 and was included in the previous subset because it had burned over 10 ha, did not exceed the 20 ha threshold and was left out of this second subset.

The next subset with the threshold burned area set at 30 ha, had a minimum FWI of 13.95 and N_{30}=69. The same minimum FWI remained for the next subsets until the threshold was set to 170 ha (N_{170}= 22) and the minimum FWI became 20,672.

Following the same logic, the plot of Figure 3 was created. It shows the minimum FWI thresholds that make it possible for fires to exceed initial attack capabilities and, as long as there is available fuel in their path, to become large or very large.

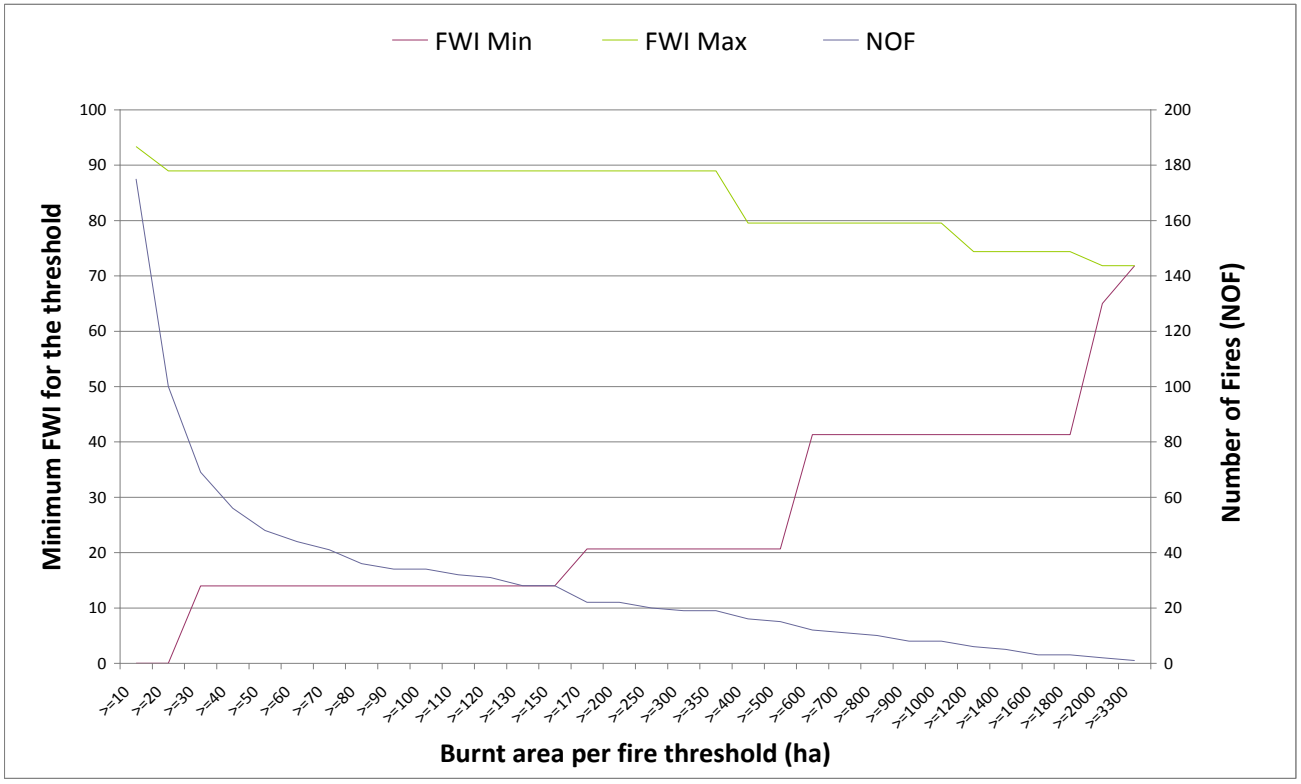

Figure 3. Minimum FWI that may allow forest fires to exceed certain burned area thresholds for the conditions (vegetation, firefighting resources, etc.) in the study area around Athens, in Greece.

Discussion and conclusions

The efforts spent looking for a mathematically expressed relation between FWI and burned area did not produce any results. This is in agreement with the conclusions of Dimitrakopoulos *et al*. (2011). It is clear that whereas fire ignition probabilities correlate reasonably well with the weather conditions as captured by FWI, things are quite different in regard to burned area. The varying capability of firefighting resources, temporally and spatially, is a significant factor affecting the evolution of each fire. The existence of fuel in the path of a fire is also another important factor that acts randomly on every fire depending on where it starts and on the direction of its spread. Further to the above, there are various sources of errors in the data set that may have added "noise" reducing correlations further. These sources of error are:

- Inaccuracy of reported burned area per fire by the Fire Service (it is called an estimate, not a measurement)
- Calculation of FWI over broad areas rather than based on the local conditions of each fire.
- Using one value of water potential per species (average of two measurements) from one location in Attica and from the closest available date to the date of the fire.

On the other hand, the alternative method of analysis used here, as shown in Table 1 and Figure 3, provides some thresholds that can be useful for setting mobilization levels according to predicted

weather conditions and FWI, and also for guiding pre-fire positioning of firefighting resources and for supporting dispatching decisions in case of fire eruption. More specifically, it can be concluded that:

- If the FWI exceeds 0,01 fires exceeding 20 ha are possible.
- If the FWI exceeds 13,95 fires exceeding 30 ha are possible.
- If the FWI exceeds 13,95 fires exceeding 30 ha are possible.
- If the FWI exceeds 20,67 fires exceeding 170 ha are possible.
- If the FWI exceeds 41,32 fires exceeding 600 ha are possible.
- If the FWI exceeds 64,99 fires exceeding 2000 ha are possible.
- If the FWI exceeds 71,84 fires exceeding 3300 ha are possible.

Abstract
Wildland fire is an important component of the earth system and global carbon cycle, burning about 350 M ha of vegetated land and contributing 2.0 Pg C to the atmosphere in direct emissions every year. Wildland fire carbon emissions are directly related to fuel consumption, which is a key component of fire behaviour. Fuel consumption varies greatly by fuel (vegetation type, load, size, spatial distribution, moisture content) and weather (temperature, relative humidity, wind speed, rainfall) parameters. In forested regions where wildfires may burn for extended periods of time, carbon emissions can vary by an order of magnitude between stands within a single fire due to complex fuel structures and distribution patterns, and constantly changing fire weather conditions. Modelling stand-level fire behaviour and carbon emissions and compiling simulation results over large areas is commonly used as a bottom-up approach to summarizing fire regimes and estimating wildland fire emissions at large scales.
This paper presents a summary of studies simulating stand-level fire behaviour and carbon emissions using the Canadian Fire Effects Model (CanFIRE). CanFIRE simulates fire behaviour in standing timber, grass, and slash vegetation types, or combinations of these vegetation types. In standing timber vegetation types, the forest stand is simulated as 3 distinct fuel components: forest floor (herbaceous plant, litter and organic soil layers), surface fuels (dead woody debris), and overstory (tree) fuels. Modelled fire behaviour and carbon emission results from studies in various global regions of different vegetation types and climate zones are presented, including comparisons using different fuels and weather/climate datasets and comparison to other carbon emission estimation methods. Sensitivity of the model outputs to driving input variables is presented. In particular, the influence of stand composition, structure, surface fuel load and distribution, and organic soil characteristics are reviewed. Annual and seasonal trends in fire behaviour and carbon emissions are also presented. Recommendations for basic data standards to provide reliable and consistent modelling results are discussed.

Introduction

Numerous studies have been conducted over the last decade to estimate wildland fire carbon emissions using various models and methods (e.g., French *et al*. 2011). Global-level estimates have been produced using the Global Fire Emissions Database (GFED3) (Van der Werf 2010). At national and sub-national scales, wildfire carbon emissions are typically estimated using a fire behaviour-based, bottom-up method using models such as the Canadian Fire Effects Model (CanFIRE, de Groot 2006, 2010), the First Order Fire Effects Model (FOFEM, Reinhardt *et al*. 1997), CONSUME (Ottmar *et al*. 2009) and the Wildland Fire Emissions Information System (WFEIS, French *et al*. 2009), which is based on the CONSUME model. These models quantify fuel consumption at the stand level and scale-up by aggregating stand emissions data over landscapes with fire mapping products (e.g., de Groot *et al*. 2007, French *et al*. 2011) Stand-level fuel consumption can be calculated with fuels data from a variety of sources and spatial resolution, and fire weather data with a range of spatial and temporal resolutions. Using different databases with various scales contributes to the variability of wildland fire carbon emission estimates that are produced (c.f., French *et al*. 2011). Adding to this uncertainty is that there are very few verified field data sources to compare with modelled results (Ottmar 2014).

The purpose of this paper is to review applications of the Canadian Fire Effects Models to estimate carbon emissions in the circumpolar boreal forest region, in North American forests (including boreal and western forest regions), and within the Canadian boreal forest region, and to compare results using different fuels and weather data bases at different scales.

The Canadian Fire Effects Model

The Canadian Fire Effects Model (CanFIRE) is an integrated science-management model of the Canadian Forest Fire Danger Rating System (Stocks *et al*. 1989). It was originally developed as the Boreal Fire Effects Model (BORFIRE) to conduct fire, climate change, and vegetation dynamics research in the Canadian boreal forest (de Groot *et al*. 2002, 2003). The model was later expanded to include all Canadian forest regions (renamed CanFIRE) for use as an operational model to calculate annual national wildland fire carbon emissions (de Groot 2006, de Goot *et al*. 2007). The model has since been re-designed for fire and forest management applications and is available as an Excel spreadsheet[1], a cross-platform Windows and Unix application[1], and as a web application[2].

CanFIRE simulates stand-level physical and ecological fire effects. It is a fire behaviour-based model driven by fuels and fire weather data. Fuels are characterized by tree species in the stand (including age, height, dbh, and density data) and fuel loads for stand components of the forest floor (litter and other fine fuels, fermentation, and humus layers), dead and downed woody debris (multiple roundwood diameter size classes), and aboveground tree biomass (live and dead; stem, branch, bark and foliage components). Fire weather data are provided to CanFIRE using the Canadian Forest Fire Weather Index (FWI) System (Van Wagner 1987) components. The model calculates fire behaviour (rate of fire spread, fuel consumption, type of fire, and fire intensity) and resulting physical (depth of burn, crown scorch, carbon emissions) and ecological (tree mortality/survival, regeneration rate, long-term post-fire succession) effects. CanFIRE uses the rate of spread algorithms of the Canadian Forest Fire Behavior Prediction (FBP) System (Forestry Canada Fire Danger Group 1992); type of fire is determined using Van Wagner's (1977) crown fire threshold model; fuel consumption is calculated using fuel load data and new fuel consumption algorithms (de Groot *et al*. 2009); and resulting fire intensity is calculated using Byram's (1959) equation. CanFIRE can be used to simulate fire behaviour and effects of a single fire event, or the accumulated effects of many fires occurring over many years on a defined landscape (i.e., simulating fire regime).

CanFIRE has been modified and used for numerous fire and carbon modelling applications in different regions since the original BORFIRE model. The purpose of this paper is to provide a review of CanFIRE applications to estimate wildland fire carbon emissions using different data sources and simulation methods, and to compare with results from other emission models.

Wildland Fire Carbon Emission Studies with CanFIRE

Circumpolar Boreal Fire Carbon Emissions

A comparison of wildfire carbon emissions in western Canada and central Siberia, Russia during 2001-2007 was conducted with remotely-sensed area burned polygons and fire weather data used to simulate fire behaviour and carbon emissions with CanFIRE (de Groot *et al*. 2013a). Russia-specific fuel models were setup in CanFIRE by assigning an FBP System fuel type, and adjusting tree heights and crown length factors for Russian tree species. The primary effect of this was to adjust the crown fire

[1] Contact Bill de Groot (bill.degroot@nrcan.gc.ca) or Alan Cantin (alan.cantin@nrcan.gc.ca)
[2] http://www.glfc.forestry.ca/canfire/index.cfm

threshold for Russian boreal tree species. Fuels load and type data were obtained from national sources and fires were mapped with different remote sensing products. As a result, input data had different spatial characterization and resolution. However, the data was sufficient to calculate stand-level fire behaviour for all large (>200ha) fires in both study areas for the 7-year period. All fires were burned using fire weather conditions interpolated from station data to all MODIS hot spots within a 1 km buffer around each fire and taking the mean, thus weighting the fire weather to the date of greatest fire activity. Results of the study comparison indicated divergent continental fire regimes in the circumpolar boreal region, which was attributed to differences in tree species morphology and fire ecology traits. In particular, the fire regime of the Canadian study area was characterized by infrequent, very large, high intensity crown fires; whereas, the Russian study area was characterized by moderately frequent, large surface fires of moderate to high intensity (Table 1). Fire seasons were also different with most large fires occurring in Russia in the spring, and during summer in Canada. The carbon emissions rate (t C·ha^{-1} within burned area polygons) in Canada was 50% higher than in Russia mostly because of higher forest floor fuel loadings and fuel consumption but also, to a lesser degree, due to higher crown fuel consumption rates in Canada. However, the total C emissions rate (t C·ha^{-1} per 100 M ha of forest area) was two times greater in Russia because of the much higher annual area burned rate.

CanFIRE was also used to simulate C emissions in the same Canadian and Russian study areas under future climate change scenarios (de Groot *et al*. 2013b). That study examined the impact of changing fire weather on carbon emissions by the end of this century. Three Global Climate Models (Canadian CGCM3.1, HadCM3, and IPSL-CM4) and three climate change scenarios (A1B, A2, and B1) (IPCC 2000) were used to determine nine sets of future fire weather conditions for the CanFIRE simulations. All climate change models and scenarios indicated greater fire weather severity across the circumboreal region, although conditions will be slightly more severe in the western Canada study area. The future fire season will have two extreme fire intensity peaks in western Canada in spring and later summer, and one extreme peak in central Russia in late spring/early summer. Higher carbon emission rates (t C·ha^{-1}) will occur in western Canada due to a higher fuel consumption rate but central Russia will have greater total carbon emission rates (t C·ha^{-1} per 100 M ha forest area) due to higher annual area burned rates.

Table 1. Summary of annual average fire regime characteristics in western Canada and central Russia boreal forest during 2001-2007 (de Groot et al. 2013a)

	Canadian Study Area	Russian Study Area
Number of fires (per 100 M ha forest)	93.7	1441.9
Area burned (M ha/100 M ha forest)	0.56	1.89
Mean fire return interval (yrs)	179.9	52.9
Large fire size (ha)	5930	1312
Crown fire (%)	57.1	6.5
Head fire intensity (kW/m)	6017	4858
Fuel consumption (kg/m^2)	5.68	3.73
C emissions rate (t/ha)	28.4	18.5
Total C emissions rate (Mt/100 M ha forest)	15.8	35.0

North American Wildland Fire Carbon Emissions

In a study of six terrestrial models, French *et al*. (2011) compared wildland fire carbon emissions from five large fires across North America. CanFIRE was applied to the three forest-dominated fires of that study, but not to the two fires in southern California chaparral because CanFIRE does not currently

have a shrub fuel model. Fuels data for the large fires in Oregon and Alaska were provided from the Fuels Characteristic Classification System (FCCS, Ottmar *et al*. 2007) and from fuel load models of Lutes *et al*. (2009). Fuels data in the Saskatchewan large fire were obtained from provincial forest inventory and interpreted as FCCS fuels. All fires burned over many days and were simulated in CanFIRE and WFEIS as multi-day events using daily fire progression (as determined by MODIS hot spots) and daily fire weather data. Additional WFEIS, CONSUME and FOFEM estimates were obtained using single day simulations with standard fuel moisture scenarios. FBP estimates were multiple day simulations using FBP System fuel types interpreted from the FCCS data (Oregon and Alaska) or forest inventory data (Saskatchewan).

Despite using the same original fuels and weather databases, emission estimates showed considerable variation depending on model and fire location. A detailed field-based survey of carbon emissions was available for the Oregon Biscuit fire (Campbell *et al*. 2007), which reported an average carbon emissions rate of 1.9 kg $C \cdot m^{-2}$. The CanFIRE estimate was 3% higher, and FOFEM 5.7 ranged from 17% lower to 4% higher (3 scenarios using revised fuels map); the FBP System was 11% lower, GFED was 14% higher, CONSUME 3.0 was 10-30% lower (3 scenarios using revised fuels map), and WFEIS was 61-63% higher (3 scenarios using revised fuels map). A field-based survey was also available for the Alaska Boundary fire, resulting in an emissions rate of 2.59 kg $C \cdot m^{-2}$. For that fire, the GFED estimate was 14% lower, CONSUME was 10-45% lower, CanFIRE was 40% higher, the FBP System was 48% lower, and FOFEM was 73-136% higher. Field data were not available for the Saskatchewan Montreal Lake fire for comparison, but the estimated emission rates were 0.79 kg $C \cdot m^{-2}$ (FBP), 1.26 kg $C \cdot m^{-2}$ (GFED), 1.6 kg $C \cdot m^{-2}$ (WFEIS), 2.32 kg $C \cdot m^{-2}$ (CanFIRE), 2.23-3.32 kg $C \cdot m^{-2}$ (CONSUME), and 4.76-6.51 kg $C \cdot m^{-2}$ (FOFEM). A previous estimate for the same fire using CanFIRE and national forest inventory data (Power and Gillis 2006) was 1.70 kg $C \cdot m^{-2}$, and using the national fuels database (Nadeau *et al*. 2005) with the FBP System was 1.20 kg $C \cdot m^{-2}$.

Canadian Wildland Fire Carbon Studies

CanFIRE has been used operationally since 2004 to calculate annual national wildland fire carbon emissions as part of the National Forest Carbon Monitoring, Accounting and Reporting System (Kurz and Apps 2006) to meet United Nations Framework Convention on Climate Change and other international reporting obligations (de Groot *et al*. 2007). CanFIRE was modified to utilize a national database of carbon pools provided by the Carbon Budget Model of the Canadian Forest Sector (CBM-CFS3, Kurz *et al*. 2009) as a replacement for fuel type and fuel load data. This is a spatially-explicit procedure using primarily satellite-mapped burned areas, daily hot spots and fire weather data. In brief, every forest stand within each mapped fire perimeter was burned in the model as a single-day event. Fire weather was calculated by interpolating FWI System values to each MODIS and AVHRR hot spot, and averaging all those data annually for the fire season for each ecoregion-provincial unit, and applying those results to all fires contained in each unit. In this way, the FWI system data are weighted by days of highest fire activity within the ecoregion-provincial unit for the year.

More recently, 43 large fires from Ontario, Saskatchewan, Alberta, and British Columbia were used in an ongoing study to compare Canadian wildland fire carbon emissions using different fuels data and simulation methods. The initial phase of the study examined 24 large boreal wildfires from 2006–2008 ranging in size 95–62,670 ha. These fires were selected because they occurred in areas where detailed provincial forest inventory data were available, which allowed stand-level simulations with CanFIRE to calculate direct carbon emissions. In a second analysis, an additional 10 large fires (446–22,116 ha) occurred in Alberta during the same time period and were combined with the original 24 fires plus 9 large fires from 2010 (1,943–28,182 ha) in British Columbia and used for carbon emission calculations using the national fuel type map of Nadeau *et al*. (2005) (resolution of 1 km^2) and standard fuel loads for FBP System fuel types. The fires were simulated as a single-day event (date selected by weighted average of hot spots), and as a multi-day event (daily fire spread using hot spots) for comparison.

Results using the large scale national fuels database (n=43 fires) and standard FBP System fuel types and fuel loads showed very little difference when using single- or multi-day simulations (Figure 1). Emissions were generally higher in Alberta and lower in Ontario. In the comparison of 33 fires with forest inventory available to use as input fuels data (Figure 2), carbon emission estimates increased for the British Columbia fires and decreased for all others, including a very sharp decrease in the Alberta and Saskatchewan fires (although there were only two large fires in Alberta with forest inventory available). These results were consistent for both single- and multi-day simulations. When all provincial data were combined, the forest inventory method produced lower carbon emissions estimates than the FBP method. Overall, there was almost no difference between single- and multi-day estimates (Figure 3).

Discussion

The previous studies using CanFIRE to estimate wildland fire carbon emissions have demonstrated that many different fuel and weather data sets can be used as input variables to CanFIRE (Table 2). The question of which database and/or what data resolution is the most appropriate or accurate to use is still not clear. As Ottmar (2014) pointed out, there are very few datasets available to test model accuracy, and there is also very little information available about the sensitivity of models to data input variability.

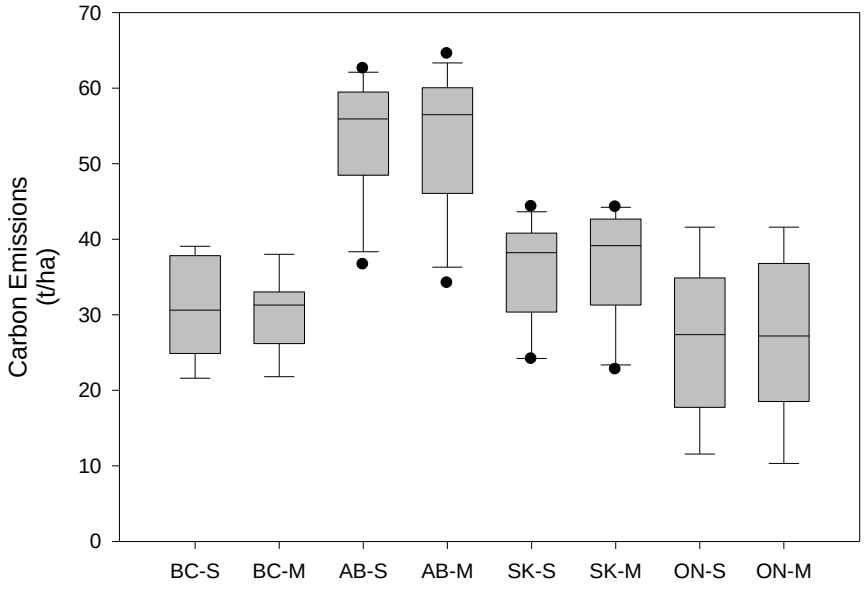

Fig 1. Summary of wildland fire carbon emissions in the provinces of British Columbia (BC) (n=9), Alberta (AB) (n=12), Saskatchewan (SK) (n=13), and Ontario (ON) (n=9) using single-day (S) and multi-day (M) simulation methods with CanFIRE. Fuels data were obtained from the spatial national fuel type map of Nadeau et al. (2005) using standard fuel loads for FBP System fuel types.

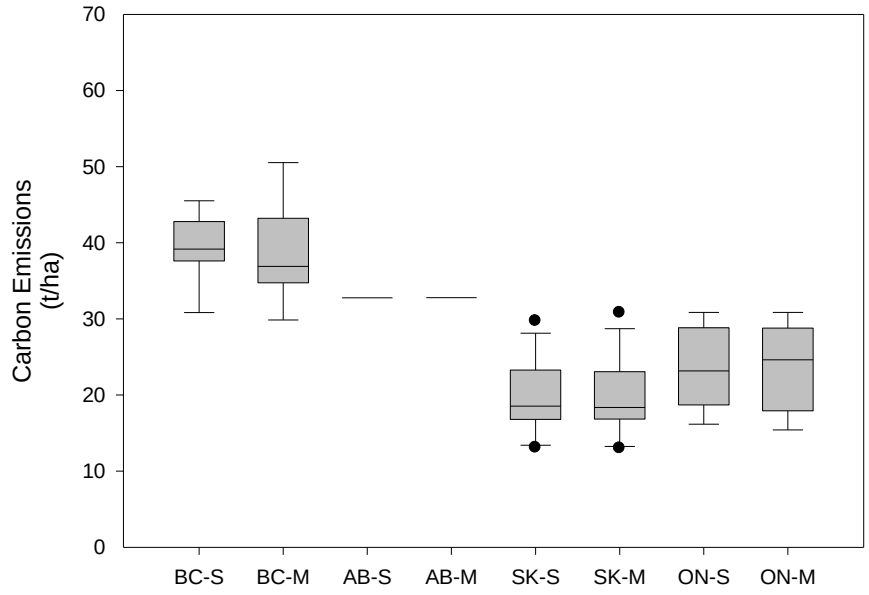

Fig 2. Summary of wildland fire carbon emissions in the provinces of British Columbia (BC) (n=9), Alberta (AB) (n=2), Saskatchewan (SK) (n=13), and Ontario (ON) (n=9) using single-day (S) and multi-day (M) simulation methods with CanFIRE. Spatial provincial forest inventory was used to interpret stand-level species composition and corresponding fuel load was calculated using forest inventory with provincial growth and yield models.

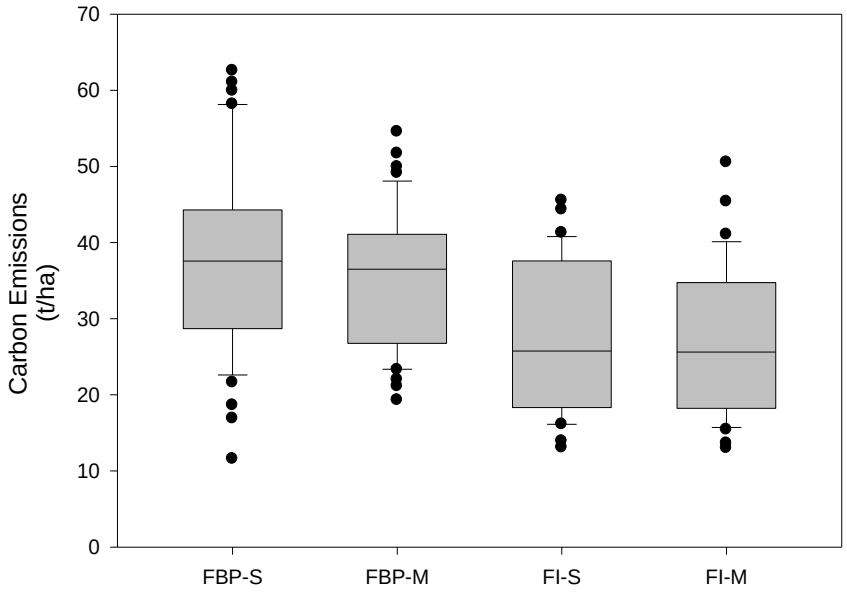

Fig 3. Summary of average wildland fire carbon emissions in the provinces of British Columbia, Alberta, Saskatchewan, and Ontario using the national fuels database (FBP) and provincial forest inventory (FI) for fuels information, and using single-day (S) and multi-day (M) simulation methods with CanFIRE.

One of the most important observations in comparing these wildland fire carbon emissions studies is the influence of fuels input data. The CanFIRE estimate of emissions on the Montreal Lake fire in French *et al*. (2011) was almost twice as high as the previous estimate in de Groot *et al*. (2007), which was entirely the result of different input fuels data. Similarly, emission estimates using CONSUME

and FOFEM on the Biscuit fire were up to three times higher for the same model, depending on the fuels data source (original and revised fuels maps; French *et al*. 2011). The impact of different fuels data on emission estimates was also identified in the circumboreal comparison study (de Groot *et al*. 2013a), which showed substantially higher carbon emissions rates (t/ha) from Canadian fires than Russian fires. That result was attributed to underestimated forest floor fuel loads in the Russian database because fire weather conditions were fairly similar.

French *et al*. (2011) provide a good summary of differences in the six tested models that can lead to different emission estimates. In that study, emission estimates from a few models aligned fairly close on some fires but not on others, and there was no obvious overall trend. This suggests that wildland fire emission models may need to be regionally calibrated. However, one common result was that FBP System estimates were lower than most of the other model estimates. This agrees with previous results from de Groot *et al*. (2007) that indicated FBP System estimates were about 30% lower than CanFIRE estimates in central Canada. Low emission estimates from the FBP System are attributed primarily to an underestimation of forest floor fuel consumption. CanFIRE uses more recent forest floor fuel consumption algorithms (de Groot *et al*. 2009) than currently included in the FBP System, but which will be incorporated in the next generation FBP System.

Table 2. Summary of fire simulation methods, weather and fuels data for wildland fire carbon emission studies using CanFIRE

Study	Fire simulation method	Weather data		Fuels data	
		Source	Resolution	Source	Resolution
Boreal fire emissions in Canadian and Russian study areas (2001-2007) (de Groot *et al*. 2013a, 2013b)	Canadian large fires burned as single day events on most active fire day (by MODIS hot spots)	Canadian national weather station network	Daily	National fuel type map, standard FBP fuel loads	1 km^2
	Russian large fires burned as single day events on most active fire day (by MODIS hot spots)	Russian national weather station networks	Daily	National forest carbon database	Ecoregion and oblast-level summaries (semi-spatial)
North American study (French *et al*. 2011)	3 large fires (Oregon, Alaska, Saskatchewan) burned as single and/or multi-day events	Nearby fire weather stations	Daily	FCCS and FLM[a]	1 km^2
Canadian annual carbon emissions reporting (de Groot *et al*. 2007)	All fires burned as single day event using averaged fire weather from active fire days	National and provincial fire weather station network	Daily, averaged seasonally by hot spot occurrence over ecoregion-provincial units	CBM-CFS3 carbon pools	Stand-level
Canadian large fires	Large fires burned as single- and multi-day events	National and provincial fire weather station networks	Daily	National fuel type map and standard FBP system fuel loads	1 km^2

[a] Fuel Characteristic Classification System (Ottmar *et al*. 2007) and Fuel Loading Models (Lutes *et al*. 2009)

The amount of detail (or scale) to use for wildland fire emissions modelling has been a lingering question. Forest inventories have many advantages as a fuels data source: they are small scale (stand-level), have detailed species information for fuel typing, integrate well with forest growth and yield models for dynamic fuel modelling, and integrate well with tree biomass algorithms to properly distribute fuel load in multiple stand components. However, there are many deficiencies: inventories are often old, they are only as reliable as the original photo interpretation and areas are so vast that ground checking is often limited, fuels data for some stand components are usually missing (e.g., forest floor and dead woody debris), inventory methods are usually not consistent across land jurisdictions which makes large scale simulation difficult, and there are many areas without forest inventory. There are numerous other vegetation, fuels, and biomass inventories that can be used for calculating wildland fire emissions, and all will produce different results. The question remains: what are the best criteria to use for selecting a fuels database, understanding that many factors have to be balanced (i.e, accuracy vs. efficiency)? It is still an open question because test datasets to assess accuracy are very few. However, large-scale data consistency is important in terms of modelling efficiency. At this point, the general recommendation is to use stand-level data if it is consistent in content across the simulation area, and if not available, then to use coarser resolution fuels data at a larger scale. To provide the best fire behaviour-based estimate of wildland fire carbon emissions, the selected fuels database should provide fuel type and load data that can be separated into discreet stand components (forest floor, dead woody debris, tree crown, etc.) in order to properly simulate stand-level fire behaviour dynamics.
In terms of temporal scale, the question of detail is much less critical. In the Canadian fire study, CanFIRE emission estimates showed very little difference between single- and multi-day simulations (Figure 1-3) even though some fires burned for over a month. The comparison of single- and multi-day WFEIS simulations (French *et al*. 2011) also showed the same results. This suggests that the procedure used for single-day simulation (i.e., using fire weather and fuel moisture data based on daily-weighted hot spot occurrence) captures the most important weather information driving these fire behaviour-based models.

Conclusions

Fuels data source is a critical factor influencing wildland fire carbon emission estimates for all fire behaviour-based models, including CanFIRE. Consistency in data content across the simulation area is important, and it is preferable to have stand-level detail so that fuel load can be distributed in the different stand components. Multiple-day simulations of fire spread do not appear necessary, as single-day simulations using a hot spot-weighted average of daily fire weather provide very similar emission estimates.

Acknowledgments

We thank David McNeice for preparing the FBP System database; Nathan Sauvé for translating provincial inventory to CanFIRE input data; Edward Fong (Inventory Branch, BC Ministry of Forests) for providing VRI data; and Richard Carr and Peter Englefield (CFS) for providing FWI System data.

Abstract
The possibility of reducing losses caused by forest fires, apart from preventative activities, should be sought primarily in limitation of the area burnt as a result of fires. This objective may be achieved through optimisation of extinguishing activities. The basic requirement of such activities is accurate forecasting of forest fire risk depending on meteorological and physical conditions in forests. The purpose of the research was to prepare a new method of forecasting forest fire risk, which would enable a more precise method of evaluation of the risk of an outbreak of fire in relation to existing and forecast meteorological conditions in forests.

Establishing provisional assumptions of the new method accepted:
- possibility of determining actual fire risk,
- possibility of forecasting forest fire risk for the afternoon hours in the morning hours of the given day and the following day,
- possibility of forecasting the moisture content of pine litter (Pinus silvestris L.),
- preparation of a method enabling limitation of fire prevention system operating costs.

To enable drawing up a fire risk forecast (in the morning for the hours of the afternoon and the following day) formulae were drawn up equally enabling calculation of predicted moisture content of pine litter on the basis of its actual current values and forecast meteorological values. The basis for assessment of the proposed method were data relating to the frequency of occurrence of particular degrees of risk, average number of fires in forecast zone depending on the degree of risk and also the average area of fire at the given degree.
The drawn up method is based on moisture measurements of flammable material, which has a significant relationship to its precision. Selection of test material – pine litter is adjusted to the specific conditions occurring in the majority of pine stands (Pinus silvestris L.) in Poland. As a result of the work it was possible to create a prognosis method enabling precise establishment of the fire risk in forests according to the accepted assumptions. The results obtained during testing of this method indicate a high accuracy in forecasting fire risk and a satisfactory precision of formulae for calculating moisture content of litter. On this basis it may be stated that the drawn up method enables a decidedly better means to define the actual fire risk, simultaneously providing its forecast for later hours and it is currently introduced for application in fire protection of Polish forests. Such a solution may bring about a significant limitation of fire protection operating costs in forests and facilitate organisation of the work of the services responsible for it.

***Keywords**: Forecasting fire risk, forest fires, moisture of flammable material*

Introduction

Permanent increase of fire risk, the effect of which is the increasing number of fires and area burnt and also the increasing operating costs of the fire prevention system were the stimuli to undertake research intended to limit fire losses. The possibility of reducing losses, apart from prevention activities, should be sought primarily in limiting the surface area burnt as a result of fires. This objective may be achieved by optimising fire extinguishing activities. The basis for this is accurate forecasting of fire risk of forest based on meteorological and physical conditions prevailing in the forest. This information enables specification of the required state of operational readiness of the services responsible for forest fire prevention.

The objective of the research was the drawing up of a new method of forecasting the risk of forest fire, which enables a more precise means of evaluation of the risk of occurrence of fire in relation to actual and forecast conditions in forests.
The basis for evaluation of conditions of the occurrence of fires in forests was data of the National Forests from the years 2002-2008. This analysis equally included the occurrence of fires in relation to stand conditions, types of fires, temporal analysis of occurrence in particular months and times of day, as also the occurrence of fires in relation to meteorological conditions.

Methods and results

On the basis of this analysis it may be clearly seen, that most of the frequently burning stands are pine of a young age class growing in coniferous habitats. The decided majority of them are fires of the soil covering, which constitutes 85.5% of the general number of fires. The majority of fires occur from March to September, and the most, close to 25% occur in April. Approximately 70% of all fires in total occur between the hours of 11.00 and 19.00. Whereas the greatest intensity - 10.7% occurs at the hour of 15.00. (figure 1)

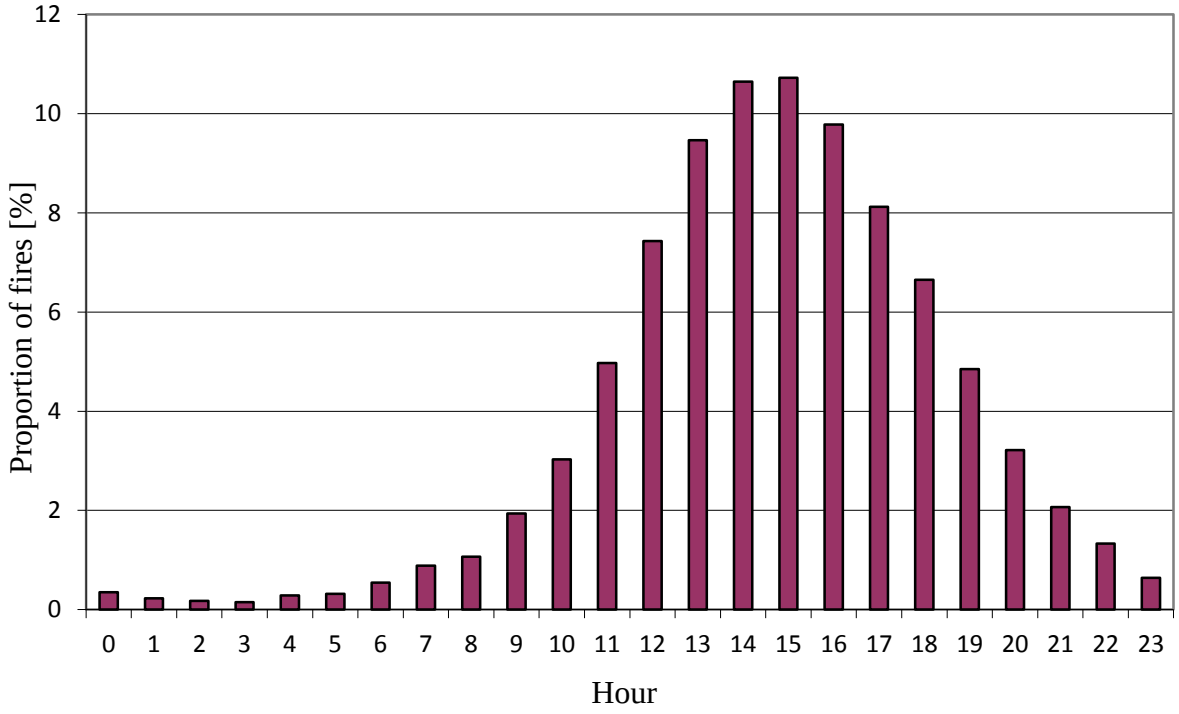

Figure 1. Occurrence of forest fires depending on the time of day

In the analysis of occurrence of fires in relation to meteorological conditions and moisture of litter 25,000 fires were considered. It consisted primarily of evaluation of the number of fires in relation to the values of these parameters. In the analysis of this value from the hour of 9.00 in relation to fires, this occurred between the hours of 9.00 and 13.00. The dependency of the occurrence of fires on the given parameter may be characterised by the frequency of occurrence of fires, being in relation to the number of occurrences of the given value of this parameter. In figure 2 is presented an example schedule of frequency of occurrence of fires depending on moisture of litter as also is presented the expected schedule and the strength of the connection between observed and expected values expressed as a value of the coefficient of determination and R2.

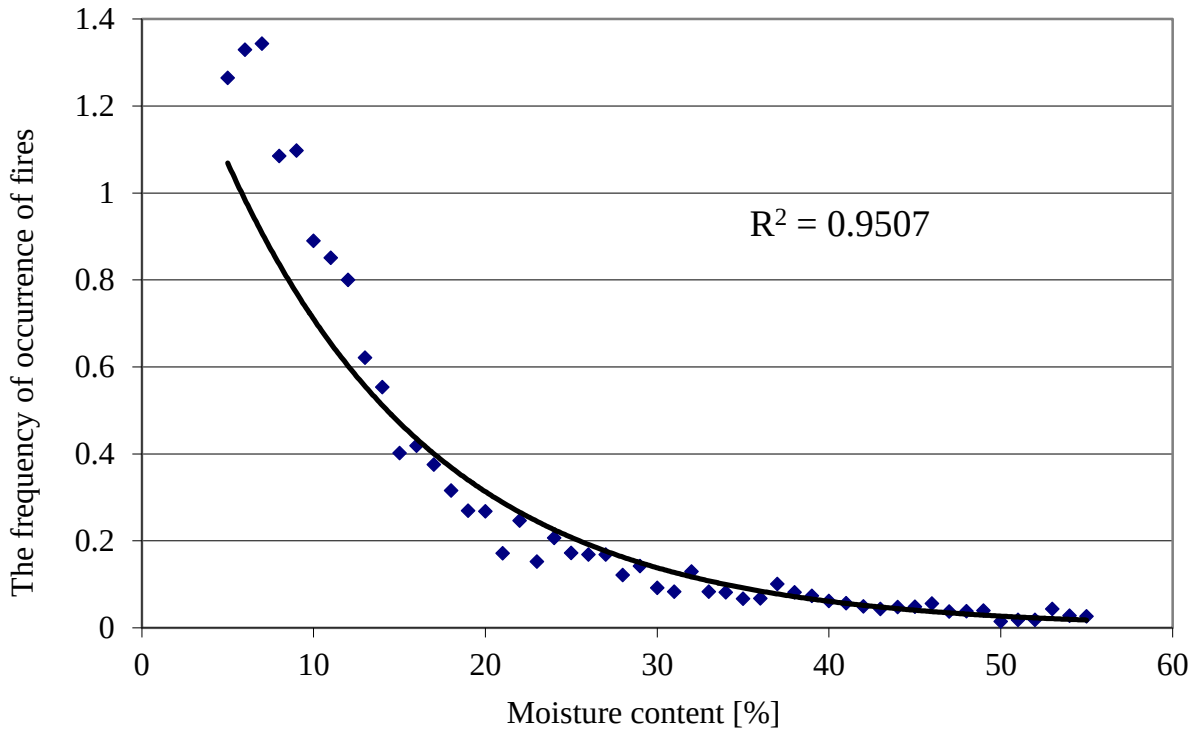

Figure 2. Frequency of occurrence of fires after the hour 13.00 in relation to moisture content of litter at 13.00

Establishing provisional assumptions of the new method included:

- possibility of determining actual risk of fire for given area, being the average for all measurement points located on the terrain equally those in which the moisture content measurement of litter has not been performed.
- possibility of forecasting the risk of forest fire for the afternoon in the morning hours of the given day,
- possibility of forecasting fire risk for the following day,
- forecasting moisture content of litter for the afternoon and of the given day and for the following day,
- drawing up a method enabling limitation of operational costs of fire prevention system.

All analyses of occurrences of fires in relation to the above-mentioned parameters were performed using the reverse step multiple regression method. On this basis polynomials enabling establishment of fire risk for particular points were calculated. In order to standardise the principles of defining the degree of fire risk from the values of polynomials particular formulae were converted in such a manner that the specified degree of fire risk from the value of polynomial of particular formulae were converted in such a way that the specified range of polynomial values always corresponded to the same degree of fire risk. Depending on the values thus calculated for the polynomial, it is possible to establish the degree of fire risk for the given point.

Polynomial risk for forecast point at the hour of 9.00

Polynomial _forecast_09 = f $_{(TP\_09, WP\_09, OP\_09, WS\_09)}$

Polynomial risk of forecast point at 13.00

Polynomial_forecast_13 = f $_{(TP\_09, WP\_09, WS\_09, TP\_13, WP\_13)}$

Polynomial risk for forecast point at 13.00 with regard to moisture content of litter at 13.00
Polynomial_forecast_13P = f (TP_09, WP_09, OP_09, WS_09, TP_13, WP_13, WS_13)

Polynomial risk for auxiliary point at 9.00
Polynomial_measurement_09 = f (WP_09, WS_09P)

Polynomial risk for auxiliary point at 13.00
Polynomial_measurement_13 = f (WP_09, TP_13, WP-13, TP_09P, WP_09P, WS_09P, WP_13P)
where:

TP_09	- air temperature at 9.00,
TP_13	- air temperature at 13.00,
WP_09	- relative air moisture at 9.00,
WP_13	- relative air moisture at 13.00,
OP_09	- 24-hour sum of atmospheric precipitation at 9.00,
WS_09	- moisture content of litter at 9.00,
WS_13	- moisture content of litter at 13.00,
TP_09P	- air temperature at 9.00 at forecast point,
WP_09P	- relative moisture content of air at 9.00 at forecast point,
WP_13P	- relative moisture content of air at 13.00 at forecast point,
WS_09P	- moisture content of litter at the 9.00 at forecast point.

To enable drawing up a fire risk forecast (in the morning for the hours of the afternoon and the following day) formulae were calculated also enabling calculation of forecast moisture content of litter on the basis of its actual value and also current and forecast meteorological conditions. During analyses of the dependency of litter moisture content in the afternoon hours and the following day on its actual value and also on meteorological parameter values not included in the previously referred to data, used in forecasting meteorological parameter values based on a numerical weather model obtained from the Interdisciplinary Mathematical Modelling Centre of the University of Warsaw. The accepted principle was to achieve the highest possible verifiability of prognosis with maximal error tolerance amounting to 20% of actual value, for actual values of litter moisture content less than 40%. Such an assumption guarantees appropriate calculation of litter moisture content for the extent of its moisture, at which the occurrence of fire is possible, so doing taking into consideration the possibility of a certain variation in moisture contents in the area of the whole zone. Similarly to the case of the previously described analysis for evaluation of the dependency between litter moisture in the hours of the afternoon and the following day on its actual value and meteorological parameters values used in multistep regression analysis, but in this instance the dependency was significantly greater (values of coefficient of determination from 0.52 to 0.83). On this basis formulae were drawn up enabling calculation of moisture content of litter both at the hour of 13.00 of the current day has also in the morning of the following day.

Moisture of litter forecast for the hour of 9.00 the following
moisture_1_09 = f (TP_09, OP_09, WS_09, WS_13_1, WS_09_A1, TP0_13, WP0_13, OP0_13, Z0_13, VW0_13, TP1_09, WP1_09, VW1_09)

Moisture content of litter forecast for the hour 9.00 on the following day with regard to measurement data from the hour of 13.00

moisture_1_09_13 = f (TP_09, WP_09, WS_09, TP_13, WP_13, WS_13, WS_09_A1, Z0_13, VW0_13, TP1_09, WP1_09, VW1_09)

Moisture content forecast for 13.00
moisture_0_13 = f (WP_09, OP_09, WS_09, WS_09_1, WS_13_1, TP0_13, WP0_13, OP0_13, Z0_13)
where:

TP_09 - air temperature at 9.00,
WP_09 - relative air moisture at 9.00,
OP_09 - 24-hour sum of atmospheric precipitation at 9.00,
WS_09 - moisture content of litter at 9.00,
WS_09_1 - moisture content of litter at 9.00 the previous day,
WS_13_1 - moisture content of litter at 13.00 the previous day,
TP0_13 - air temperature forecast for 13.00,
WP0_13 - relative air moisture forecast for 13.00,
OP0_13 - sum of forecast precipitation at 13.00,
VW0_13 - wind speed forecast for 13.00,
WP_13 - relative air moisture at 13.00,
WS_09_A1 - average moisture content of litter at 9.00 for 4 successive previous days,
Z0_13 - cloudiness forecast for 13.00,
TP1_09 - air temperature forecast for the 9.00 on the following day,
WP1_09 - relative air moisture forecast for 9.00 the following day,
VW1_09 - wind speed forecast for 9.00 the following day,
TP_13 - air temperature at 13.00,
WS_13 - moisture content of litter at 9.00,

The basis of assessment of the proposed method was data concerning the frequency of occurrence of particular degrees of risk established according to tested methods, average number of fires in the zone in relation to the degree of risk and average surface area of fire at the given degree. These values for afternoon hours are shown in figure 3 and also in table 1.

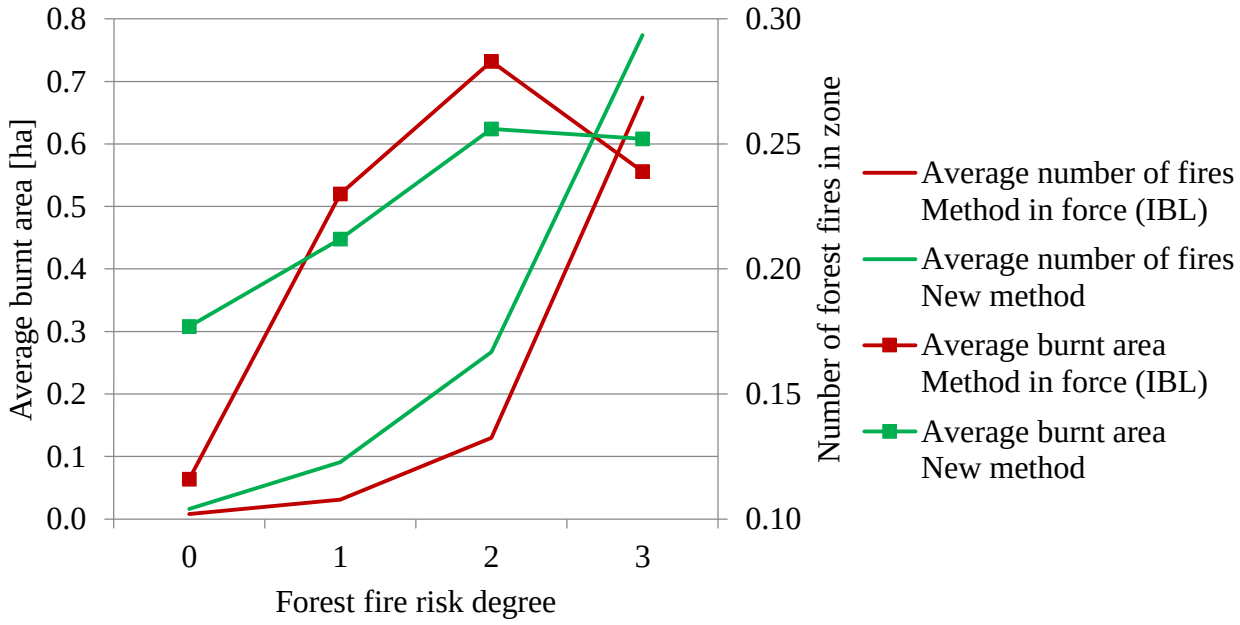

Figure 3. Average number of fires and fire area according to degree of forest fire risk at 13.00

Table 1. Presentation of data relating to forecast of forest fire risk at 13. 00

		unit	Degree of risk			
			0	1	2	3
IBL method	number of days with degree	item	3075	2458	4524	3337
	average number of fires	item	0,008	0,031	0,130	0,674
	average area of fire	ha	0,116	0,230	0,283	0,239
New method	number of days with degree	item	4210	4133	3054	1997
	average number of fires	item	0,016	0,091	0,267	0,774
	average area of fire	ha	0,177	0,212	0,256	0,252

On the basis of the data presented it is clearly seen that with the method in force in Poland a higher fire risk occurs significantly more frequently in comparison to the new method. Concerning occurrence of fires the increase in their numbers together with increased risk is clearer and more balanced for the new method. Significantly greater differences between degrees occur in the case of average fire areas. With the method in force the greatest area of fires, which occurred after 13.00 were at degree 3. Reduction in this case of the area by 3 degrees might be connected with the conduct of extinguishing activity. If it concerns the relationship of surface area of fire to the degree established according to the tested method for afternoon hours, for the new method a clear increase of average area is visible from 0 to 2 degrees whereas the area at degree 3 is almost equal to the area at degree 2. The analysis presented above clearly shows that the newly drawn up method enables significantly better definition of actual fire risk in comparison to the method currently applied.

The condition for appropriate forecasting of fire risk for the following day and the afternoon hours of the given day is precise calculation of envisaged moisture content of litter at those hours. The evaluation of accuracy performed for actual values less than 40% (with tolerance of margin of error amounting to ± 20% of actual value) of drawn up formulae enables obtaining accuracy at a level of 60% for forecasts in the morning for the following day and 70% for the afternoon of the current day.

The schedule of forecast of litter moisture content values in relation to their actual values is shown in figures 4 and 5.

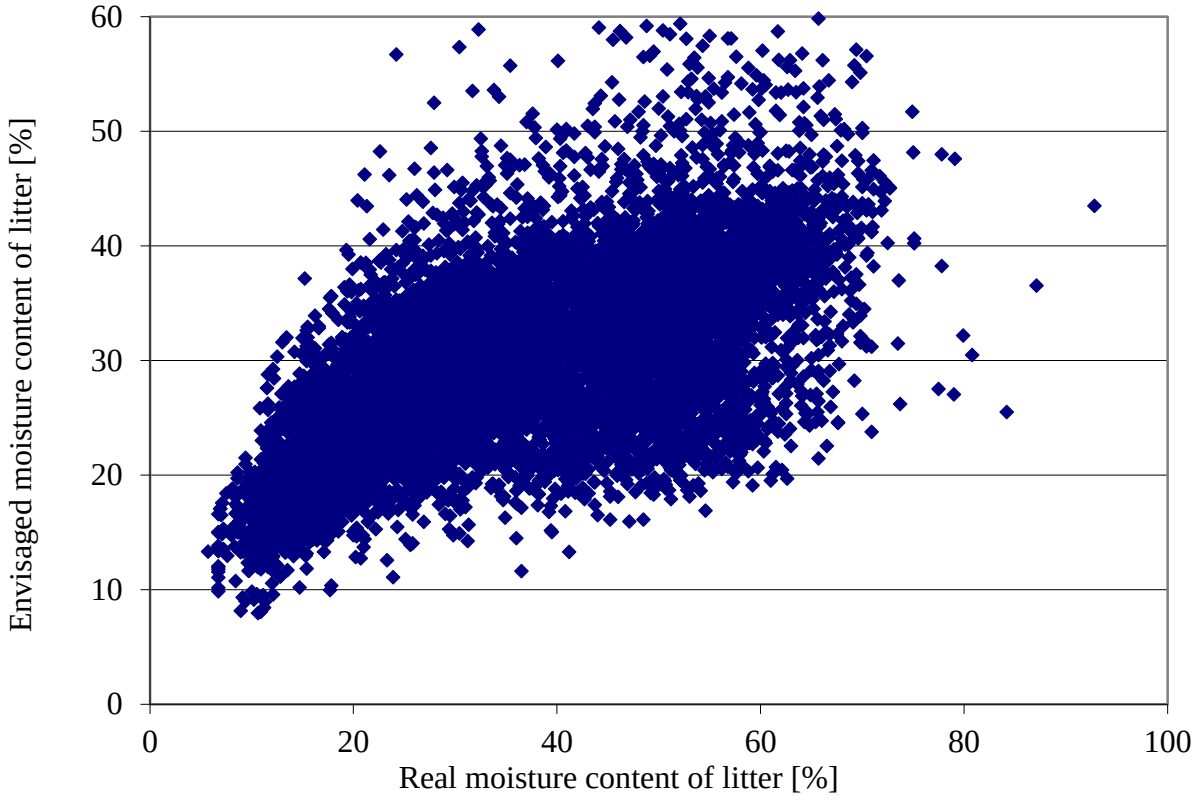

Figure 4. Schedule of litter moisture content forecast for 9.00 the following day

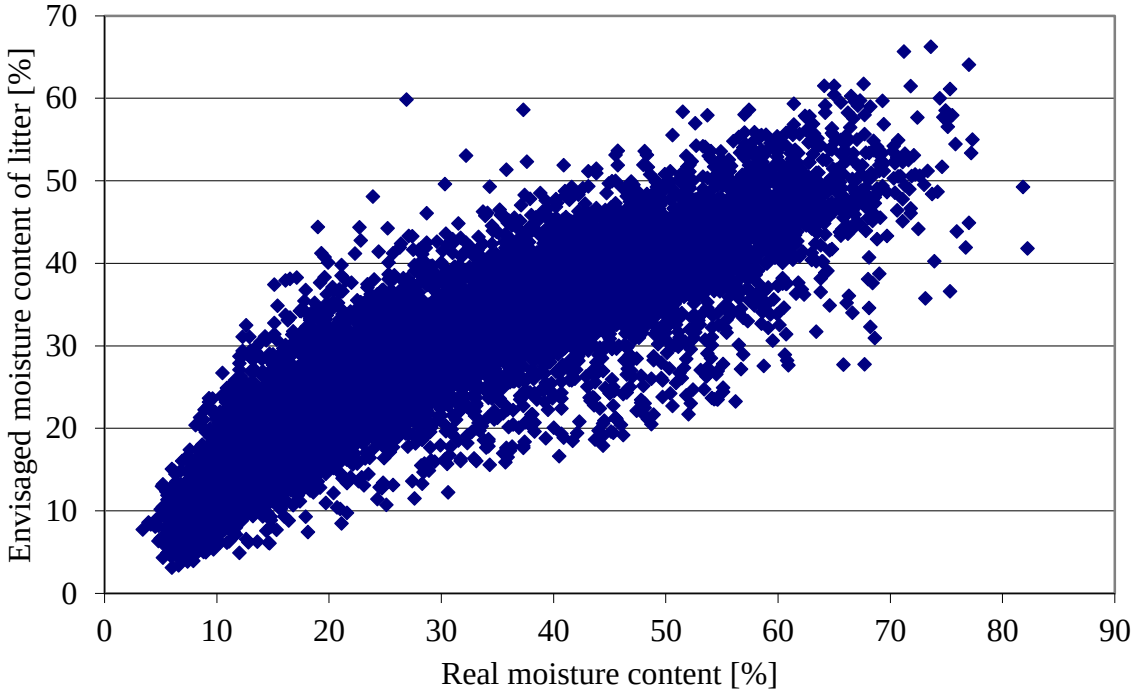

Figure 5. Schedule of litter moisture content forecast for 13.00

In the economic analysis of forest fire protection costs in relation to the applied method of forecasting forest fire risk, only those elements of the system are considered, which are operationally dependent on actual fire risk. This assessment is to a significant degree approximate, because it accepts identical costs for forestry areas counted to a specified category of fire risk. In the conduct of economic analysis

it is accepted that particular activities in the extent of forest fire protection are performed in relation to the degree of risk. On this basis is calculated the cost of the operation of fire prevention protection with regard to affiliation of particular forestry administration areas to the forecast prognosis zones. It shows the possibility of obtaining, as a result of applying the new method, economies in the operation of the forest fire prevention system at a level of 10,000,000 PLN annually or approximately 30% of these costs.

Summary

The drawn up method is based on the measurement of the moisture content of inflammable material, which to a significant extent as an influence on its precision. The choice of test material - pine litter is appropriate to the specific characteristics of forest fires occurring in Poland. As a result of the work a forecasting method was successfully established enabling precise determination of fire risk in forests. The presented results obtained during testing of this method indicate great accuracy in forecasting forest fire risk and satisfactory accuracy of formulae enabling calculation of litter moisture content. On the basis of the entirety of the material presented in this study it may be stated that the drawn up method enables a decidedly better definition of the actual fire risk, simultaneously providing the possibility of its prognosis for later hours and should be introduced for application in forest fire protection. Such a solution may bring about significant limitation of forest fire prevention operating costs and facilitate the organisational work of the services responsible for forest fire protection.

Potential impact of climate change on live fuel moisture dynamic at local scale

[b] Institute of Atmospheric Physics, Praha, Czech Republic

Abstract
According to projections on future climate, an increase in risk of summer droughts is likely to take place in Southern Europe. More prolonged drought seasons induced by climatic changes are likely to influence general flammability characteristics of fuel, affecting species composition and live and dead fuel ratio. Moreover, variations in precipitation and mean temperature could directly affect live fuel water content, and length of critical periods of high ignition danger for Mediterranean ecosystems. The flammability of vegetation is influenced by several factors that include structural properties, chemical properties and moisture content. Several studies have also highlighted the importance of vegetation moisture content in relation to ignition and rate of spread in Mediterranean shrubs.
The main aim of this work was to propose a method for evaluating possible impacts of future climate change on live moisture dynamic and length of fire danger period at local scale by using weather generator techniques. In particular, in this work i) threshold values for drought indices that indicate the end of fire season due to live fuel status in Mediterranean shrubland were identified, and ii) potential impacts at local scale of future climate changes on the duration of fire danger period were simulated. The study was carried out in Sardinia (Italy). Moisture content of live fuel (LFMC) was determined periodically for 8 years on three shrub species. Seasonal patterns of LFMC were compared with the Drought Code (DC) of the Canadian Forest Fire Weather Index and the Keetch–Byram Drought Index. A threshold value of DC useful to determine the end of the potential fire season due to fuel status was identified. A weather generator linked to climate change scenarios derived from 17 available General Circulation Models (GCMs) was used to produce synthetic weather series, representing future climates, and then the expected changes of the fire season length was determined. Results confirmed that the projected climate scenarios over the Mediterranean area will determine an overall increase of the fire season length.

Keywords*: Forest fires, Mediterranean shrubs, Fuel status, Fire danger season*

Introduction

Shrubs are an important component of Mediterranean vegetation: live shrubs are often the main component of the available fuel which catches fire and constitute the surface fuels primarily responsible for the ignition and the spread of wildland fires.
Vegetation flammability is influenced by several factors including structural properties, chemical properties and moisture content. However, it is well known that moisture content of plants is an essential factor influencing the fire ignition and spread. Several authors have found relationships between vegetation water content and ignitability in several Mediterranean species (Hernando *et al.*1994; Dimitrakopoulos and Papaioannou 2001; Pellizzaro *et al.* 2007). Some authors highlighted the importance of vegetation moisture content in relation to crown fire potential, ignition and rate of spread in shrubs (Van Wagner 1977; Chandler *et al*. 1983; Agee *et al*. 2002; Davis *et al*. 2009). Studies carried out in Mediterranean areas have shown that burned areas tend to increase as live fuel moisture decreases (Davis *et al*. 1995; Schoenberg *et al.* 2003; Chuvieco *et al*. 2004; Dennison *et al*. 2008).
The relationship between fire occurrence and drought is well known; forest fires mainly occur during dry summer periods when air temperature is high, air humidity is low and fuel moisture reduced (Piñol

et al. 1998). According to projections on future climate, an increase in risk of summer droughts is likely to take place in Southern Europe (Giorgi *et al*. 2004; Giannakopoulos *et al*. 2009). More prolonged drought seasons induced by climatic changes are likely to influence general flammability characteristics of fuel, affecting species composition and live and dead fuel ratio. Moreover, variations in precipitation and mean temperature could directly affect live fuel water content, and length of critical periods of high ignition danger for Mediterranean ecosystems (Westerling *et al.* 2006; Flannigan *et al.* 2009; Flannigan *et al.* 2013; Liu *et al.* 2013).
Therefore, considering the observed climatic variations and foreseen future scenarios, an evaluation of the impact of these variations on fire danger seems essential.
The climate data provided by the general circulation models (GCMs) are characterized by low resolution and are often not recommended for application at local scale. This constraint could be overcame by using the weather generator approach. Weather generators linked to climate model can transform the raw outputs from the climate models into data with more realistic structure and create synthetic weather series representing present and future climates at local scale.
The main aim of this work was to propose a novel methodology for evaluating the possible impacts of future climate changes on moisture dynamic and length of fire danger period at local scale in the Mediterranean area. Specific objectives were: i) identify threshold values for drought indices that indicate the length of fire season due to fuel status in Mediterranean shrubland, and ii) simulate the potential impacts of future climate changes on the duration of fire danger period.

Methods

The study was carried out in a nature reserve located in North Western Sardinia, Italy (40° 36' N; 8° 09' E, 30 m a.s.l.). The climate is Mediterranean with water deficit conditions occurring from May through September and precipitation mainly concentrated in autumn and winter. The mean annual rainfall is 640 mm and the mean annual air temperature is 16.8 °C. The vegetation cover of the study area consists mainly of Mediterranean maquis and garigue, grown after a fire event occurred in mid '70s.
Moisture content of live fuel (LFMC) was determined periodically for 8 years on three shrub species: *Cistus monspeliensis* L., *Juniperus phoenicaea* L., and *Rosmarinus officinalis* L., which are very common species in the Western Mediterranean Basin. Samples of live fine fuel, consisting of terminal twigs with diameter not greater than 6 mm, were collected from each species.
To determine the live fuel moisture, three samples of each species were weighed, dried and reweighed. Live fine moisture content was expressed as a percentage of dry weight. Meteorological data were also collected from an automated weather station located in the study site.
Drought conditions that occurred during the LFMC sampling period were assessed by calculating the Drought Code (DC) of the Canadian Forest Fire Weather Index System (Van Wagner 1987). DC is widely used worldwide in wildfire danger assessment as an indicator of the moisture content of very slow drying fuels and its values have been shown to be associated with occurrence of drought (Girardin *et al*. 2004; Wotton 2009). DC is similar to other drought models such as the Keetch–Byram Drought Index (Keetch and Byram 1968; Burgan 1988) and the Palmer Drought Index (Palmer 1965) and is calculated from daily rainfall and air temperature. Previous studies showed that DC is well related to LFMC of shrub species (Pyne *et al*. 1996; Viegas *et al*. 2001). In the current FWI System, DC values equal to 0 correspond to saturation moisture content, with increasing values indicating drier conditions without a specific maximum value (Van Wagner 1987). In this work, the DC code was calculated using the equations given by Van Wagner and Pickett (Van Wagner and Pickett 1985)

Analysis of cumulative distribution curves of DC values for only those days characterized by LFMC values over the critical threshold for fire ignition and spread was performed in order to identify the DC values that indicate the end of the fire danger season. Based on available literature, LFMC

values below 95% were used as threshold values for indicating ignition and fire spread danger over Mediterranean shrubs.
The M&Rfi weather generator (Dubrovsky *et al* 2004) linked to climate change scenarios derived from 17 available General Circulation Models (GCMs) (see Table 1 for details) was used to produce synthetic weather series, representing present and future climates, for four selected sites located in North Sardinia, Italy. The projected future climates were then used to determine the expected changes of the fire season length.

3. Results

In general, LFMC values of all species were correlated with the Drought Code values. The analysis showed significant and negative correlation between LFMC and DC for all species ($P \leq 0.05$). High correlation coefficients were obtained for *Cistus* and *Rosmarinus* throughout the entire study period ($P \leq 0.01$). Similar results were also observed for the KBDI ($P \leq 0.05$).
LFMC and DC patterns were also compared with the purpose of evaluating whether or not DC values could be useful to describe the seasonal changes of LFMC.
DC and KBDI patterns were very close to LFMC during the rising phase of moisture content (from mid-summer to autumn). During the moisture falling phase (from mid-spring to the beginning of summer), although the weather indices are correlated to LFMC values, the response of both codes does not match very well the short-term variations of LFMC due to resprouting and flowering phases of plants (Fig.1). Therefore, it seems more appropriate the use of the codes to identify the end of fire danger season rather than the date of starting.

With the purpose of evaluating the effectiveness of both indices, we performed the analysis of frequency distribution as suggested by Andrews *et al* (2003). Figure 2 shows the distribution of DC and KBDI for all days from July 1 (plots on the top), and only for those days from July 1 with LFMC values higher than 95% (plots on the bottom). For DC the distribution shifts to the right, with most of the DC values below 700, when the analysis is performed using only days with LFMC higher than 95%. This behavior is less pronounced in the case of KBDI, so that Drought Code seems to be a better indicator for predicting the end of fire danger season than KBDI.

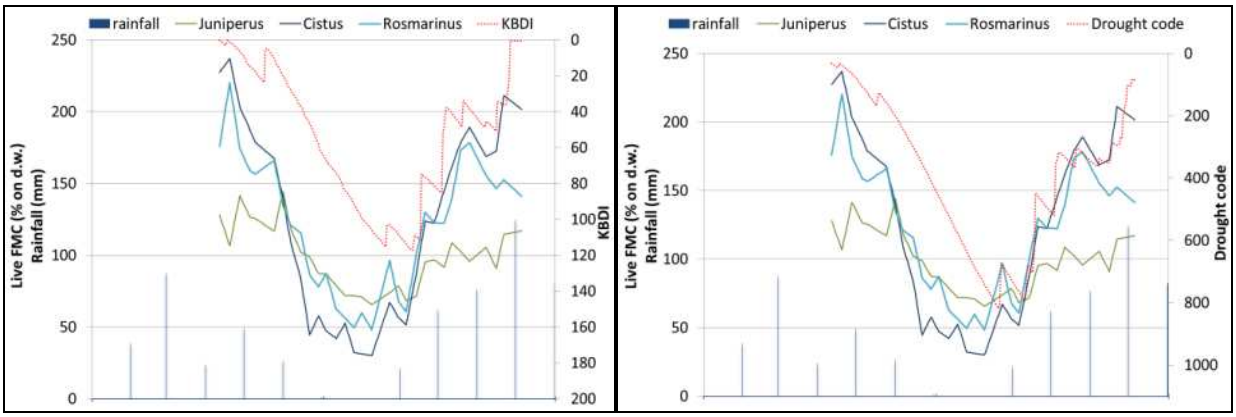

Figure 1. Seasonal trends of Keetch and Byram (KBDI) and Drought Code (DC) and live fuel moisture content (LFMC) values observed for Cistus monspeliensis, Juniperus phoenicaea and Rosmarinus officinalis at the experimental site during April-November 2005.

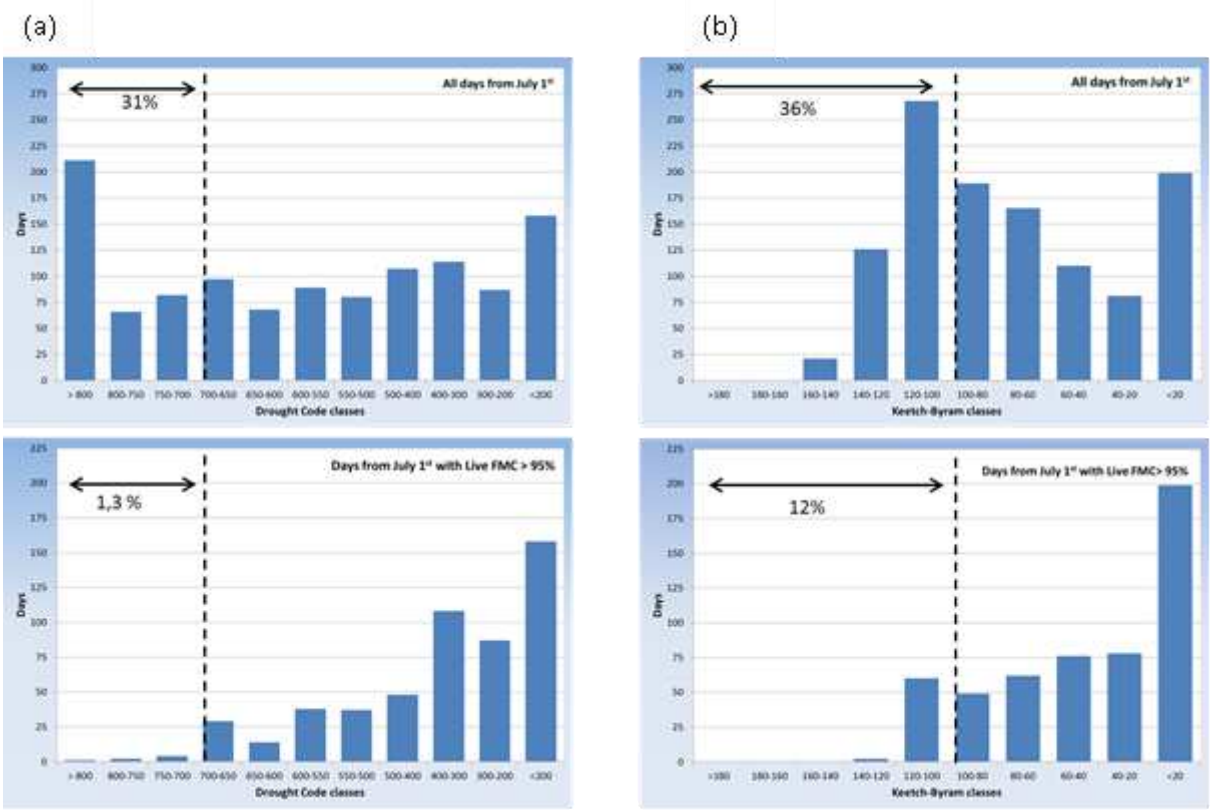

Figure 2. Frequency distribution of Drought Code (a) and Keetch and Byram Drought Index (b) for all days from July 1 (plots at the top) and for all days from July 1 with LFMC values higher than 95%.

The cumulative distribution curves of DC (LFMC rising phase), calculated for all days from July 1 with LFMC values above 95%, shows that most of the DC values are below 700 when LFMC values are above the critical moisture threshold of 95% (Figure 3). Therefore, a DC threshold of 700 was used to estimate the end of fire danger season due to LFMC of Mediterranean shrubs.

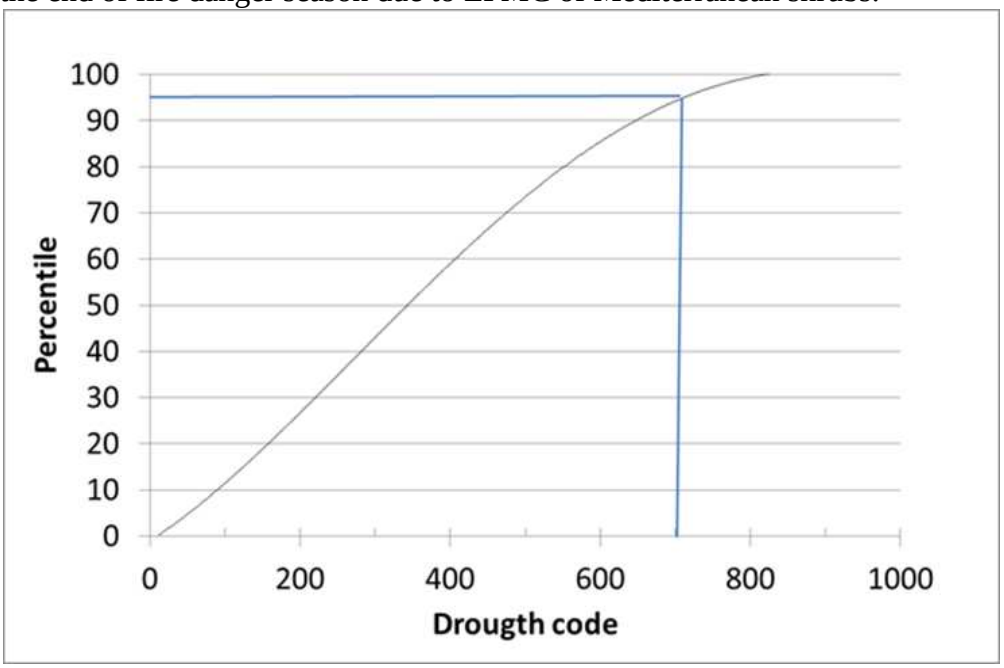

Figure 3. Cumulative distribution of Drought Code values observed during days with LFMC values above 95% (rising phase of LFMC).

Projections of future likely dates of the end of the fire season were obtained using 17 climate change scenarios derived from a subset of available GCMs combined with synthetic weather data from M&Rfi weather generator.

The actual and projected average dates of the end of fire season for the experimental site are shown in Figure 4 and Table 2. The actual ending date of the fire danger season calculated by using the synthetic weather series is October 14 (DOY = 287). The calculation of the DC values derived from 17 climate change scenarios resulted in a general increase of the duration of the fire danger season. Scenario B1 determines little variations compared to scenarios A2 e A1B. Scenario B1 shows an extension of the fire season ranging from 3 days (2050) to 5 days (2100), with a spread of predictions ranging from 1 to 14 days. Results from scenarios A1B e A2 and mid-century (2050) indicate a possible extension of the fire season of more than 1 week with a spread of the predictions ranging from few days to 3 weeks. For both scenarios A1B and A2, the fire season length indicated by 2100 projections is much larger: about 2 (A1B) and 3 (A2) weeks with a maximum spread of predictions around 1 month.

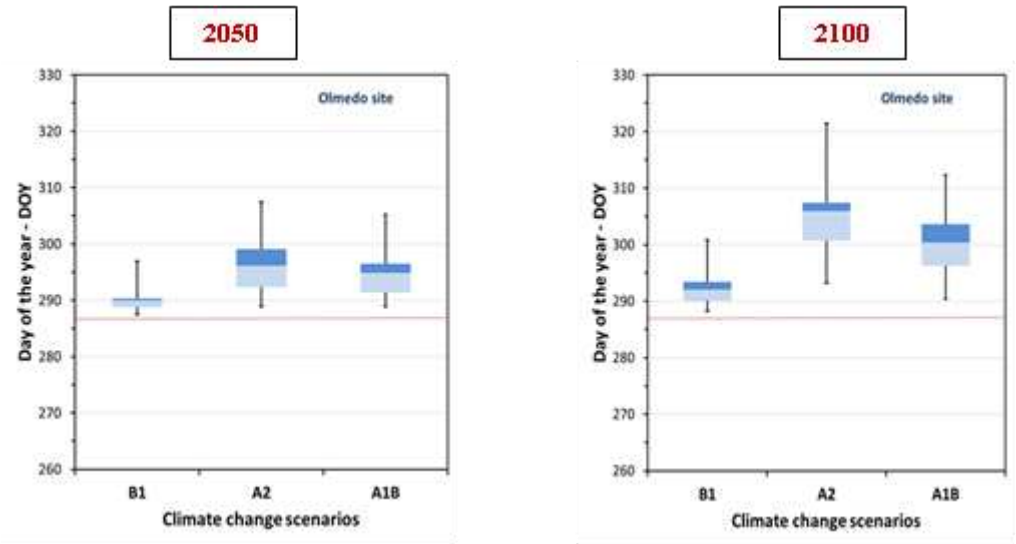

Figure 4. Boxplot of the actual (red) and projected (blue) average fire season ending dates relative to three climate change scenarios (B1, A1B, and A2). The charts show the minimum, maximum and mean values, and the lower and upper quartiles.

Table 2. Projections of future extension of fire season (in days) by climate change scenario and time period. Spread of predictions (in days) are reported in brackets.

Years	B1	A2	A1B
2050	**3 (1 – 10)**	**9 (2 – 20)**	**8 (2 – 18)**
2100	**5 (1 – 14)**	**19 (6 – 35)**	**13 (3 – 25)**

Conclusions

The results reported in this paper are based on local data and information and on the calibration of the commonly used DC code. Our study confirms that projected climate scenarios over the Mediterranean area could affect the duration of the fire danger season causing a delay in the ending dates of high ignition danger periods. Several authors suggested that an earlier spring could lead to an earlier fire season (Westerling *et al* 2006; Flannigan *et al* 2009; Matthews *et al* 2012). In this work, we did not investigate on the impact of climate change on starting date of fire season, since weather indices used as a proxy of vegetation moisture content showed poor performances in following the variations of LFMC in spring. During this period, the moisture content of living plants of Mediterranean species is also affected by phenological phases that depends by both endogenous rhythm of the plant and weather conditions occurred before vegetative growth. In this context, the use of models that also include phenological response to weather of Mediterranean shrubs could provide an appropriate tool for a better description of live fuel moisture seasonal changes in Mediterranean shrublands.

Abstract
Can fire potential forecasts assist with pre-positioning of fire suppression resources, which could result in a cost savings to the United States government? Here, we present a preliminary assessment of the 7-Day Fire Potential Outlook forecasts made by the Predictive Services program. We utilized historical fire occurrence data and archived forecasts to assess how well the 7-Day Outlook predicts wildfire ignitions and escaped fires, ultimately to help characterize the effectiveness of this tool for prepositioning national firefighting resources. The historical fire occurrence data track ignitions on all land ownerships; from this dataset, we established number and location of ignitions and final fire size for the years 2009-2011 for Predictive Service Areas (PSAs) within the Northwest and Southwest Geographic Areas. These data were then matched to the corresponding PSA and appropriate forecast for each of the seven days prior to the ignition date. Final fire size was used as a metric to establish whether an ignition escaped initial attack, with fires greater than 121.4 hectares (300 acres) considered escaped. Our results show that 7-Day Outlook values yield better-than-random prediction of large fire activity, although there is wide variation in this relationship among individual PSAs. In addition, the number of escaped fires increased with the number of ignitions, with this relationship showing a distinct regional pattern. Fires were more likely to escape during certain times of the year, with this season being earlier in the Southwest than in the Northwest. Significantly higher numbers of escaped fires per ignition occurred during days considered to be high risk by the meteorologist than on lower-risk days.

Keywords*: forecasting; fire danger; ignitions; escaped fires; large fire activity*

Introduction

Accurate predictions of days and locations with heightened potential for significant wildfire activity would be valuable for a number of planning functions, including giving land managers time to evaluate potential responses in the event of an ignition, such as prepositioning of fire suppression resources. The 7-Day Fire Potential Outlook forecasts issued by the Predictive Service program in the United States (US) might be suitable for such tasks, but they have not yet been assessed at the necessary national scale. In this manuscript, we present preliminary assessment of this product for two regions of the US.

The Predictive Services program was created under the National Wildfire Coordinating Group in 2001 to address the need for long- and short-term decision support information for fire managers and operations personnel. The primary mission of Predictive Services is to integrate fire weather, fire danger, and resource availability in order to enable strategic fire suppression resource allocation and prioritization. The conterminous United States is divided into ten Geographic Coordination Areas (GCAs; Figure 1), which are in turn comprised of individual forecast units called Predictive Service Areas (PSAs; Figure 2). PSAs are delineated within each GCA to represent geographic areas of similar

climate based on statistical correlation of observed weather and fuel moisture data, or based on political or land ownership boundaries. In 2006, Predictive Services began daily production of the 7-Day Significant Fire Potential Outlook for each PSA on weekdays during the core fire season to support efforts at informed regional and national fire suppression resource allocation and prepositioning.

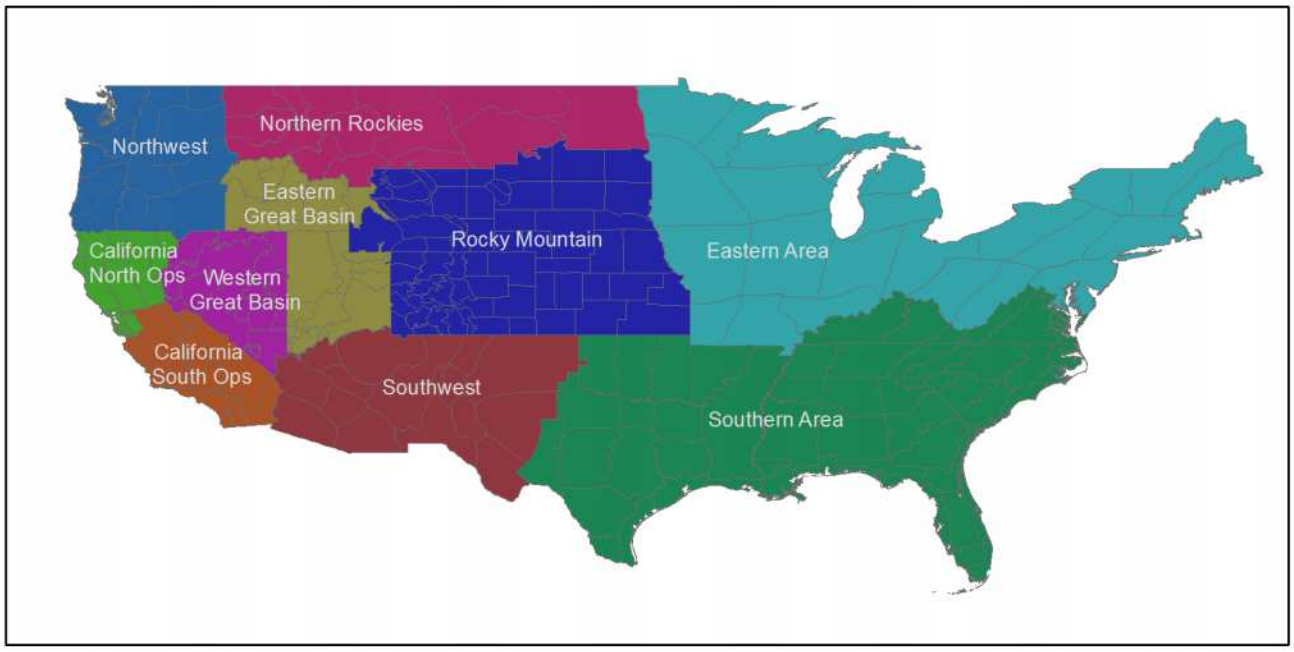

Figure 1. Geographic Coordination Areas (GCAs) of the conterminous US. The boundaries of the Predictive Service Areas (PSAs) for the year 2012 are shown in gray.

The 7-Day Outlook uses forecasted fuel dryness and specific high-risk weather events to predict the location and timing of demand for regionally and nationally shared suppression resources. Thus, it is essentially designed to anticipate significant fire activity. More specifically, Predictive Services defines "Significant Fire Potential" as "the likelihood that a wildland fire event will require mobilization of additional resources from outside the area in which the fire situation occurs" (www.nwccweb.us/content/products/fwx/fdrop/FDROP.pdf, accessed May 9, 2014). "Significant fires" are defined to be those larger than a threshold size, which varies geographically, based on historical fire sizes.

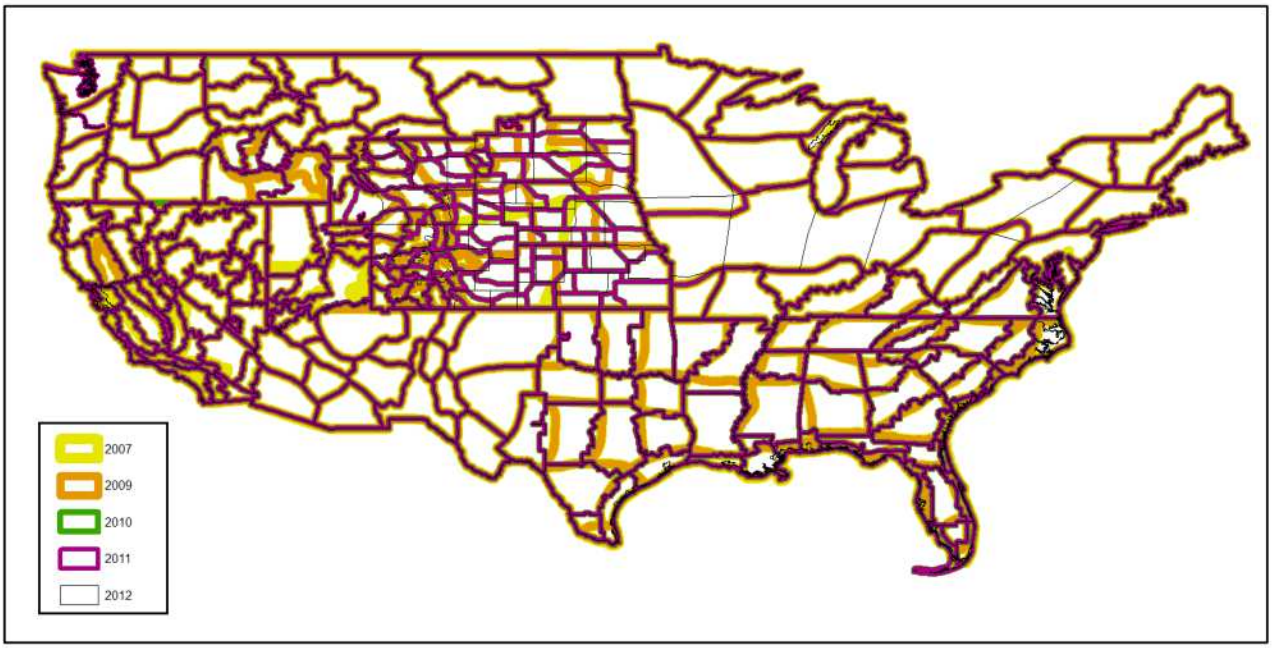

Figure 2. Boundaries of Predictive Service Areas (PSAs) in the conterminous US. Boundaries have changed significantly in some GCAs since their inception in 2006.

The Fire Potential Forecasts are made on a categorical scale of 1 to 9 for the current day and each of the following six days, and combine forecasted fuel dryness level, ignition triggers (from lightning and recreation), critical burn environment conditions (windy, unstable, hot and dry), and resource availability (Table 1). Each day's forecast consists of one and only one of the nine categorical values. Forecasting methodologies vary across GCAs and across PSAs within a GCA, based on the expert opinion of the meteorologist and statistical correlations of weather and fuel dryness variables with large fire activity. Forecast categories 1-3 are based on fuel dryness alone, and indicate increasing fuel dryness. Categories 4-9 indicate "high risk" days on which the meteorologist predicts a greater than 20% chance of significant fire activity. High risk days can be caused by an elevated chance of ignitions, from either lightning (category 4) or recreation (category 8), a forecast value which is issued primarily on the 4th of July when fireworks are commonly set off during celebrations. Weather factors may also cause the meteorologist to issue a high risk forecast, due to wind (category 5), unstable atmosphere and associated possible thunderstorm development (category 6), hot and dry weather (category 7), or dry weather (category 9).

When the forecast takes on a high risk value, regional staff often consults with the meteorologist in order to decide whether to preposition firefighting resources within the GCA. At high national preparedness levels, when firefighting resources are in high demand across the country, staff at the National Interagency Coordination Center in Boise, Idaho, use the 7-Day Fire Potential Outlook as an input into resource allocation decisions, along with existing fire activity and risks, socio-political considerations, and forecasted weather.

In this manuscript, we present preliminary analysis of the 7-Day Fire Potential Outlook, assessing the forecast's ability to predict ignitions and escaped fires in the Northwest and Southwest GCAs during the years 2009-2011.

Table 1. 7-Day Significant Fire Potential Outlook forecast values. Each day's forecast corresponds to one and only one of these values.

	Forecast Value	Forecast Description	Fire Environment
Increasing fuel dryness ↓	1	Moist Fuel Conditions	Little or No Risk of Large Fire
	2	Dry Fuel Conditions	Low Risk of Large Fire
	3	Very Dry Fuel Conditions	Low-Moderate Risk of Large Fire
High risk	4	Lightning	Ignition Trigger
	5	Windy	Critical Burn Environment Factor
	6	Unstable	Critical Burn Environment Factor
	7	Hot & Dry	Critical Burn Environment Factor
	8	High Recreation	Ignition Trigger
	9	Dry	Critical Burn Environment Factor

Methods

To assess the skill of the 7-Day Outlook, we obtained archived daily forecast values for PSAs in the Northwest (NWA) and Southwest (SWA) geographic coordination areas. Preliminary analyses were spatially constrained to these two geographic areas, and temporally constrained to 2009-2011, in order to refine our methods prior to initiating a nationwide analysis. While each day the forecast is issued for the current day and following six days, our initial analysis concentrates on the forecast values issued the for the current day (referred to as the Day 1 forecast) and Day 7 forecast.

To compare historical predicted fire occurrence (via the 7-Day Outlook) with actual historical fire occurrence, we utilized the national all-lands wildfire occurrence database (Short 2013, 2014). Fire ignition locations from the fire occurrence database (FOD) were intersected with annual PSA boundaries in ArcGIS 10.1. We utilized final fire size from the FOD to assess whether a fire escaped initial attack containment efforts; for our initial analysis, an escaped fire was defined as any incident with a final fire size greater than or equal to 121.3 hectares (300 acres).

Boxplots were used to assess the total number of ignitions by forecast level, as well as the total number of escaped fires by forecast level. We calculated 95% thresholds for number of ignitions and number of escaped fires, in order to establish confidence levels. Skill of the forecast was assessed in more detail within the NWA, where we used the log likelihood ratio to test whether the distribution of fire activity given the forecast was different from what would be expected randomly. The R statistical package was used to perform a G-test of independence with William's correction, and p-values were reported as a test of significance.

- Null hypothesis: fire activity occurs randomly with respect to forecast (therefore, the differences observed in the parallel boxplots are not statistically significant)

- Alternative hypothesis: fire activity is significantly different than random with respect to the forecast (the differences observed in the parallel boxplots are statistically significant)

In this work we conclude that a forecast has skill if the null hypothesis is rejected (in other words, fire activity is significantly different than random with respect to the forecast), and the boxplots show a positive pattern in numbers of ignition or escapes with increasing forecast risk level.
In addition, we fitted a generalized additive Poisson regression model with spline functions to describe the potentially non-linear relationships that might exist between expected number of escapes and the three explanatory variables, number of ignitions, the day of the year, and the next-day forecast value (note that the next-day forecast value is used since a fire ignited on one day is not likely to escape containment efforts until the next day). The estimated effects of each of the explanatory variables were then graphed to illustrate the additive increase or decrease from average (with 0 on the y axis corresponding to average) due to the particular explanatory variable.

Results

The most frequently issued forecast value was 1 (moist), followed by 2 (dry), and 3 (very dry). Since increasing fuel dryness is meant to convey a heightened awareness of significant fire potential, it seems appropriate for the very dry fuel category to appear less often than the moist category (Table 2). Similarly, "high risk" forecast values (category 4-9) were issued much less frequently than fuel dryness forecasts (category 1-3), which again seems appropriate since they are meant to convey elevated risk of significant fire activity to resource managers. The NWA currently uses empirical regression equations between the predicted amount of lightning, fuel dryness, and predicted number of fire starts to decide when to issue a forecast of 4 (lightning ignition trigger). They use the other high risk forecast values more rarely, since the required 20% probability of a large fire threshold is seldom attained for any weather condition other than a lightning event. The recreation ignition (category 8) trigger was issued only four times during the period of analysis, and the dry forecast (category 9) was not issued at all during the period of analysis in these two GCAs.

Table 2. Number of times each forecast level was issued for Day 1 (current day) forecasts, between 2009 and 2011, in the Southwest and Northwest Geographic Coordinating Areas (GCAs).

Forecast Level	1	2	3	4	5	6	7	8
NW	3133	1150	202	60	16	58	0	2
SW	5672	3456	2035	79	544	3	75	2
Total	8805	4606	2237	139	560	61	75	4

Patterns demonstrating the skill of the 7-Day Outlook in forecasting ignitions and escaped fires are evident in boxplots appearing in Figures 3 and 4. The number of ignitions per PSA is lower at dryness level 1 (moist) than at dryness levels 2 (dry) and 3 (very dry), which have roughly the same distribution of number of ignitions. Since the distribution of number of ignitions was similar during forecast levels 2 and 3, it seems the forecast does not exhibit skill in discerning the number of ignitions during dry versus very dry conditions. This result is perhaps not surprising, since the dryness levels were calibrated to the probability of large fires, not total ignitions.

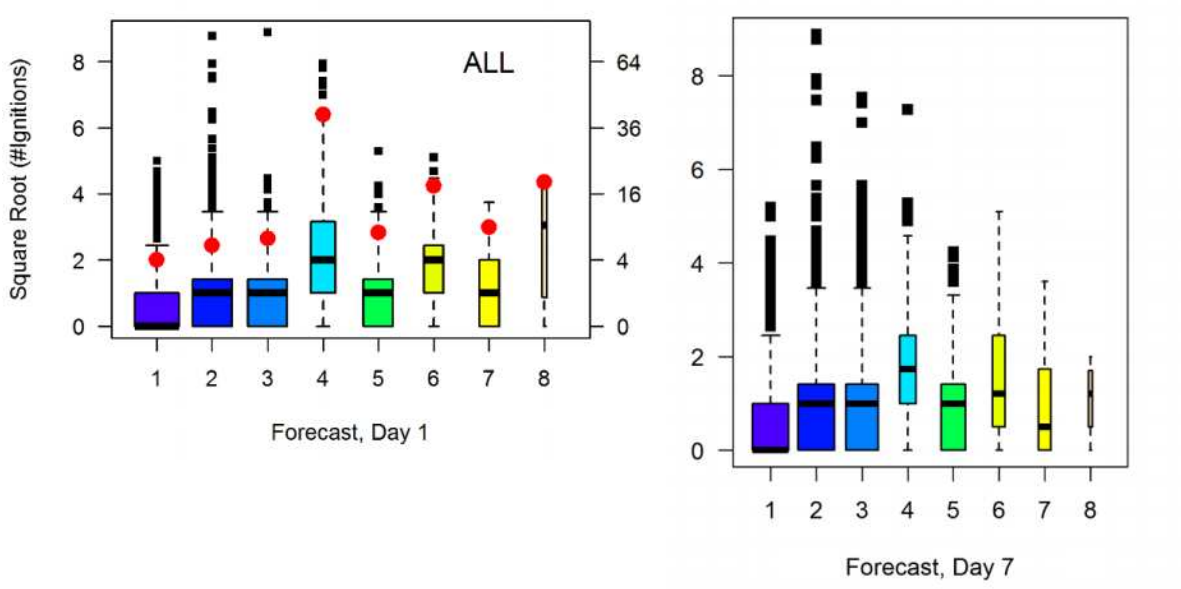

Figure 3. Distributions of number of ignitions (boxplots) in the Northwest and Southwest GCAs by forecast value, for forecast for current day (left panel) and seven days prior (right panel). Note that the y-axis represents the square root of the number of ignitions. The width of each boxplot is proportional to the square root of the number of times that value was forecasted (Table 2). Red dots in left panel indicate the 95th percentile of the distribution.

On average, a higher number of historical ignitions occurred coincident with ignition trigger and critical burn environment forecast values (4 through 8) than for dryness level 1 (moist), indicating some skill in predicting ignitions in these high risk forecast levels as well. In the same-day forecast, on average, the highest numbers of ignitions occurred under forecast level 8 (high recreation), followed by level 6 (unstable), and level 4 (lightning), with the ignition numbers being higher than those for dryness levels 2 and 3 on average. Evidently, days that the meteorologists forecast lightning do indeed experience higher lightning levels, judging by higher ignitions on those days. The level 6 forecast indicates unstable atmospheric conditions, which are often associated with thunderstorm development and lightning, and thus elevated numbers of ignitions. The level 5 forecast (windy day) had a similar distribution of number of ignitions as dryness levels 2 and 3, which is not surprising since wind would be expected to promote fire growth but not ignitions. The patterns in the boxplots are similar for the forecast values seven days ahead, suggesting that the forecast may be used up to a week ahead to indicate days with heightened levels of ignitions.

Boxplots give the 25th, 50th, and 75th percentiles of the distribution in addition to outliers. Ninety-fifth percentiles may also be a useful tool for managers. These were calculated for the number of ignitions and escaped fires by forecast value and added to the boxplots (Figures 3 and 4). For example, historically, fewer than four ignitions per PSA were observed on 95 percent of days forecasted as moist (level 1) conditions (Figure 3). The 95th percentile for ignitions is highest for days with lightning forecasts (level 4), at approximately 40 ignitions.

As noted above, the forecast was designed to predict significant fire activity rather than ignitions, although of course ignitions are a prerequisite to significant fire activity. Thus, we also assessed the performance of the forecast with regard to escaped fires (Figure 4). Because escaped fires are rare, the median (50th percentile) number of escaped fires on any given day per PSA is zero across all forecast values. However, the 95th percentile is one escaped fire during same-day forecasts of 3 (very dry), 4 (lightning), 5 (windy), and 7 (hot and dry), indicating that there is a 5% chance of having at least one escaped fire during days with these forecasts. Conversely, managers may expect no escapes on 95 percent of the days when the forecast is 1 (moist), 2 (dry), 6 (unstable), or 8 (recreation). In other words, there is less than a 5 percent chance of having at least one escape. Specifically, during days

with forecast level 4, the estimated probability of at least one escape was 0.22 for the same-day forecast in the NW, with 95% confidence limit between 0.13 – 0.31, and 0.14 in the SW, with 95% confidence limit between 0.05 – 0.23. Because a forecast level 4 is issued to indicate a 20% or greater risk of a significant fire event, this result indicates good skill of the category 4 forecast in that the 20% probability fell within the confidence interval of the observed proportion of escapes in both GCAs. However, the Day 7 forecasts for level 4 had less skill in predicting the probability of at least one escape, with estimated probability of 7.5% (1.4 -15%), which was significantly different than the expected 20% or greater risk. Thus, the forecast seven days in advance does not have as much skill in predicting escaped fires as the same-day forecast. The number of cases in forecast level 8 is too small to make any conclusions about the skill of the forecast for escapes for this level. The pattern is quite similar in both the Day 1 (same day) and Day 7 forecasts, indicating that the 7-Day Outlook forecast might be useful in indicating PSAs where firefighting resources might be prepositioned up to seven days ahead in order to prevent escaped fires. It should be noted that we used a threshold of 121.4 hectares (300 acres) across all PSAs to indicate an escaped fire, while each PSA has a different threshold for determining the size of a "Significant Fire", varying from 20.2 to 4046.9 hectares (50 to 10,000 acres), so there is some discrepancy in the definitions used to define an escaped versus significant fire.

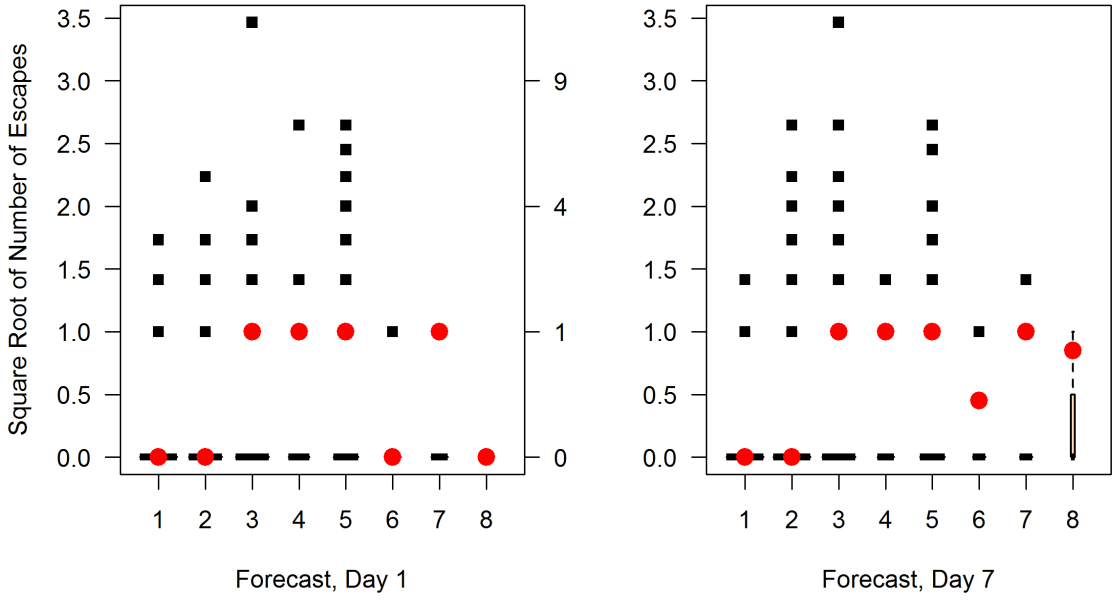

Figure 4. Distributions of number of escaped fires (final fire size >=121.4 hectares (300 acres)) using the same day forecast (left panel) and forecast value from seven days ahead (right panel) in the Northwest and Southwest GCA by forecast value. The red dot signifies the 95th percentile of the distribution. Escaped fires were lagged one day, assuming that a fire ignited on one day will not usually escape initial attack and grow to 121.4 hectares (300 acres) until the next day.

The statistical significance of the differences seen in the boxplots was tested using the log likelihood ratio. In the GCA as a whole (totals for all PSAs), fire activity with respect to the forecast occurred differently from random, indicating the forecast has skill at predicting ignitions and escaped fires at the GCA level (p<=1.06e-14). The log likelihood ratio tests, which were also performed for the Day 1 forecasts in each PSA in the NWA, indicate skill of the 7-Day Outlook in predicting ignitions in 11 of 12 PSAs and escaped fires in only 5 of 12 PSAs. Escaped fires are likely more challenging to predict than ignitions for several reasons, including their rarity. In fact, the log likelihood ratio test may not have had an adequate number of escaped fires in some PSAs, and may have failed to indicate statistical significance due to the low sample size.

Although the skill of the forecasts look good probabilistically, in absolute numbers there may be many days where the forecast missed predicting high fire risk. For example, although the chance of at least one escape was very small (approximately 2 percent) on days with forecast prediction level 1 (moist) or 2 (dry), indicating low risk of significant fires, the actual number of days that had at least one escape in these forecast levels and over the three years of the study was 318. Seven of those 318 days had more than three escapes. Up to 10 escaped fires occurred within a PSA on days when the forecast was not being issued; sometimes these days were during winter months that may not have been considered part of the core fire season, but other times these days occurred during the summer months.

We analysed the number of escaped fires as a function of number of ignitions, day in year, and next day forecast level (grouped into two groups, the "high risk" forecast values of 4-7 and the dryness levels 1-3), using Poisson regression (Figure 5). The number of escapes increased with the number of ignitions in both the NWA and SWA. In the SWA, an increase in the number of escaped fires is seen up to about 10 ignitions, after which there is no further increase. In the NWA, we see a similar pattern up to about 50 ignitions, with perhaps another increase above 60 ignitions, although the standard errors are large. The seasonal patterns in the SWA and NWA are different, with the SWA showing more escapes on average around 100-150 days into the year (mid-April through late May), corresponding with spring dryness before the arrival of monsoon rains, while the NWA shows more escapes around 210-250 days into the year (early August through mid-September), corresponding with dry fuels at the end of the summer season and possibly convective thunderstorm development. In the SWA, the high risk forecast days (categories 4-7) show an estimated 2.35 times more escaped fires per ignition than days with a dryness level forecast (categories 1-3), with a 95% confidence interval of 1.9 – 2.87. In the NWA, a similar pattern is evident, with about four times more escaped fires per ignition on high risk forecast days (95% confidence interval 2.5 – 6.4).

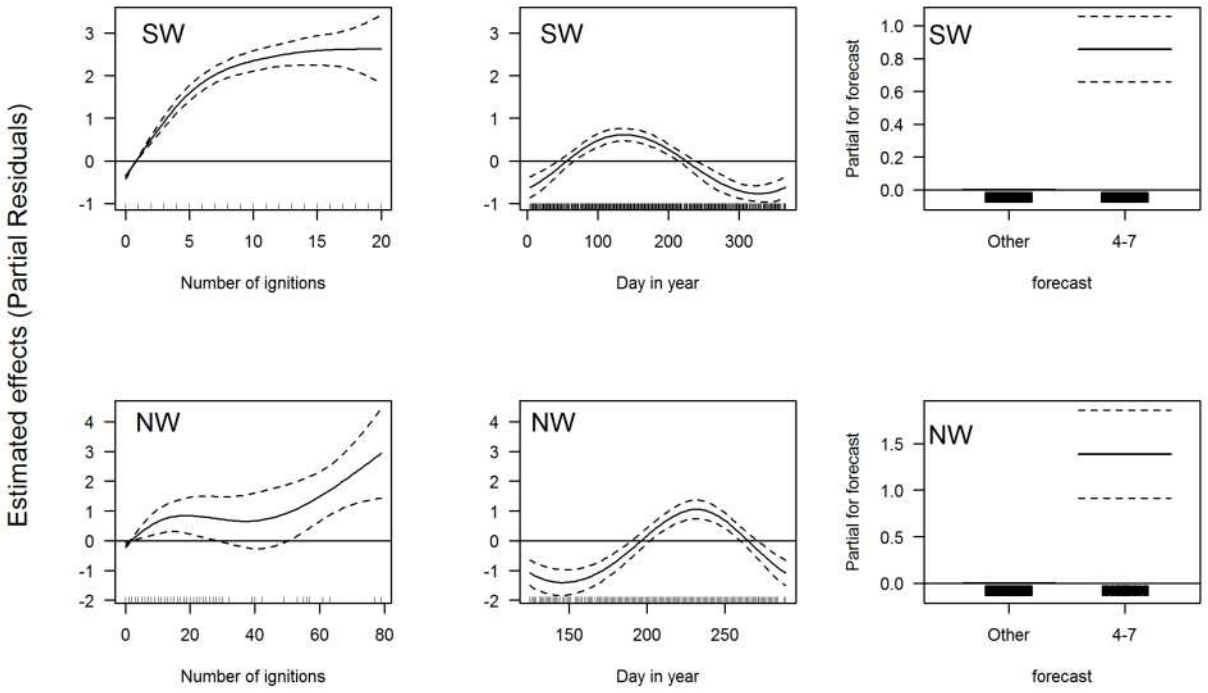

Figure 5. Partial residuals from Poisson regression demonstrating estimated effects of number of ignitions, day in year, and 7-Day Outlook forecast on number of escaped fires in the Northwest (NW) and Southwest (SW) Geographic Coordinating Areas. The partial residual plots show the additive increase or decrease from average (with 0 on the y axis corresponding to average) due to the particular explanatory variable. The y axis is in units of the natural log.

Discussion and Conclusions

Generally speaking, the 7-Day Fire Potential Outlook demonstrated better than random prediction of wildfire activity in the NWA. In the NWA and SWA, numbers of ignitions were lower at dryness level 1 (moist) than at dryness levels 2 (dry) and 3 (very dry) and on days with forecasts indicating lightning, unstable conditions, high recreation, windy conditions, or hot and dry conditions. Escaped fires were more likely under forecast levels 3 (very dry), 4 (lightning), 5 (windy), and 7 (hot and dry) than forecasts 1 (moist) and 2 (dry), with forecasts 6 (unstable) and 8 (high recreation) showing predictive skill seven days ahead but not during the same-day forecasts. In general, the forecasts showed skill in identifying days with elevated numbers of ignitions and potential for escaped fires not only for the current day's forecast, but also for forecasts made a week before, indicating the forecast might be useful in prepositioning of fire suppression resources nationally up to seven days in advance. In spite of this demonstrated skill, the forecasts missed many days with escaped fires.

The relationship between fuel dryness and fire ignitions is well established in the literature (Andrews *et al.* 2003), and thus the increasing number of ignitions across dryness levels 1 to 3 makes sense, but the weather conditions leading to significant fire activity are less well understood, adding to challenges in predicting fire activity and escapes. The rarity of escaped fires alone makes their prediction challenging. Adding to the difficulty in forecasting rare events, gridded weather model output also contains uncertainties and imperfections, which are then passed to the fire models. Wind speeds and directions tend to vary considerably within PSAs, causing spatial variation in the potential for fires to grow large. Additionally, if regional and national decision makers utilize a skilled forecast to effectively preposition suppression resources, which then successfully contain a fire while it is small, the performance of the forecast could appear poor in some cases, since it would appear that significant fires did not occur on days with high risk forecasts, when in fact the forecast itself contributed to containment during initial attack.

We found that the number of escaped fires increased with the number of ignitions in both the SWA and NWA, with the number of escaped fires per ignition being higher in the SWA than in the NWA. Different seasonal trends in escaped fires are present in the SWA and the NWA, with the most common period for escaped fires coming earlier in the year in the SWA (mid-April through late May, corresponding with spring dryness before the arrival of monsoon rains) than in the NWA (early August through mid-September, corresponding with dry fuels at the end of the summer season and possibly convective thunderstorm development). These findings illustrate the different fire regimes and response capabilities of fire suppression resources in these two GCAs. Forecasted high risk days (categories 4-7) had about twice as many escaped fires per ignition in the SWA and about four times more escaped fires per ignition in the NWA. On days with high risk forecasts, prepositioning of fire suppression resources or implementation of fire prevention measures might bring down the number of escaped fires, where desired in order to meet land management objectives.

In this initial work, we focused only on the three years 2009, 2010, and 2011, and on two of the ten geographic areas in the conterminous US. We are currently in the process of expanding the analysis to include a total of six years of reliable historical forecast data (2007 to 2012). Expanding the dataset will help to address the statistical issues with small sample sizes of escaped fires. We will also incorporate analysis of additional GCAs, in order to begin to be able to address national-level resource allocation issues. In addition, we will examine geographical and fuels characteristics as well as longer term fire history data to determine if additional non-weather-related variables (e.g. fuel type, land ownership) may improve the skill of the forecasts, in particular, by decreasing the number of days when escaped fires occurred but were not predicted.

Pyroclimatic classification of Mediterranean and mountain landscapes of south-eastern France

Thibaut Fréjaville, Thomas Curt

IRSTEA, UR EMAX, 3275 route Cézanne, F-13185 Aix en Provence, France.

Abstract
Fire risk is expected to increase in the Mediterranean Basin like in many areas worldwide. Climate is likely the main driver of fire activity by conditioning fuel dryness and fire weather. However fire-climate relationships are conditioned by other environmental dimensions like fuel structure (composition and spatial arrangement of flammable vegetation) and human activities. Therefore assessing how climate controls fire activity in heavily anthropized landscapes like European Mediterranean regions requires to design analyses in appropriate geographic units to encompass the dominant fire drivers. We aimed to assess how spatiotemporal patterns of both fire activity and climate structured south-eastern France into homogeneous geographic unit which we defined as 'pyroclimatic' regions.
We performed a pyroclimatic classification of Mediterranean and mountain areas of south-eastern France at 2 km resolution from the national fire database and daily atmospheric parameters over 1973-2009. This classification was based on multidimensional and clustering analyses. South-eastern France is characterized by three main 'pyroclimatic' regions and ten sub-regions from high fire-prone maritime mountains to moderate fire-prone hot lowlands and low fire-prone inner moist mountains. These geographic units are discriminated from each other by fire activity, fire seasonality, fire weather and their recent evolution.
We demonstrated that fire activity and fire weather of south-eastern France are highly dynamic in space and time. Characterizing pyroclimatic regions offers new regional perspectives of fire management and policy because two areas having similar fire weather, fire regime and recent temporal trends would benefit for specific attention.

Keywords*: pyrogeography, climate change, fire danger, fire activity, fire density, burned area, Mediterranean ecosystems, mountain.*

Introduction

Future changes of fire activity would be highly heterogeneous in space and time (Flannigan *et al.* 2009; Moritz *et al.* 2012). Spatial patterns of fire activity are governed by environmental gradients of climate, vegetation and ignition which drive pyrogeography worldwide (*sensu* Krawchuk *et al.* 2009). In this sense, authors argued that global changes are likely to have different effects on fire regimes respective to the predominant drivers (Bradstock, 2010; Krawchuk & Moritz, 2010). Climate is likely the main driver of fires because it controls both fire weather and fuel moisture (e.g. Flannigan *et al.* 2000) such as fuel amount (Bond and Keeley 2005). Otherwise, human influence on current and past fires has been emphasized as a key process (Bowman *et al.* 2011). In particular, the fire-climate relationship at a regional scale should be offset by temporal changes in land use and or fire management policies (Mouillot and Field 2005; Marlon *et al.* 2008). Therefore, it appears that no description or prediction of climate effects on wildfires makes sense without reference to particular climatic, ecological and human contexts. Human influence on fire activity has already been highlighted in Mediterranean areas through transformation of land cover and ignition potential (Loepfe *et al.* 2012). On the other hand, the northern Mediterranean Basin are facing an increasing fire risk with ongoing climate change (Bedia *et al.* 2013) and because fires are expected to be primarily limited by weather conditions in these areas (Batllori *et al.* 2013). We aimed to assess the diversity of French Mediterranean 'pyroclimates', i.e. regions having similar fire regime, similar climate, and similar recent trends of both. We expect that partitioning south-eastern France into pyroclimates will allow testing the variability in local fire drivers

because fire activity varies strongly across the study area (Figure 1). Moreover characterizing 'pyroclimates' has management implications since two areas having similar fire weather, fire regime and temporal trends would benefit from similar fire management and policy. So we aimed to assess the spatiotemporal patterns of fire weather and fire regime across south-eastern France and test how they are distributed into homogeneous geographic units, i.e. pyroclimatic regions.

Methods

Fire regime and fire weather of south-eastern France were quantified over 1973-2009 at two kilometre resolution from the national fire georeferenced database (Prométhée 2011) and daily atmospheric parameters of Safran reanalysis system (Vidal *et al.* 2010).

Fire regime was quantified from 2*2 km aggregates of i) fire season length (number of days between the first and the last fire of the year), ii) yearly and seasonal fire occurrence (fire density) and iii) yearly and seasonal cumulated size of fires which ignited in a given pixel. As we aim to capture regional variation in fire regime, we applied an inverse distance weighting function to smooth fire statistics over a larger moving window (30 km). A spatial smoothing of fire metrics allowed us to emphasize their deterministic part by reducing the stochasticity inherent to the fire process. Moreover, as fire regime may need more than four decades to be assessed in the less fire-prone regions, we expanded the spatial search range of fire occurrence in a given pixel from two (pixel resolution) to ten kilometres (moving window of 5 km radius). Fire danger was assessed from components of the Canadian Fire Weather Index System which rate the initiation, spread and control of forest fires. Fire weather index (FWI) and its drought components (FFMC, DMC, DC) were computed from the equations of Van Wagner and Pickett (1985) based on daily noon parameters (Van Wagner 1987). The use of instantaneous conditions (12h GMT) instead of daily means was recently pointed out to get reliable estimates of mean and extreme conditions of fire danger (Herrera *et al.* 2013). Climate patterns were assessed from monthly and yearly averages of temperature and precipitation whose computations are based on daily mean temperature and cumulated rainfall respectively. All these indices were downscaled from height to one kilometre resolution by the help of regional statistical modelling following standard procedures (Zimmermann and Kienast 2009; Zimmermann *et al.* 2013). Specifically downscaling procedure was based on vertical gradient modelling *per* homogeneous climatic regions ('symposium', Vidal *et al.*, 2010) and anomaly inference. Fire danger and bioclimatic indices were first computed before downscaling and then aggregated to 2*2 km (fire database resolution). Temporal trends over 1973-2009 were quantified for all fire regime variables and downscaled climatic indices by the statistics of a modified Mann-Kendall trend test (Hamed and Ramachandra Rao 1998).

We carried out the pyroclimatic classification of south-eastern France by ordination and clustering analyses on four subsets: i) fire regime metrics, ii) climate (fire danger and bioclimatic indices) and iii-iv) their past temporal trends. First, we independently synthesized each of the four subsets from Principal Components Analyses (PCA) with backward selection procedure. Backward selection was applied to remove the least contributory variables in order to synthesize the multidimensional variability of fire, climate and temporal trends into a reduced number of gradients (i.e., principal components). We prior standardized seasonal fire and climatic variables by pixel (0-1) to limit autocorrelation with annual means and to study the seasonal distribution of them among pyroclimatic regions. Secondly, we performed a hierarchical agglomerative clustering (HAC) on principal components based on a Euclidean distance matrix and the Ward criterion (Ward 1963). The number of group was given by the Calinski-Harabasz criterion (Caliński and Harabasz 1974) applied on an independent k-means clustering with Monte Carlo simulations (Makarenkov and Legendre 2001). All analyses and calculations were performed on R environment (R Core Team 2013), with the help of the 'fume' package for FWI calculations and trend tests (Santander Meteorology Group 2012).

Results and discussion

Average patterns over 1973-2009 of annual fire density and size show a high variability of fire activity across South-eastern France (Figure 1). We find the most fire prone areas in the eastern Mediterranean coast where from west to east, calcareous and siliceous Provence, the maritime pre-Alps and Corsica have experienced both the highest density of fires and the highest burned area. In the western coast, we find several fire-prone islands around major cities with high burned areas and moderate fire density. A third area with high density and cumulated size of fires was found in north-western inlands (Ardeche plateau). Elevated mountain areas in Eastern Pyrenees, Cevennes and Southern Alps (from west to east) are less fire-prone. These spatial gradients of fire activity are partly related to fire weather ones, depicted by the drought code (DC) and the fire weather index (FWI) of the Canadian Fire Weather Index System (Figure 1). Annual extremes (95th percentile) of DC and FWI are maximal in the western Mediterranean coast and minimal in elevated mountain areas which are relatively characterized by high *versus* low fire activity respectively.

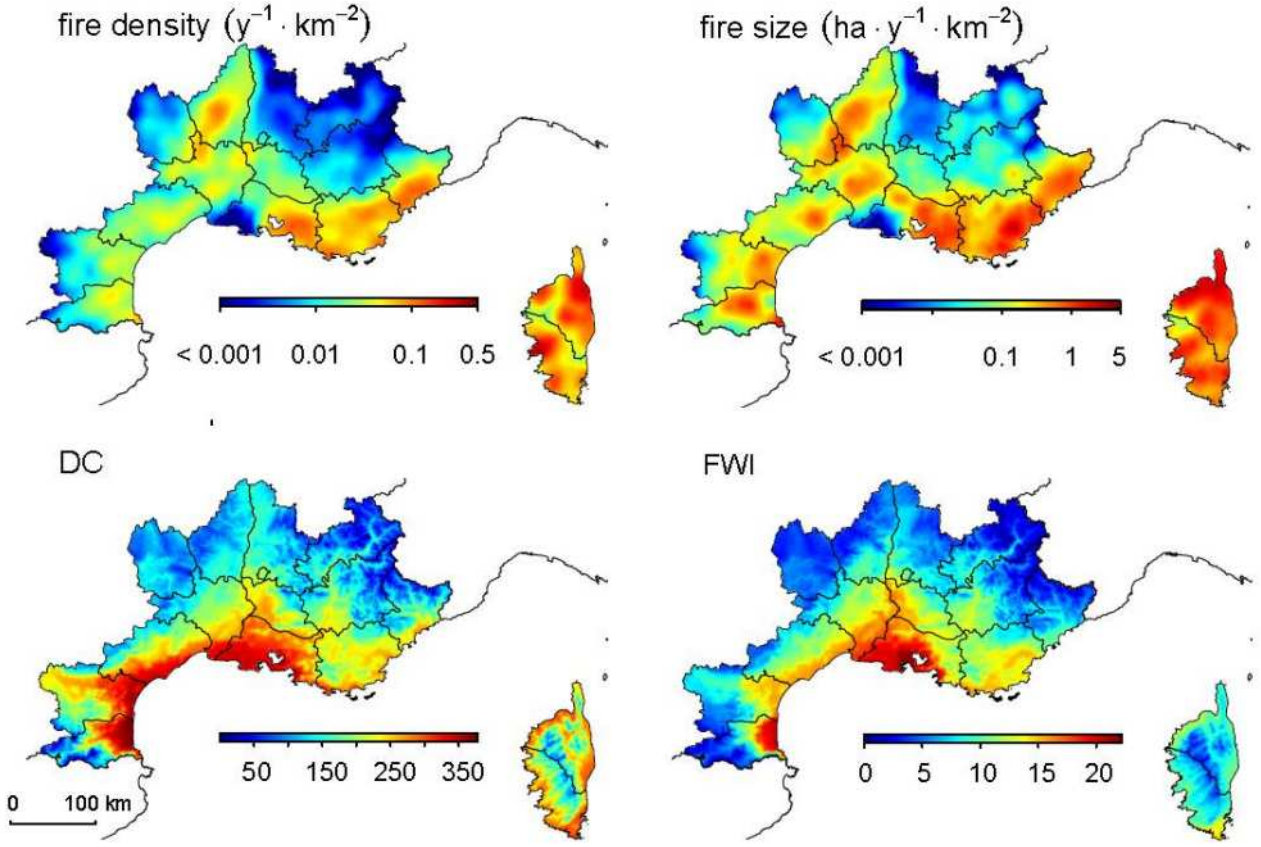

Figure 1. Spatial patterns of annual fire density, fire size, Drought Code and Fire Weather Index in the 15 departments of south-eastern France (1973-2009 averages). Fire metrics were smoothed by an inverse distance weighting function on a 30 km moving window (log-scale). Fire size represents here the cumulative size of fires which ignited in a given square kilometre per year. Maps of fire weather indices have been computed from extreme annual values (95th percentile).

By taking into account fire activity, fire weather and their temporal trends over 1973-2009, clustering analyses indicated that south-eastern France is divided into three pyroclimatic regions and 10 sub-regions (Figure 2). These regions constitute specific combinations of climate and fire regime from the highest fire-prone maritime mountains (Corsica and maritime pre-Alps, PCr-1) to high fire-prone Mediterranean-climate lowlands (Mediterranean coast and Rhone valley, PCr-2) and low fire-prone moist and cold inner mountains (eastern Pyrenees, Cevennes and southern Alps, PCr-3).

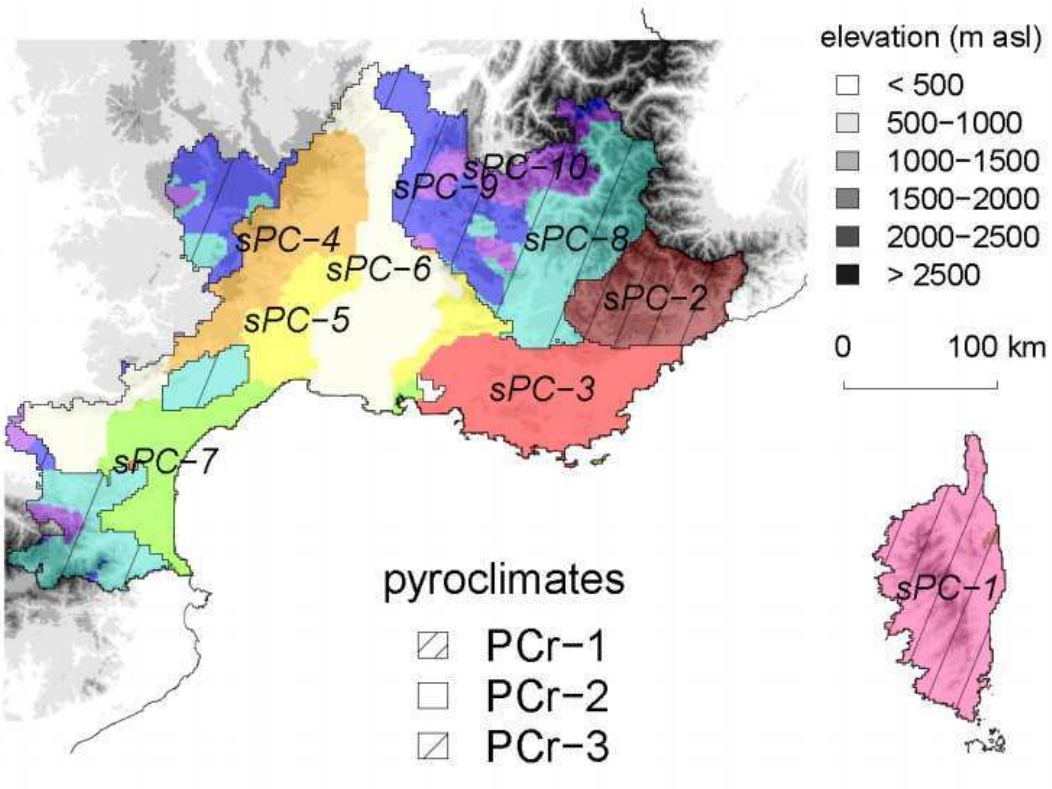

Figure 2. Pyroclimatic regions of south-eastern France. Pyroclimatic regions (PCr) were subdivided into 10 sub-pyroclimates (sPC). Sub-regions sPC-1 and 2 belong to pyroclimate PCr-1; sPC-2 to sPC-7 belong to PCr-2 and sPC-8 to sPC-10 belong to PCr-3. See Method section for details on pyroclimate partitioning.

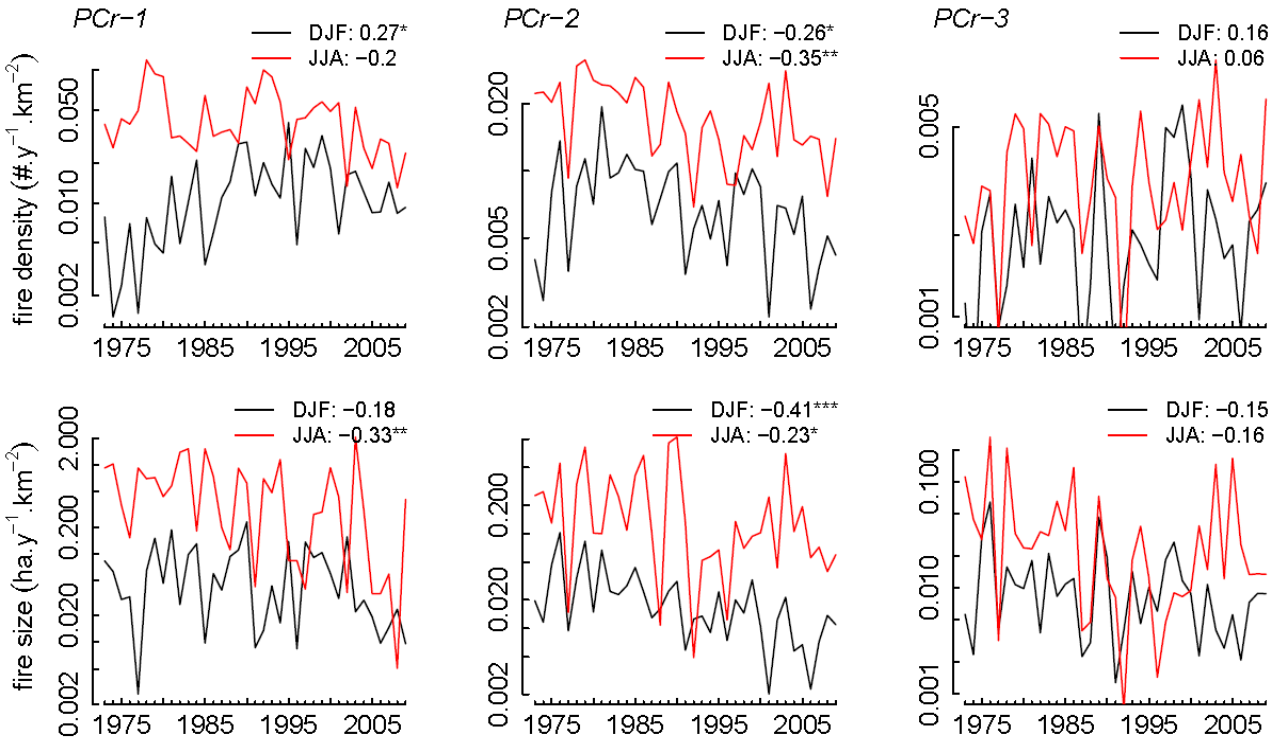

Figure 3. Averaged temporal trends (1973-2009) of winter (DJF) and summer (JJA) fire density and fire size (log-scale) within the three pyroclimatic regions. Correlation coefficient (t) and significance ($p < 0.05$, ** $p < 0.01$, *** $p < 0.001$) are presented for Mann-Kendall modified trend tests. Fire size represents here the cumulative size of fires which ignited in a given square kilometre per year.*

Fire danger is the highest in PCr-2 and the lowest in PCr-3 in respect to annual mean and 95th percentile of FWI and DC (Figure 1). Trend tests over the four past decades indicated that mean fire danger has significantly increased in all three regions, depicted by yearly mean FWI (tau > 0.42, p < 0.01). Fire danger extreme conditions have followed the same increasing trend (95th percentile FWI: tau > 0.39, p < 0.05). These findings corroborate previous study in Mediterranean areas (Carvalho *et al.* 2008; Bedia *et al.* 2013). Otherwise fire activity is largely seasonally restricted with one peak in winter and one in summer. The two most fire-prone regions PCr-1 and PCr-3 are characterized by a predominant fire activity in summer compared to PCr-3 (69, 73 and 45 % of annual burned area, respectively). On the contrary, winter burned area is higher in annual proportion within the less fire-prone elevated-mountain region PCr-3 (30 % against 19 % and 10 % in PCr-1 and PCr-2 respectively). In these more weather-limiting landscapes spring fires contribute to 18 % of annual burned area, whereas autumn fires are poorly contributing with less than 7 % of annual burned area whatever the pyroclimatic region. 1973-2009 trends of seasonal fire activity showed contrasted patterns too (Figure 3). Indeed winter fire density has increased in PCr-1 (p < 0.05), decreased in PCr-2 (p < 0.05) while both fire density and size have not significantly changed in winter and in summer across PCr-3 (p > 0.05). Overall in the two most fire-prone regions, both summer fire density as winter and summer fire size have decreased these past decades (Figure 3) with higher significant trends for the hotter and dryer pyroclimatic region (PCr-2, p < 0.05).

We demonstrated that south-eastern France has contrasted geographic units, i.e. pyroclimatic regions, which revealed differences in both spatial and temporal patterns of fire and climate. This classification would offer new regional perspectives in fire management policy by defining regional affinities in both fire weather and fire regime dynamics. In the heavily anthropized landscapes of south-eastern France, fire activity appear likely more heterogeneous in space and time than in other Mediterranean areas where burned area has increased since the seventies (Pausas 2004; Carvalho *et al.* 2008). Indeed we found that fire density and fire size have increased in some regions and decreased in others with season-specific trends. These findings point out that changes in fire activity may strongly differ between closed regions without *a priori* evident climatic explanation. This may involve a stronger expression of climatic-independent altering dimensions such as fire suppression strategies (Mouillot and Field 2005; Brotons *et al.* 2013) or land cover transformation (Loepfe *et al.* 2012). This study highlights that the predominance of fire drivers among climate, vegetation and human factors may likely differ across small spatial ranges and may counteract the effects of climate change on future regional fire activity.

Rainfall effects on fine forest fuels moisture content

Sérgio Lopes[a], Domingos Xavier Viegas[b], Luís de Lemos[a], Maria Teresa Viegas[b]

[a] *Environment Department, Technology and Management School of Viseu, Polytechnic Institute of Viseu, Campus Politécnico de Repeses 3504-510 Viseu, Portugal;slopes@estv.ipv.pt*
[b] *ADAI/Mechanical Engineering Department, University of Coimbra, Polo II, Pinhal de Marrocos, 3030-790 Coimbra, Portugal; xavier.viegas@dem.uc.pt*

Abstract
The main purpose of the present study was to develop and test different approaches to predict fuel moisture content after rainfall episodes based on field measurements. These approaches were validated also with field measurements that indicate which as the best performance. It was also an objective to establish a low risk or safe period in terms of forest fires occurrence through the analyses of fuel moisture content after rainfall episodes comparatively to the value observed before the episodes.
Although the influence of rainfall on forest fuel moisture content is quite complex we found that the simplified assumptions made in the present study and the simple mathematical models that were proposed exhibit suitable performances in the prediction of fuel moisture content change after rainfall episodes. In the present study good prediction results were obtain for dead foliage of the tree species of *Pinus pinaster* and *Eucalyptus globulus*. It was also verified that a safe time period regarding the occurrence of forest fires depending on the summer rainfall episode intensity could be established.

Keywords*: Fuels, moisture content, rainfall, fire risk.*

Introduction

Rainfall has a significant effect in forest fire danger. Depending on the period of the year, it can contribute to increase fine fuel growth and therefore increase fire danger during the fire season (Viegas and Viegas 1994). On the other hand rainfall episodes during the fire season will increase fuel moisture content (FMC) and therefore reduce fire danger, establishing a low risk period regarding the occurrence of forest fires. In order to predict FMC it is important to estimate the increase of moisture as a result of a given amount of rainfall and also to predict the decrease of moisture and consequently the duration of the low risk period. The influence of rainfall on FMC of dead fine fuels is well known but it is a complex process that cannot be simply a matter of directly equating the changes in moisture content with the amount of rainfall (Viney 1991).
The increase of FMC can decrease with the increase of rainfall amount and initial FMC. Thus as the amount of rainfall increases, a smaller proportion of it could be held by the fuels, also the higher the fuel's initial moisture content, the less rain it could absorb (Van Wagner 1987).
The main purpose of the present study is to develop and test different approaches to predict FMC after rainfall episodes based on field measurements. These approaches will be validated also with field measurements that will indicate which as the best performance. It is also an objective to establish a safe time period regarding the occurrence of forest fires through the analyses of FMC after rainfall episodes comparatively to the value observed before the episodes.

Field measurements

In the present study, FMC of dead foliage from *Pinus pinaster* and *Eucalyptus globulus* tree species and living shrub foliage and extremities from *Calluna vulgaris* and *Chamaespartium tridentatum* (that are very common in the forests of Central Portugal) was measured by field sampling throughout the year from 1996 to 2010. Samples were daily collected at Lousã during the summer months (June to September) and once or twice a week during the rest of the year (October to May), between 12:00h

and 14:00h LST. FMC was determined by oven-drying the fuel samples for 24 hours at 105°C, as presented in Figure 1. The total daily rainfall measured at the Lousã Weather Station obtained by the Portuguese Institute of Meteorology for the same period was used in the present analysis. Similar sampling was performed in Viseu (80km apart from Lousã) for the following species: dead foliage of *Pinus pinaster* and *Eucalyptus globulus* and living *Calluna vulgaris* from 2007 to 2010.
For FMC prediction after rainfall episodes, model evaluation was performed using data from of a series of rainfall episodes at Lousã and model validation was performed comparing predicted values with FMC measured in Viseu for well characterized rainfall episodes. For establishing the low risk period after the rainfall episodes data from Lousã and Viseu were used.

Figure 1. Sampling and determination procedures on the FMC research program of Lousã and Viseu

In Figure 2 some examples of studied rainfall episodes occurred in Lousã and Viseu are presented. As can be seen there are some rainfall episodes with only one day while in other examples there are several consecutive days of precipitation. In some of them rainfall intensity increased and in other cases rainfall intensity decreased.
Analysing all the available episodes occurred in Lousã and Viseu, depending on rainfall intensity and on the initial moisture content of forest fuels, after the rainfall episode we can establish period of time with low risk of fire ignition.
It can be observed that an episode with intensity up to 10 mm/day shows a 1 to 2 days safe period till it returns to the initial value of FMC before the episode. An episode with intensity higher than 10 mm/day can result in at least 3 days of low risk period.

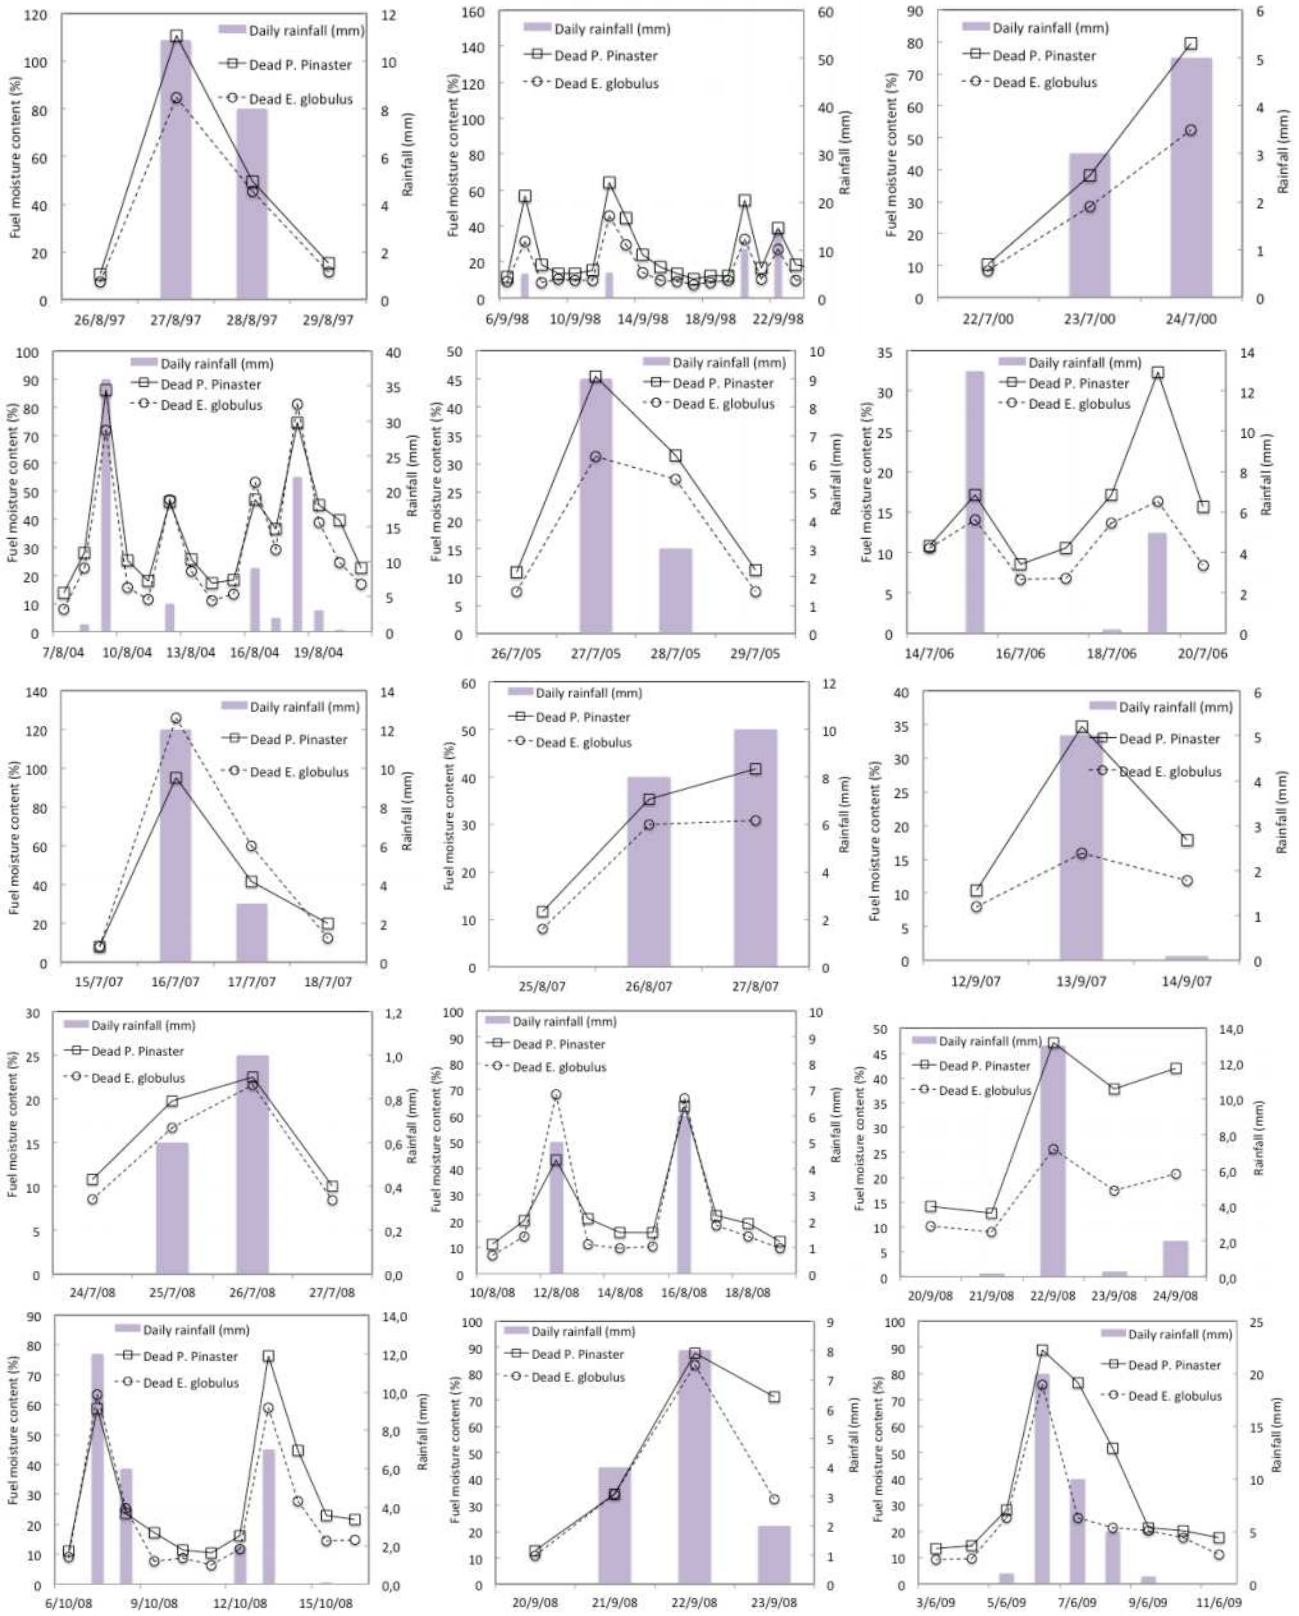

Figure 2. Examples of studied rainfall episodes that occurred in Lousã and Viseu.

FMC Variation Models

As can be seen in Table 1, for a correlation analysis, the Spearman nonlinear correlation coefficients were calculated between the FMC variation, Δm (variation between the FMC of one day and the FMC of the day before**)** and the rainfall intensity**,** I_d (total rainfall of the last 24h), rainfall variation, ΔI (variation between the rainfall intensity of one day and the rainfall intensity of the day before) and the initial FMC, m_0 (FMC of the day before).
The correlation analysis shows that, for dead foliage (*Pinus Pinaster* and *Eucalyptus globulus)*, rainfall intensity I_d and rainfall variation ΔI have a significant positive correlation with FMC variation Δm and a significant negative correlation with FMC variation/rainfall intensity $\Delta m/I_d$. For shrub foliage of *Calluna vulgaris* a medium positive correlation with Δm and also a significant negative correlation with $\Delta m/I_d$ was observed.

***Table 1. Correlation analysis between the FMC variation and rainfall intensity**, rainfall variation and initial FMC*

			FMC variation	FMC variation/ Rainfall intensity
			Δm (%)	Δm /I_d (%.mm^{-1})
Dead Pinus pinaster	Rainfall intensity	I_d (mm)	0.683$^{(**)}$	-0.763$^{(**)}$
	Rainfall variation	ΔI_{d-d-1}(mm)	0.692$^{(**)}$	-0.611$^{(**)}$
	Initial FMC	m_0	0.059$^{(ns)}$	-0.380$^{(**)}$
Dead Eucalyptus globulus	Rainfall intensity	I_d (mm)	0.597$^{(**)}$	-0.750$^{(**)}$
	Rainfall variation	ΔI_{d-d-1}(mm)	0.608$^{(**)}$	-0.656$^{(**)}$
	Initial FMC	m_0	0.122$^{(ns)}$	-0.361$^{(**)}$
Calluna vulgaris	Rainfall intensity	I_d (mm)	0.316$^{(**)}$	-0.755$^{(**)}$
	Rainfall variation	ΔI_{d-d-1}(mm)	0.328$^{(**)}$	-0.651$^{(**)}$
	Initial FMC	m_0	0.291$^{(**)}$	0.025$^{(ns)}$
Chamaespartium tridentatum	Rainfall intensity	I_d (mm)	0.128$^{(ns)}$	-0.815$^{(**)}$
	Rainfall variation	ΔI_{d-d-1}(mm)	0.060$^{(ns)}$	0.000$^{(ns)}$
	Initial FMC	m_0	0.041$^{(ns)}$	-0.086$^{(ns)}$

$^{(**)}$ Significant at 0.01 level; $^{(*)}$ Significant at 0.05 level; (ns) Not significant

Based on the Lousã FMC field measurements and considering the previous correlation analysis, three models were developed and tested, each one with the same purpose of determining the FMC m_d of the day d by adding a FMC increase/decrease value Δm to the FMC observed before the episode m_0 as defined in Eqn 1.

$$m_d = m_0 \pm \Delta m \qquad 1$$

A daily basis time resolution for FMC modelling was adopted, not considering crown interception, fuel immersion in water, changes of intensity and duration of rainfall with less than 24h resolution.
It is observed that for a given fuel with initial FMC value equal to m_o, expressed in [%] in a given day d if there is a rainfall with intensity I_d, expressed in [mm] on the previous 24 hours then there will be a FMC variation Δm.

In Model 1 we assume that for fine dead fuels this Δm is an increase value to m_o depending only on the amount of rainfall of day d as defined in Eqn 2.

$$\Delta m = a_1 . I_d{}^{b_1} \quad (2)$$

It was also found that Δm could depend not only on I_d but also on m_o.

We propose Model 2 to estimate the relationship between the increase in FMC and rainfall intensity expressed by $\Delta m / I_d$ and the initial FMC m_o as defined in Eqn 3.

$$\Delta m / I_d = a_2 . m_0{}^{b_2} \quad (3)$$

Models 1 and 2 do not consider FMC change due to consecutive days with rainfall, which are observed quite often. For this purpose we propose Model 3 to take into account, not only the occurrence of rainfall in one day but also in two consecutive days with values I_d and I_{d-1}, respectively for the last 24 hours and the previous 24 hours. Depending on the sign of rainfall variation $\Delta I = I_d - I_{d-1}$ we will have two situations:

(i) If $\Delta I > 0$ then the FMC variation value Δm is positive and we will have a moisture increase given by Eqn 4:

$$\Delta m = a_3 . \Delta I_{d-d_{-1}}{}^{b_3} \quad (4)$$

(ii) If $\Delta I < 0$ then the FMC variation value Δm is negative and we will have a moisture decrease given by Eqn 5:

$$\Delta m = -a_4 . \left|\Delta I_{d-d_{-1}}\right|^{b_4} \quad (5)$$

Where a_1, a_2, a_3, a_4, b_1, b_2, b_3 and b_4 are empirical model parameters estimated with field measurements.

Results

In Table 2 the FMC prediction model parameters estimation defined in Eqn 2 to 5 are shown. This estimation was performed using linear least squares fitting based on the field measurements. The graphical representation of the studied models is shown in **Erro! A origem da referência não foi encontrada.**.

Table 2. Model parameters of Eqns 2 to 5 and statistical parameters

Model	*Species*	*i*	a_i	*Std. dev.*	b_i	*Std. dev.*	*n*	R^2 *adj.*
Model 1	*Dead Pinus pinaster*	1	15.180$^{(**)}$	1.100	0.445$^{(**)}$	0.037	14	0.917
	Dead Eucalyptus globulus		18.476$^{(**)}$	1.811	0.364$^{(**)}$	0.049	15	0.794
	Calluna vulgaris		22.961$^{(**)}$	1.458	0.211$^{(**)}$	0.029	9	0.794
Model 2	*Dead Pinus pinaster*	2	189.453$^{(*)}$	77.246	-0.981$^{(**)}$	0.137	9	0.863
	Dead Eucalyptus globulus		172.720$^{(**)}$	44.379	-0.960$^{(**)}$	0.091	8	0.940

	Dead Eucalyptus globulus		7.789(*)	5.254	0.591(ns)	0.290	9	0.282

(**) Significant at 0.01 level; (*) Significant at 0.05 level; (ns) Not significant

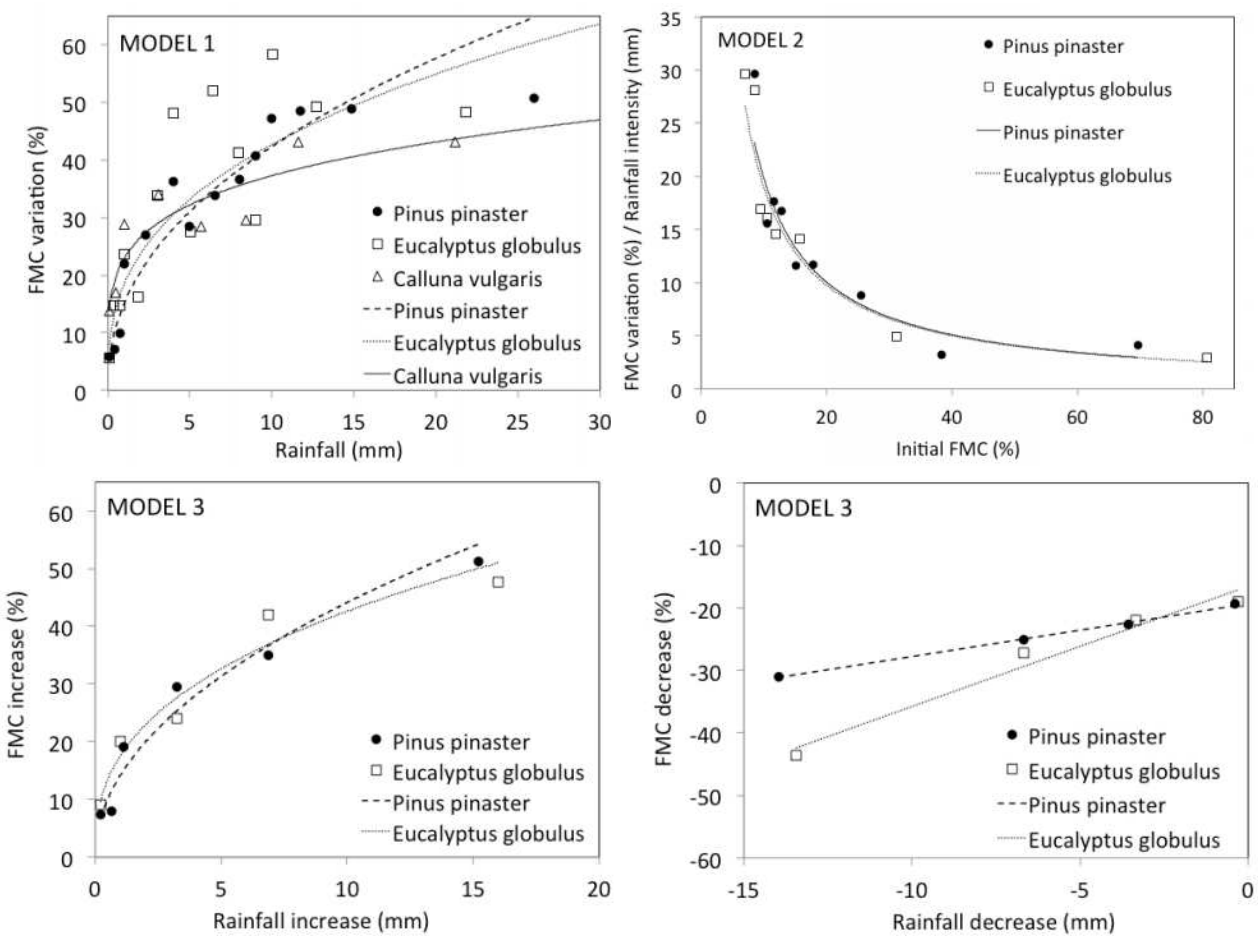

Figure 3. Graphical representation of the studied models

Model validation

In order to validate the previously developed models 1 to 5the predicted FMC values with *Pinus pinaster* dead needles, *Eucalyptus globulus* dead leaves and *Calluna vulgaris* live extremities FMC measured in Viseu between 2007 and 2010 were compared.

In Figure 4, an example comparing predicted FMC values with the ones measured between July and September 2008, taking into account the rainfall effects is presented. Note that the predicted FMC values are calculated only when there is occurrence of rainfall.

Results of the Statistical model validation are presented inTable 3, comparing Viseu field measured values with predicted values, in terms of mean absolute error (MAE), root mean squared error (RMSE) and determination coefficient (R^2), for dead foliage (*Pinus pinaster* and *Eucalyptus globulus*) the best

performance was obtained with Model 3 (MAE: 15.8%, RMSE: 23.6% and R^2: 0.668). Although Model 2 showed a medium R^2 (0.514) the MAE is very high (46.6%), thus indicating that the difference between the model and the measured data is significant.
The results for shrub foliage of *Calluna vulgaris*, considered only in Model 1, that are shown in Table 3 did not exhibit a suitable performance (MAE: 44.5%, RMSE: 64.2% and R^2: 0.287).

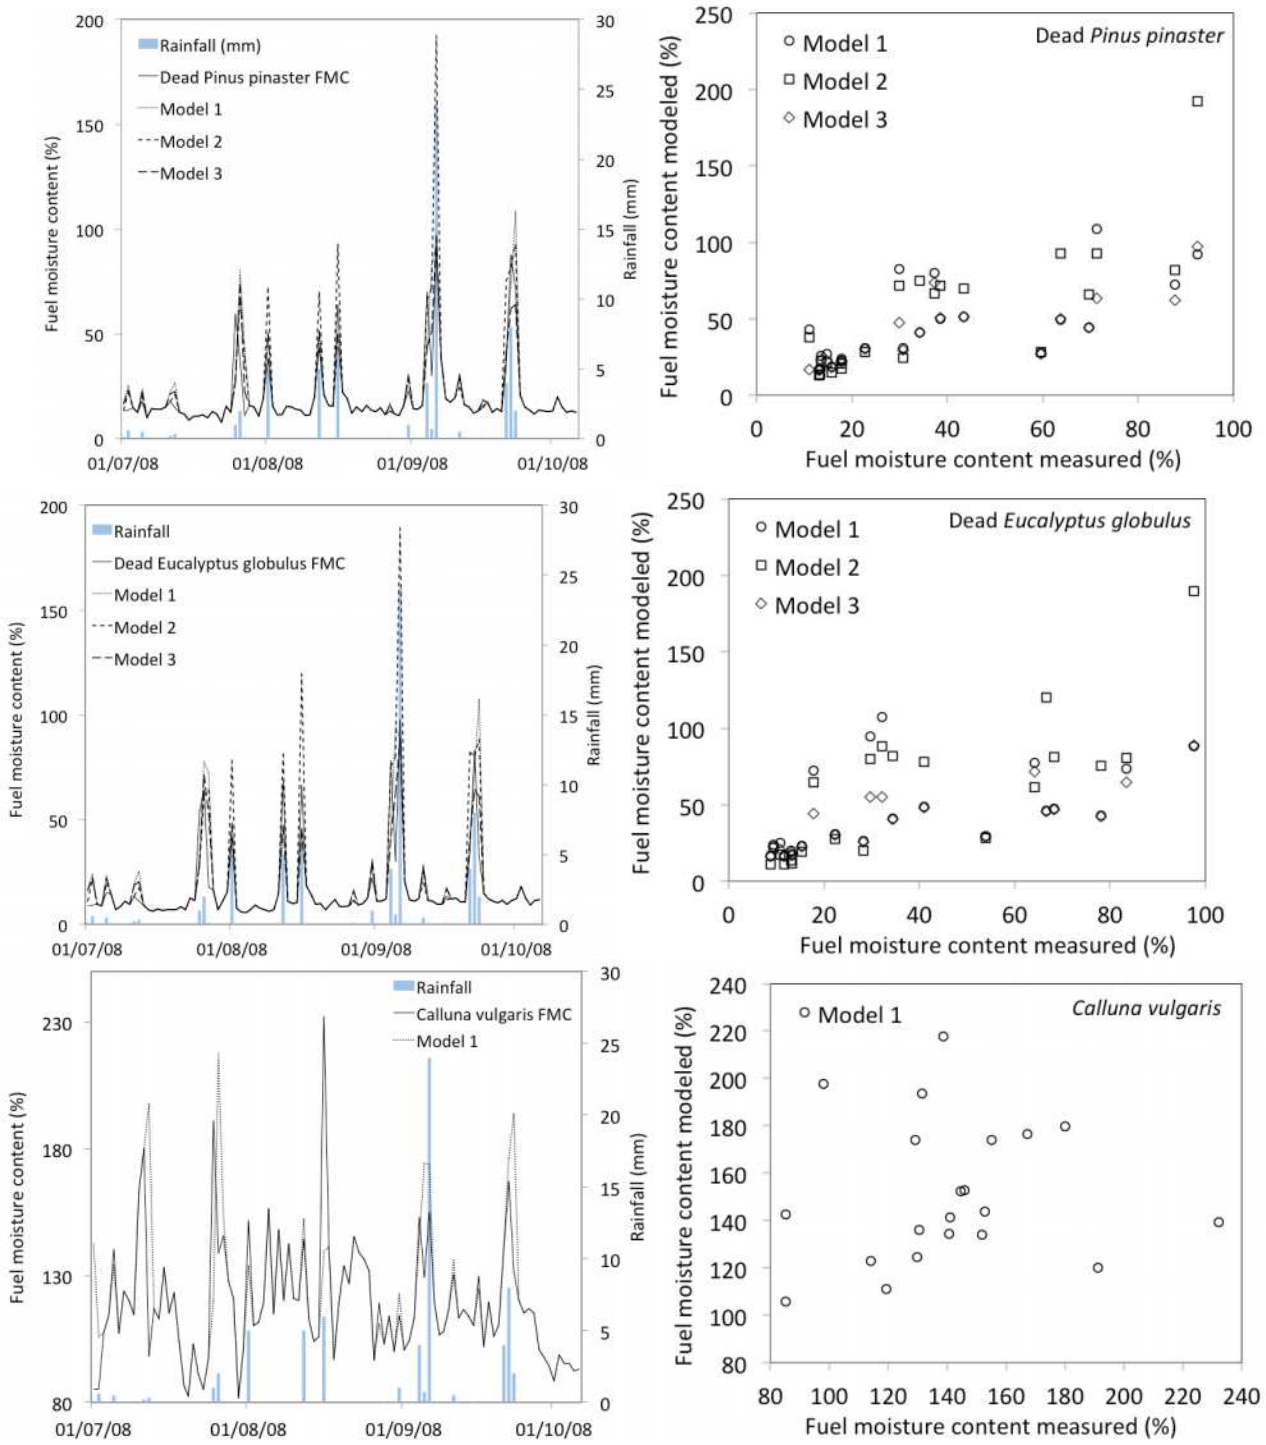

Figure 4. Example comparing predicted FMC values with the measured ones taking into account the rainfall effects.

Table 3. Model validation results

Specie	Statistical parameters	Model 1	Model 2	Model 3
Pinus pinaster	MAE	0.223	0.466	0.158
	RMSE	0.304	0.794	0.236
	R^2	0.596	0.514	0.668
Eucalyptus globulus	MAE	0.242	0.498	0.177
	RMSE	0.323	0.848	0.224
	R^2	0.627	0.529	0.743
Calluna vulgaris	MAE	0.445	-	-
	RMSE	0.642	-	-
	R^2	0.287	-	-

Conclusion

Although the influence of rainfall on forest fuel moisture content is quite complex we found that the simple assumptions that were made in the present study and the mathematical models that were proposed show suitable performances in the prediction of FMC change after rainfall episodes.
In the present study good results for dead foliage of *Pinus pinaster* and *Eucalyptus globulus species* prediction were obtained. In validation tests the best performance was obtained with Model 3, a model that takes into account, not only the occurrence of rainfall in one day but also in two consecutive days. Analysing all the available episodes that occurred in Lousã and Viseu, we found that a low risk period can be established after a rainfall episode. The duration of this period depends on rainfall intensity and on the initial value of moisture content of forest fuels. After an episode up to 10 mm/day a low period of one or two days can be expected while for an episode of more than 10 mm/day this duration can be extended to three days or more.
Further research has to be carried out to check the validity of the proposed models in other conditions and to compare their performance with that of other models.

Abstract
Wildfires are great threat to nature and humans. Predicting fire occurrence, early fire detection and intervention can significantly diminish hazardous consequences. Therefore, fire risk index is used to quantify probability of fire occurrence at certain time and place, in order to help fire managers to organize fire protection in a better way. In this paper we have performed statistical analysis of past fires detected by satellites in respect to various parameters. We have taken into account meteorological, topological and anthropological parameters and study their influence on fire occurrence. Based on this study we proposed an improved method for calculating a site-specific fire risk index (SWRI), especially tuned for the Adriatic region.

***Keywords**: wildfires, wildfire risk index, Adriatic region, statistical evaluation*

Introduction

Wildfires are important class of natural hazards especially in areas with mild and hot climate such as Mediterranean region. Fire management deals with predicting, preventing and detecting wildfires, as well as fire suppression after it ignites. For all these activities, fire risk index can be useful indicator. Fire risk index represents a numerical description probability of fire ignition and spread on a certain place and time. Wildfire risk index determination is of great importance for both wildfire prevention and protection. Even before the actual wildfire, identifying the fire danger is of great importance as it can be useful for planning firefighting activities. By using wildfire risk index, it is possible to achieve a more successful surveillance of the surrounding terrain by raising the level of alertness of automatic fire detection system or human observers on areas where current risk index is high. Beside that, wildfire risk index could help improve fire alertness for all the citizens who may be affected by wildfires.
Most countries exposed to wildfires have either developed or use one of the existing methods for wildfire risk index calculation. However, most of these indexes are not adequate for the use in the Adriatic region. Even more, not many existing wildfire risk indexes were site-specific developed with a focus on a micro-location, and therefore they have a rather low spatial resolution.
In this paper we propose a calculation method for **Site-specific Wildfire Risk Index (SWRI)** with quite satisfactory spatial resolution. The proposed wildfire risk index is not based solely on the meteorological parameters, like most existing wildfire risk indexes. It also takes into account other parameters for which we have, after carrying out a detailed statistical analysis, proven that they have a significant influence on the risk of wildfires in the Adriatic region, particularly on the central part of the Adriatic. More specifically, the proposed wildfire risk index is based on the following parameters: climatological and meteorological parameters, vegetation, terrain configuration and anthropogenic parameters. An example of the developed site-specific wildfire risk index for Split and Dalmatia County in Croatia, during a relatively high-risk index is shown in Figure 1.

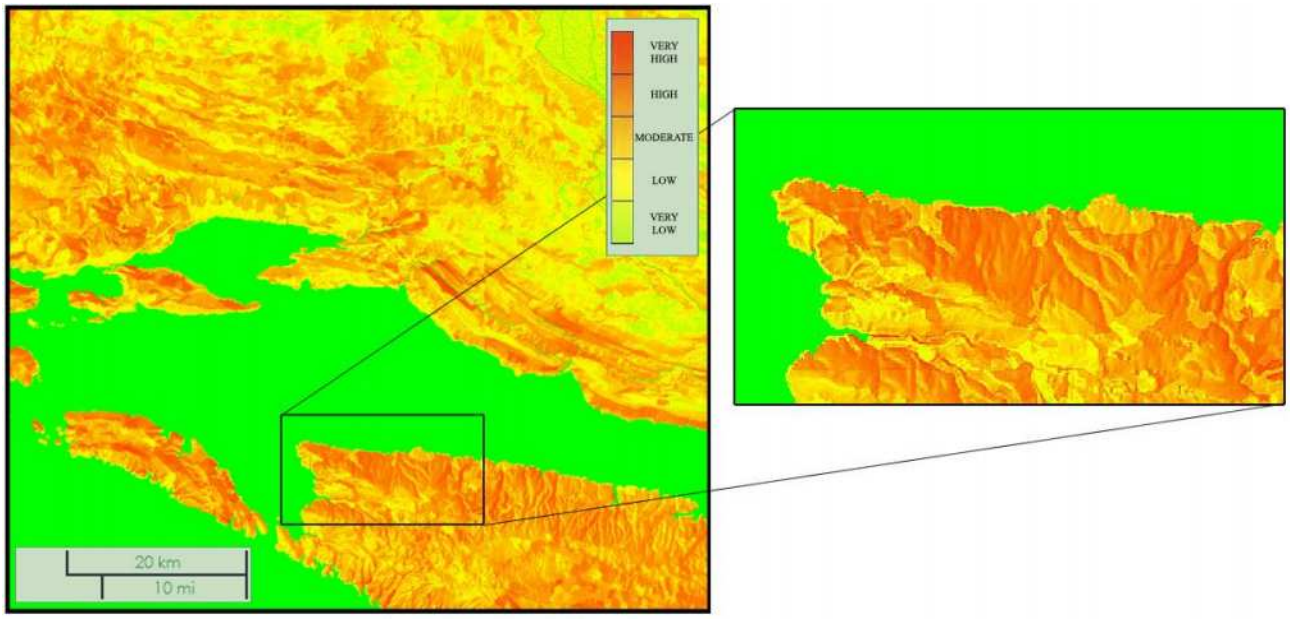

Figure 1. An example showing the proposed micro-location wildfire risk index

Our paper is organized as follows: In Section 2 we give a short overview of the existing wildfire risk indexes. In Section 3 we describe all the data required for a statistical evaluation of the proposed wildfire risk index in the Adriatic region. In Section 4 we studied different parameters in detail and calculated the correlation with wildfire frequency in the past for the Adriatic region. In Section 5 we define what we mean by a site-specific wildfire risk index. Finally, in Section 6 we carried out the evaluation of the proposed index.

Related work

In fire management, operatives usually use some kind of risk predication and assessment. Also, many counties adopted or developed a method for fire risk index calculation. Wildfire risk indexes are often classified into two categories: static and dynamic ((Gould, 2003, (Hernandez-Leal, 2008, (San-Miguel-Ayanz, 2002). Static indicators of wildfires change slowly over time; therefore they can be computed once before each fire season. In contrast, dynamic indicators of wildfires depend upon current conditions and must be calculated at least on a daily basis.
In the United States, National fire danger rating system (NFDRS, 1988) is used for ignition and spread risk assessment. Widely used fire risk index is Canadian Fire Weather Index (FWI), based on Canadian empirical fire model (FWI, 2009). FWI is calculated on the basis of weather conditions (temperature, humidity, wind, rain). Some authors also propose risks estimation based on Normalized Difference Vegetation Index (NDVI, 2014) obtained by remote sensing. In Europe, frequently used wildfire risk index is European Forest Fires Risk Forecasting System (EFFRFS) ((Gould, 2003, (San-Miguel-Ayanz, 2002), where the probability of fire occurrence and likely damage belong to static indicators, and meteorological fire risk and vegetation stress fire risk belong to dynamic indicators.
Geographic information system is used in wildfire risk models described in ((Erten, 2002, (Setiawan, 2004). In ((Zhijun, 2009) elevation, meteorological conditions and vegetation belong to main parameters for wildfire risk index. Other solutions were also proposed like (Silveira, 2008, Preisler, 2004, Vasilakos, 2007, (Netolicki, 2012, (Bugaric *et al*., 2009).
We used a slightly different approach. First we performed a detail statistical analysis of input parameters important for wildfire risk index calculation for Split and Dalmatia County. Based on this analysis a number of parameters were selected and in this first version of our model a linear correlation

of selected parameters was considered. Genetic algorithms were used for calculation of coefficients in the model. The final evaluation has confirmed the reasonable assumptions of our model.

Input data for the statistical analysis

Meteorological data used for the impact assessment of different parameters on a site-specific wildfire risk index were collected for the time period from January 1st 2012. to January 1st 2014. Croatian Meteorological and Hydrological Service (DHMZ) calculates Canadian wildfire index (FWI) for several meteorological station across Adriatic coast several times a day. In collaboration with DHMZ, we have collected for Split-Dalmatia County their FWI as well as other meteorological data concerning wind, rain and humidity, with spatial resolution of 2km.
Vegetation parameters were based on Corine Land Cover (CLC) categorization. Unfortunately, fuel maps that classify vegetation in relation to the characteristics of combustibility were not developed for the Adriatic region. We proposed a simple conversion table to convert from CLC classification to a well-known Fire Behaviour Prediction System (FBPS) models introduced by ((Burgan, 1998, (Anderson, 1982, (Scott & Burgan, 2005).
Terrain configuration data was based on NASA SRTM (Shuttle Radar Topography Mission) ((van Zyl, 2001). These data are currently distributed free of charge, and provide digital elevation model with 3-arc seconds resolution (approximately 90m) for the Adriatic region.
Anthropogenic parameters were extracted from OpenStreetMap ((OpenStreetMap,) that is open data, licensed under the Open Data Commons Open Database License (ODbL). More specifically, we extracted information about roads, railroads, buildings and transmission lines.
The evaluation of the proposed site-specific wildfire risk index was performed using history of wildfires database. This database is based on MODIS ((NASA,) data from Terra and Aqua satellites, which are capable of detecting wildfires with minimal area 1km2. History of wildfires was collected for the period from January 1st 2001 to January 1st 2013 and consists of 1146 records of fire in Split-Dalmatia County.
A site-specific wildfire risk index (SWRI) was completely implemented using GRASS GIS ((NASA, 2014) http*://earthdata.nasa.gov/data/near-real-time-data/data/firms/active-fire-data, Active Fire Data | EOSDIS - Earth Data Website, 06. June 2014.*
(NDVI, 2014) http://earthobservatory.nasa.gov/Features/MeasuringVegetation/
(Neteler & Mitasova, 2008) software and for visualization Mapserver (Mapserver, 2014) as well as Open Source Web GIS technology based on Openlayers (Openlayers, 2014) were used. First the impact assessment of input parameters on the site-specific wildfire risk index in the Adriatic region is given. Please note that all the values were normalized into interval [0-255] where 0 represents low, and 255 high wildfire risk index. For most of the parameters we have calculated Pearson correlation coefficient (Pearson, 1805), later used in model definition.

Impact assessment of input parameters on wildfire risk index

4.1. Climatological and meteorological parameters

While meteorological parameters refer to current weather parameters, climate refers to pattern of meteorological parameters over long periods of time. Climatological parameters can influence wildfire risk index in several ways. Climatological parameters determine the type of vegetation growing at certain territory. Drier climate usually means higher value of insolation and air temperature. Finally, strong winds can also have a great impact on the wildfire rate of spread, and thus on wildfire risk index. The proposed SWRI index is a dynamic index, where dynamics depends mostly on meteorological and climatological parameters. In our solution, wildfire risk index depends on: temperature, relative humidity, rainfall, wind speed, wind direction and cumulative FWI.

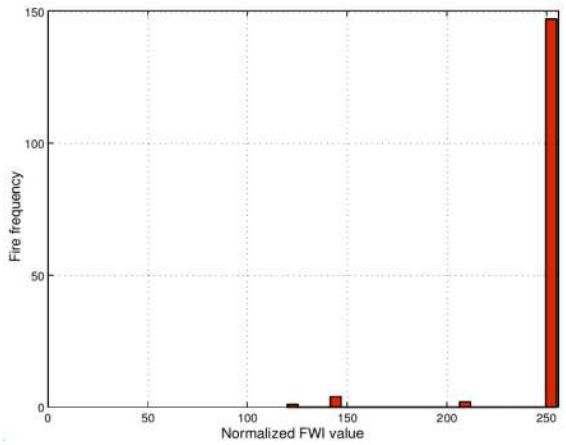

Figure 2. Relation between normalized FWI index R_{FWI} and fire frequency during year 2012.

Figure 2 shows the relation between FWI index and 154 historical wildfires that occurred during the year 2012. As we can see from the figure, most of the wildfires occurred under a very high FWI index; however, this is due to the low spatial resolution of FWI index where most of the terrain during the summer season is labelled as a high-risk territory. Although we believe that there exists territory with lower level of wildfire risk, we decided to take FWI index as a parameter in the calculation of the proposed site-specific wildfire risk index. Let us denote parameter based on Canadian fire feather index as RFWI.

Our study has shown that the slope of the terrain in combination with wind speed (Rst) as well as the aspect of the terrain in combination with wind direction (Rat) have greater influence on wildfire risk than wind speed and wind direction alone. We use the following equations to calculate those two sub-indexes:

$$R_{st} = (wind_{speed} + slope)_{norm\_0-255}, R_{at} = (|\cos(\frac{wind_{dir} - aspect}{2})|)_{norm\_0-255} \quad \textbf{(2)}$$

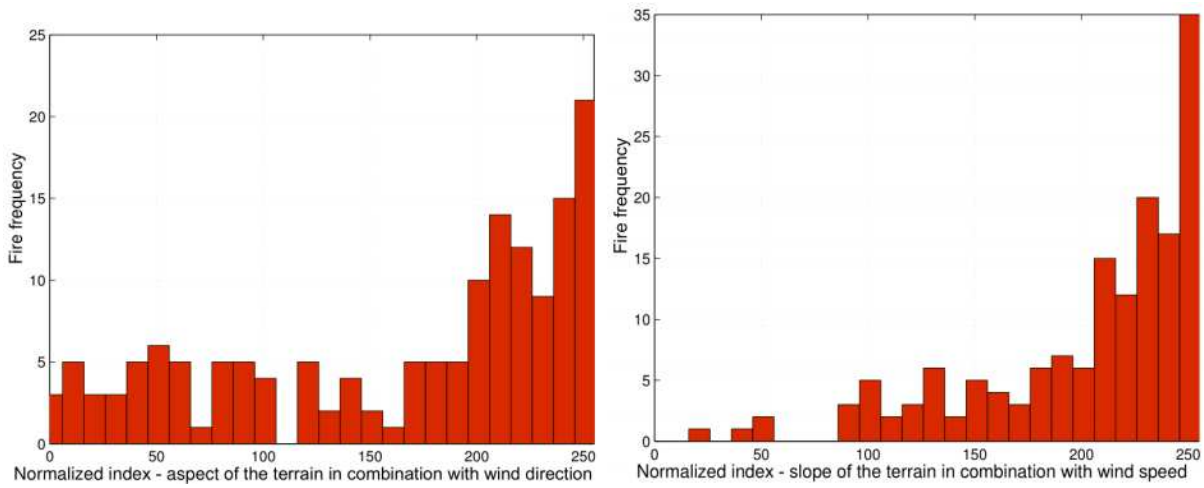

Figure 3. Relation between normalized indexes based on terrain and wind conditions (R_{at},R_{st}) and fire frequency during year 2012.

The graphs showing the normalized indexes are presented in Figure 3. Again, 154 historical wildfires that occurred during the year 2012 were taken into account.

4.2. Vegetation parameters

Fire spreads after ignition by igniting surrounding fuel in presence of oxygen. Amount of fuel depends on type of vegetation and soil. As already mentioned, FBPS fuel model was not developed for the Adriatic region, therefore in this paper we propose a conversion table used to convert from CLC classes to FBPS fuel model (Table 1).
Categories from FBPS fuel model were also normalized into interval [0 255]. Relation between the fuel model sub-index (Rfm) and 1146 historical wildfires that occurred in Split-Dalmatia County from January 1st 2001 to January 1st 2013 is given in Figure 4 (left).

Table 2. Conversion of CLC (Corine Land Cover) classes to FBPS fuel classes

CLC	111	112	121	122	123	124	131	132	133	141	142	211	212	213
FBPS	0	0	0	0	0	0	0	0	0	0	0	11	0	0
CLC	221	222	223	231	241	242	243	311	312	313	321	322	323	324
FBPS	2	10	7	1	12	12	12	9	8	8	1	0	5	2
CLC	331	332	333	334	411	421	422	423	511	512	521	523		
FBPS	0	0	0	0	0	0	0	0	0	0	0	0		

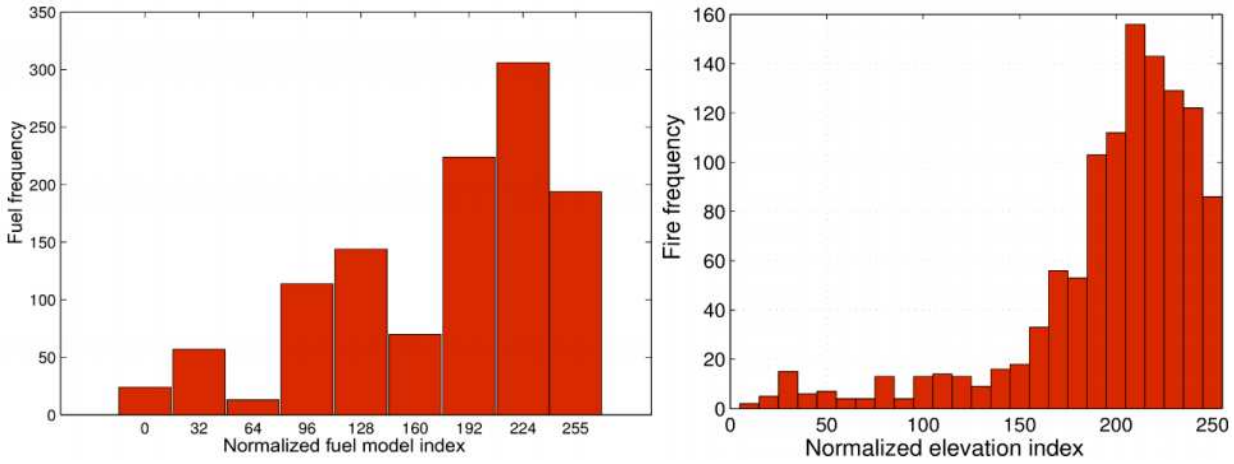

Figure 4. Relation between normalized fuel model index R_{fm} and historical wildfires (left) and relation between normalized elevation index R_{el} and historical wildfires (right)

4.3. Terrain configuration

Terrain configuration has two effects, first it has an influence on wildfire risk, but also it has an inevitable impact on the way the fire spreads after the ignition. In the previous sections we have already shown how terrain configuration in combination with wind speed and wind direction affects the wildfire risk index. In this section we investigate the influence of the terrain elevation.
Higher altitude means lower temperatures, what has a direct impact on the risk of fire ignition. There is also an indirect impact on wildfire risk index through the type of vegetation growing at certain altitudes. Normalized elevation sub-index (R_{el}) was created by normalizing altitudes from 0m to 1000m into interval [0 255] (whereas lower altitude represents higher index). The relation between normalized elevation index and 1146 historical fires is shown in Figure 4 (right).

4.4. Anthropogenic parameters

In most cases of wildfires, humans are often responsible for fire ignition. Human activity is highly correlated with wildfires, no matter if fires were caused deliberately, or started by human negligence or ignorance. Fires caused by arson are often in a close proximity to humans and human infrastructure.

On the other hand, negligence, such as uncontrolled agricultural burning, can also be a significant cause of wildfires. These are just a few examples where the human is the main culprit for wildfire ignition.

A first group of anthropogenic parameters refers to the distance from the human activities. In our study we investigated: the distance from roads and the distance from settlements. In order to determine the influence of the roads, we first formed a corridor close to the roads because we suppose that close to the roads the wildfire risk is higher. The width of the corridor was set to 2000 m, since in our study we observed that most of the historic wildfires occurred within this distance. Similarly, for the influence correlated with the distance from settlements, we formed a zone around the settlements of 15 000 m (again, highest value of the normalized sub-index is in the close vicinity of the settlements). Graphs representing the relation of historical wildfires with normalized sub-indexes representing distance from roads (R_{ro}) and buildings (R_{bu}) are given in Figure 5.

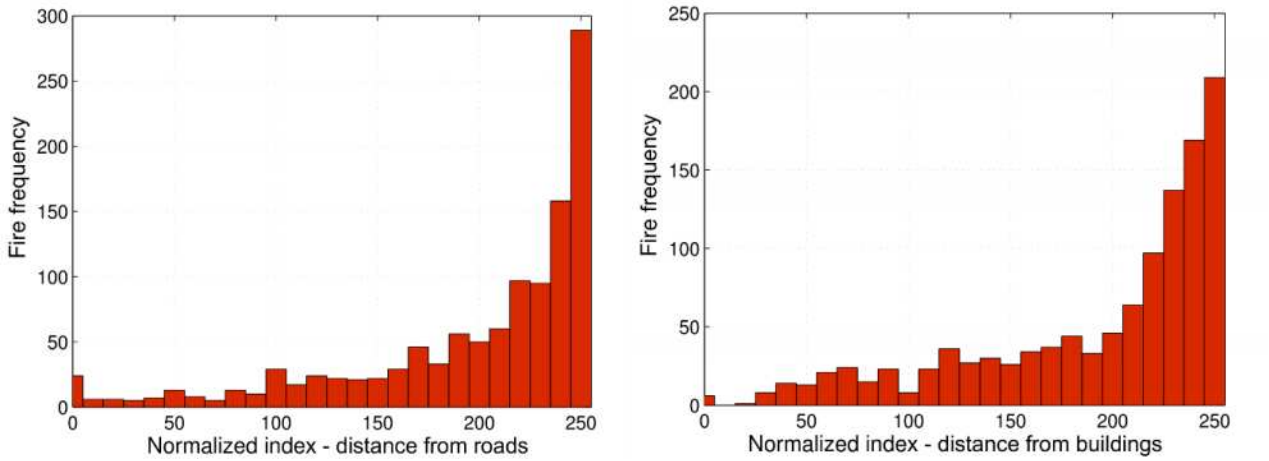

Figure 5. Relation between normalized index based on distance from roads R_{ro} and historical wildfires (left), relation between normalized index based on distance from settlements R_{bu} and historical wildfires (right)

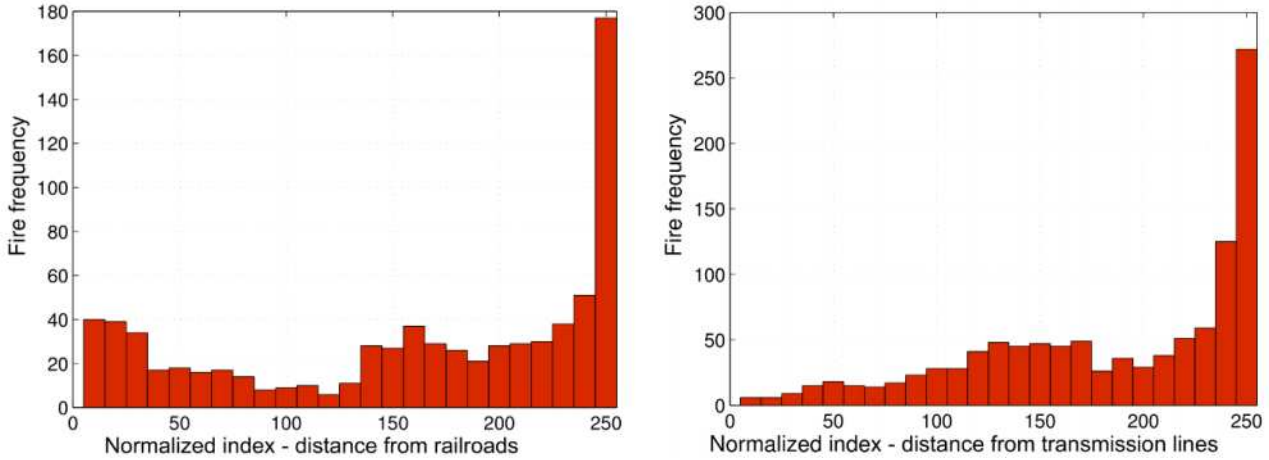

Figure 6. Relation between normalized index based on distance from railroads and historical wildfires (left), relation between normalized index based on distance from transmission lines R_{tl} and historical wildfires (right)

The second group of anthropogenic parameters refers to the distance from human infrastructure, i.e., the distance from railroads and the distance from transmission lines. In the vicinity of the railroads wildfires often start from sparks caused by braking of the trains. However, our study has shown low correlation between historical wildfires and distance from railroads, therefore we decided to omit this sub-index from the final model (Fig 6 (left)). When we studied influence of transmission lines on

wildfire risk index, we formed a corridor with width 2000 m. Normalized index that takes into account the distance from transmission lines (R_{tl}) is shown in Figure 6 (right).
For all the parameters we have calculated Pearson correlation coefficients, as shown in Table 2. Pearson correlation coefficient is a measure of the linear correlation (dependence) between two variables, in this case between a certain sub-index and fire frequency. Maximal correlation is 1.

Table 2. Pearson correlation coefficients for sub-indexes building used for SWRI index calculation

	Sub-index	**Pearson correlation coefficient**
R_{el}	Elevation index	0.8404
R_{fm}	Fuel model index	0.8340
R_{bu}	Index based on distance from buildings	0.7814
R_{st}	Index based on slope of the terrain and wind speed	0.7740
R_{ro}	Index based on distance from roads	0.7044
R_{at}	Index based on aspect of terrain and wind direction	0.6470
R_{tl}	Index based on distance from transmission lines	0.6408

Site-specific wildfire risk index (SWRI) model definition

Site-specific wildfire risk index (SWRI) takes the following sub-indexes as inputs: Canadian fire weather index (R_{FWI}), elevation index (R_{el}), fuel model index (R_{fm}), index based on the distance from buildings (R_{bu}), index based on the slope of terrain and wind speed (R_{st}), index based on the distance from roads (R_{ro}), index based on the aspect of the terrain and wind direction (R_{at}) and index based on the distance from transmission lines (R_{tl}). An overview of all sub-indexes and their dependencies is given in Figure 7.
In order to calculate SWRI index we have used in this phase a simple linear model of superposition of input parameters, as shown in the following linear equation:

$$SWRI = k_1 \cdot R_{FWI} + k_2 \cdot R_{el} + k_3 \cdot R_{fm} + k_4 \cdot R_{bu} + k_5 \cdot R_{st} + k_6 \cdot R_{ro} + k_7 \cdot R_{at} + k_8 \cdot R_{tl} \qquad (3)$$

where $\sum_{n=1}^{8} k_n = 1$. In order to determine the values k_n we have decided to use genetic algorithms (**Goldberg, 1989**). Genetic algorithm is a search heuristic that mimics the process of natural selection. It is used to generate solution to optimization problems using techniques inspired by natural evolution, such as inheritance, mutation, selection and crossover. The most difficult task in genetic algorithm designing is to define a fitness function for measuring the quality of the represented solution.
Our approach was to defined two sets of geographic locations for which we wanted to calculate a site-specific wildfire risk index. The first set consisted of locations of real historical wildfires that occurred during year 2012 in Split-Dalmatia County (we have randomly chosen 100 historical wildfires from that period). The second set consisted of randomly chosen locations in Split-Dalmatia County (we have selected 250 locations).
The following requirements for the data set representing the SWRI index calculated for locations of real historical wildfires were defined: a) the data set should be as close as possible to maximal value 255, b) the data set should be normally distributed - for normality test we used the Spiegelhalter test (Spiegelhalter, 1983), and c) the data set should be maximally skewed to the left, measured using Fisher-Pearson standardized moment coefficient (Doane & Seward, 2011).

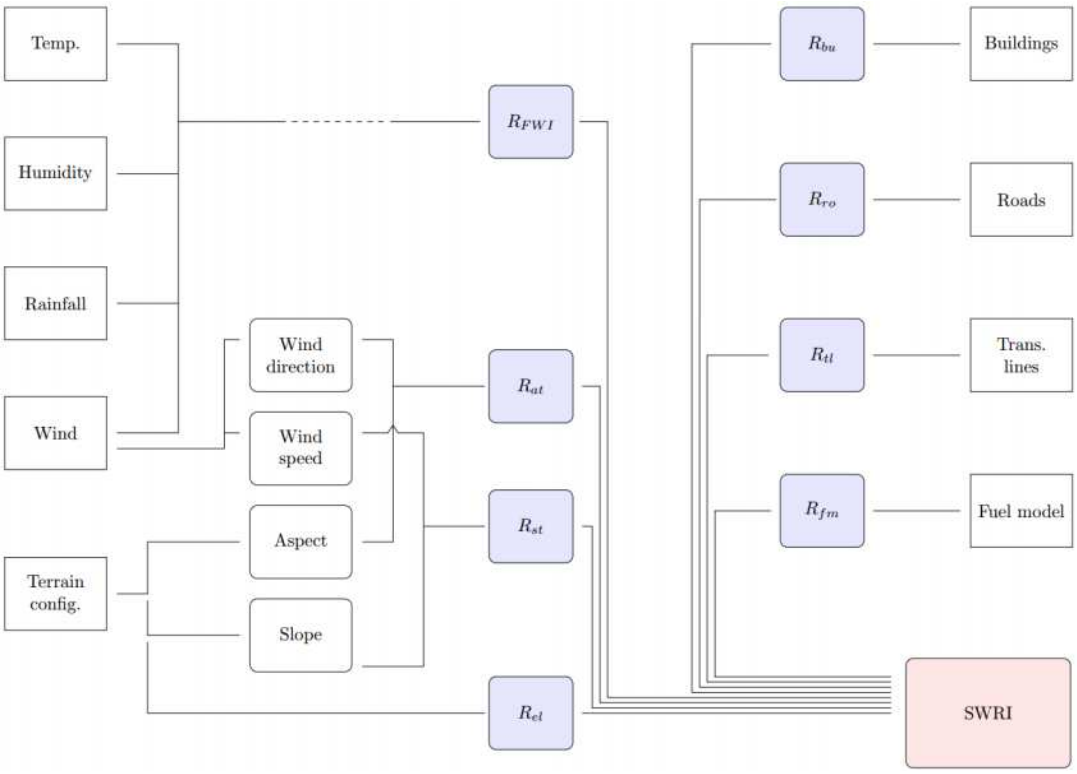

Figure 7. Overview of all inputs and sub-indexes that build up the final site-specific wildfire risk index

The requirements for the data set representing the SWRI index calculated for randomly chosen locations were defined as follows: a) the data set should be normally distributed (also measured using Spiegelhalter test for normality), b) the standard deviation of the data set should be as high as possible. Using the aforementioned requirements we represented the wildfire risk index model definition as an optimization problem. We included Pearson correlation coefficients into the fitness function for the genetic algorithm in a way it defines the mutual ratio of coefficients k_n with the following restriction $\sum_{n=1}^{8} k_n = 1$. The value of the fitness function z was defined by:

$$z = -0.5 \cdot |G_{real} \cdot \overline{Mode_{real}} \cdot p_{real}| - 0.5 \cdot |\overline{\sigma_{random}} \cdot p_{random}| \tag{2}$$

where subscript $(\cdot)_{real}$ represents real historical wildfires, and $(\cdot)_{random}$ represents randomly chosen locations. Parameter G represents Fisher-Pearson standardized moment coefficient where negative values represent skewness to the left, $\overline{Mode}$ is the mode of the dataset normalized into interval [0 1], p the value of Siegelhalter test for normality where value 1 represents normal distribution, and $\overline{\sigma}$ represents a standard deviation normalized into interval [0 1]. Siegelhalter test for normality p is calculated using a set of equations shown in (3):

$$p = 1 - \left|\frac{2}{\sqrt{\pi}} \int_0^{\frac{s}{\sqrt{2}}} e^{-t^2} dt\right|, \quad s = \frac{R - 0.73 \cdot I}{0.8969 \cdot \sqrt{I}}, \quad R = \sum_{i=1}^{I} \left[\left(b_i - \bar{b}\right) \cdot \rho\right]^2 \cdot \ln\left\{\left[\left(b_i - \bar{b}\right) \cdot \rho\right]^2\right\}, \quad \rho = \sqrt{\frac{1}{I} \sum_{i=1}^{I} (b_i - \bar{b})^2} \tag{3}$$

where $\bar{b}$ represents the arithmetic mean of the data set and I represents the number of elements of the same data set. Fisher-Pearson standardized moment coefficient G is defined by

$$G = \frac{I}{(I-1)(I-2)} \cdot \sum_{i=1}^{I} \left(\frac{b_i - \bar{b}}{\sigma} \right)^3 \quad (4)$$

Table 3. Results of the genetic algorithm

Randomly chosen locations representing historical wildfires			**Randomly chosen locations**		
$\overline{Mode_{real}}$	p_{real}	G_{real}	$\overline{\sigma_{random}}$	p_{random}	z
0.8824	0.9216	-0.6951	0.1522	0.0788	-0.2886

Please note that the more negative values of the fitness function z, the better the results. The output of the genetic algorithm (Table 3) provided us with the final linear equation that defines the site-specific wildfire risk calculation:

$$SWRI = 0.399 \cdot R_{FWI} + 0.097 \cdot R_{el} + 0.096 \cdot R_{fm} + 0.09 \cdot R_{bu} + 0.089 \cdot R_{st} + 0.081 \cdot R_{ro} + 0.075 \cdot R_{at} + 0.073 \cdot R_{tl} \quad (5)$$

Equation was implemented into Grass GIS software to calculate SWRI index several times a day. The output of the calculation is a SWRI index in a raster format. Using Mapserver we create a WMS layer that can easily be shown using Openlayers in a web based user interface. As shown in Figure 8, our system automatically communicates with Croatian Meteorological and Hydrological Service (DHMZ) several times a day in order to retrieve the latest data such as current temperature, wind speed, wind direction, rainfall, humidity, as well as the Canadian Forest Fire Weather Index (FWI).

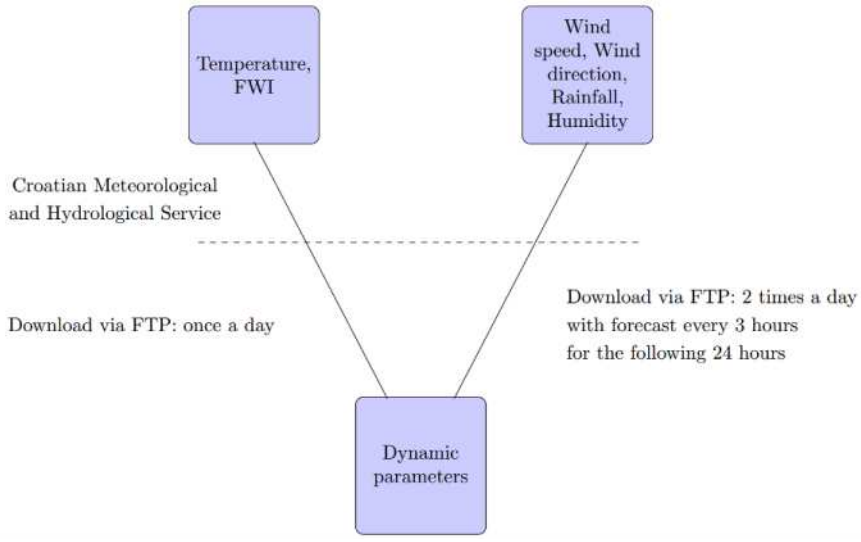

Figure 8. Communicating with Croatian Meteorological and Hydrological Service

SWRI model evaluation

The level of forest fire risk in Croatia is determined by the "Static forest fire risk" defined in the *"Criteria for assessing the risk of forest fires"* (**(MUP, 2003)**, therefore we decided to compare it to

the proposed SWRI index. Parameters taken into account in "Static forest fire risk" are as follows: vegetation cover, anthropogenic parameters, climate, habitat, insolation and forest order. For this index, regions are classified into 4 categories depending on the level of risk: i.e., category IV: low risk, category II: moderate risk, category II: high risk and category I: very high risk. Figure 9 (left) shows the region of Split-Dalmatia County classified into 4 aforementioned categories, while Figure 9 (right) shows the relation between 154 historical wildfires (that happened during year 2012. in the Adriatic region of Croatia) and the *"Static forest fire indexes".* As seen in this figure, most of the wildfires occurred in low risk regions, meaning that the *"Static forest fire risk"* does not predict wildfire risk index with high accuracy.

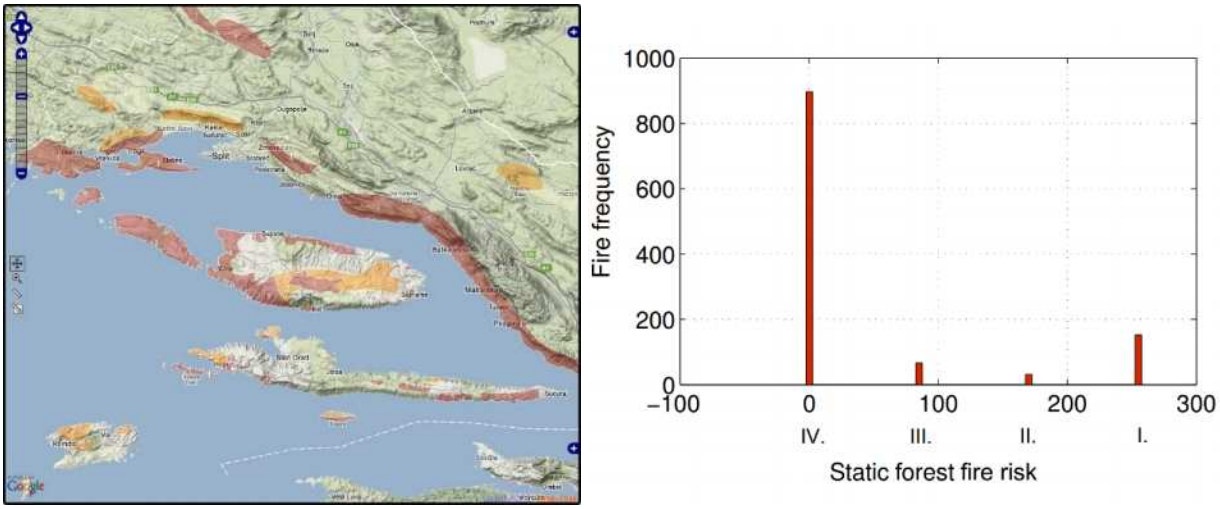

Figure 9. The region of Split-Dalmatia County classified into 4 static risk categories, where dark red colour represents the highest risk (left), and relation between historical wildfires that occurred during year 2012 "with Static forest fire indexes" (right).

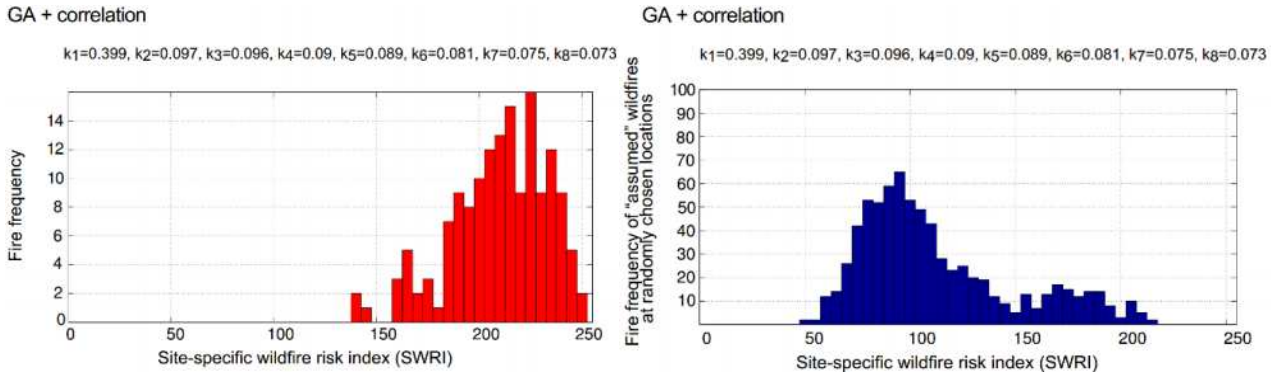

Figure 10. SWRI index for the 154 actual wildfires that occurred during year 2012 (left), and SWRI index for a randomly chosen locations and time moments during the same year

On the other hand, Figure 10 (left) shows the proposed SWRI index for the same 154 historical wildfires that occurred during the year 2012. From this figure it is obvious that most of the wildfires occurred in high risk regions. Nevertheless, in Figure 10 (right) we can see that, for 750 randomly chosen locations and time moments during the same year, the value of SWRI in most cases does not exceed 150, meaning that most of the regions are labelled as low or moderate risky regions. This is expected, as we have modelled SWRI index to be a site-specific index with a focus on a micro-location.

7. Conclusions

In this paper we proposed a novel method for wildfire risk index calculation - the **Site-specific Wildfire Risk Index (SWRI)**. The overall SWRI index is calculated based on 8 sub-indexes: Canadian fire weather index, elevation index, fuel model index, index based on the distance from settlements, index based on the slope of terrain and wind speed, index based on the distance from roads, index based on the aspect of the terrain and wind direction and index based on the distance from transmission lines. All sub-indexes were chosen based on the statistical evaluation, where we have, for all sub-indexes, calculated Pearson correlation coefficients that show their relation to the historical wildfires in the Adriatic region. In other words, for all sub-indexes we have proven their influence on the actual wildfires that occurred in Split-Dalmatia County in the history.

Using genetic algorithms and calculated Pearson correlation coefficients, we have created a final model of SWRI index. We carried out the evaluation of the proposed site-specific wildfire risk index and compared it to the "Static forest fire index", where we have shown that SWRI index provides good correspondence with the actual wildfires that occurred in the Adriatic region in recent years. On the other hand, for randomly chosen locations, the value of SWRI index in most cases indicated a low or a moderate level of risk. This was expected, since SWRI index was modelled with focus on a micro-location and the fact that even in the fire season not all regions should be labelled as regions of high risk.

SWRI index is calculated using geographical information system (GIS), and its main purpose is to display relevant information important for firefighting activities before and during the actual wildfire. The SWRI index should also be optimized for other parts of Adriatic regions besides Split-Dalmatia County using the same methodology for more general results.

Abstract
Lebanon's National strategy for forest fire management emphasizes the need to enhance the capacity of stakeholders in Lebanon to assess and manage wildfire in light of future climate change and residential expansion into wildland areas. In this context, we developed a web-based decision framework to improve fire risk management. The primary objective of the application (FireLab) was to provide an online user-friendly interface for displaying data that are critical for making informed fire-management decisions. Data include 257 variables related to fire activity, risk, and hazard and are generated at the municipality level for all of Lebanon. FireLab is delivered through a web browser, making it widely accessible to the public in a format that allows users to easily display wildfire conditions and to describe and share modeled wildfire potential scenarios of current and future conditions.

Keywords*: wildfire risk management, climate change, web-application, decision framework*

Introduction

During the past decade, Lebanon has experienced a number of large wildfires that have had dramatic impacts on large areas of forests and the livelihoods of local communities. In addition, projections for continued climate warming are likely to further promote fire risk (Salloum and Mitri, 2014).
While the risks of fires are increasingly becoming a concern, a common database documenting spatial and temporal patterns of fire and their proximity to settlements is lacking. Currently, there is little information with which to anticipate and predict which areas of Lebanon are most vulnerable to future fire risk and hazard data.
Previously, we set out to assess drought conditions in Lebanon based on climatic variability to gain a better understanding of the temporal and spatial changes in wildfire potential (Mitri *et al.*, 2014). Wildfire potential was assessed with the use of spatial climatic data, and the temporal and spatial variability of wildfire potential was investigated accordingly. In addition, an updated wildfire risk map of Lebanon was produced involving the use of extensive biophysical and socio-economic datasets.
Maps and models have long been an integral part of the environmental decision making process (Walker and Chapra, 2014). However, the abilities of resource managers, policy makers, and stakeholders to understand how these maps and models work and what they represent are limited due to the required technical expertise (NRC, 1999).
In this context, it was essential to build a generic and simple data infrastructure for individual communities to access in relation to their needs. The development of this infrastructure was important because land owners, managers, and decision makers have a major role in fire risk reduction for communities with different needs.
According to Goodall *et al*. (2011), the availability of online databases and models as web services allows for their inclusion not only in professional workflows, but also in interactive tools for data querying and simulation aimed at decision-making. The science of visualizing data has a long history (Tufte, 2001; Spiegelhalter *et al*. 2011). Implementing environmental models in a web context is necessary to help bridging the gap between high-level environmental data analysis and access and

usability for and by the general public. This approach promises greater transparency and inclusive participation of citizens in environmental data monitoring, research, and decision-making (Buytaert *et al*., 2012).
Lebanon's National strategy for forest fire management (Decision No. 52/2009) highlighted the need of information to describe the magnitude and urgency of the problem to decision makers and make them prioritize the necessary measures to prevent or minimize fire risk (MOE/AFDC, 2009). In this context, the development and dissemination of detailed information on fire risk assessment and monitoring across Lebanon is critical to improve fire risk management at both local and National levels.
To address these needs, we developed a web-based application to host multiple data types related to fire risk and management. The primary objective of the application (called FireLab) was to provide an online user-friendly interface where relevant fire data can be accessed to make informed fire-management decisions.

Methods

The development of the web-application model comprised 1) the web browser or the user interface, 2) the dynamic content generation technology, and 3) the database server containing all generated data (Figure 1).

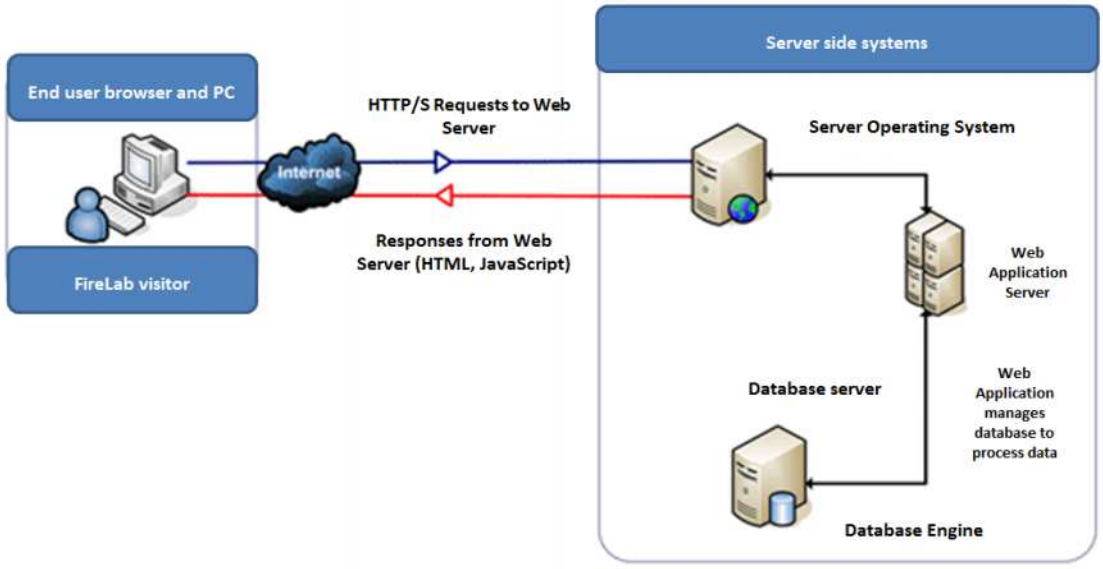

Figure 1. Architecture of the web-application model

The user interface was designed to be self-exploratory and easy to use. Users only need to provide minimal input to achieve the desired outputs. Technically, the web-application queries the content server (a content repository database) and dynamically generates web documents to serve to the user. The documents are generated in a standard format to allow support by all browsers (e.g., HTML).
In addition, the development of the web-application involved the use of Microsoft Visual Studio 2010, C#, asp.net and JQuery. The technology is accessible by all electronic tablets and mobile phones, easily accessed by mobile operators, reliable, secure, and without major technological restrictions.
The database comprised 257 variables generated at the village level and covering the entire country. The variables included information about landcover/landuse, fire hazard, vulnerability, overall fire risk (Figure 2), future fire hazard in association with projected climatic data, and Wildland-Urban Interface (WUI), among others. Most importantly, the application allows data to be constantly updated in the system so that new information can be used to guide management. Finally, a comprehensive glossary

was developed and integrated in the system describing the main terminologies employed in the queries of the application.

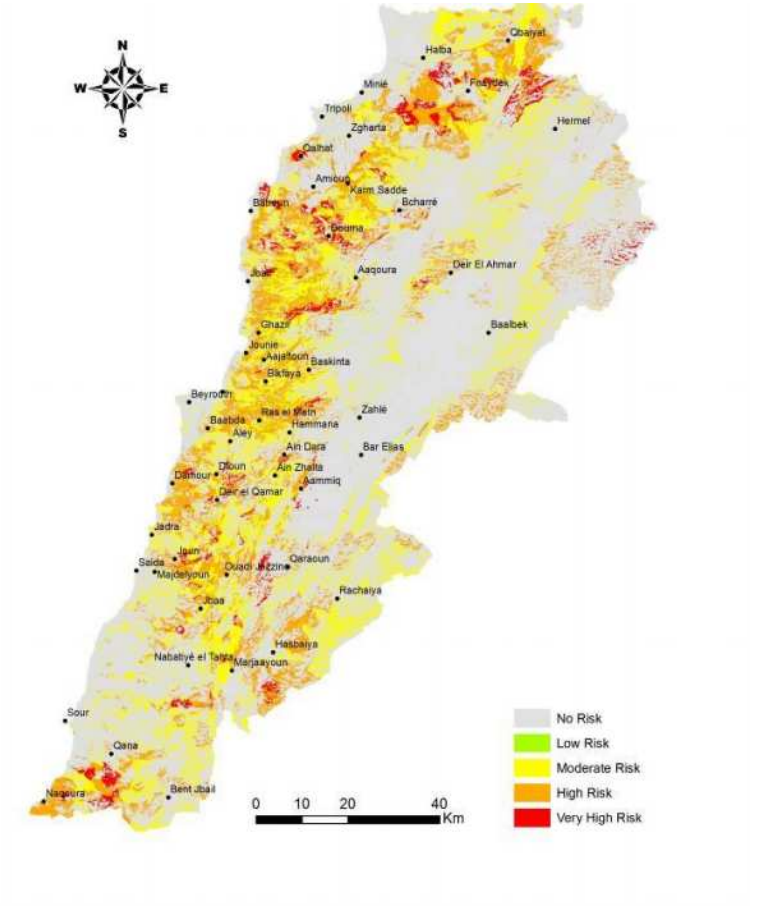

Figure 2. Overall fire risk map of Lebanon

Results and discussion

The main four queries of the web-application interface (Figure 3) included: 1) the selection of the area of interest (e.g., village) and the visualization of a specified type of information for the selected area in form of tables and diagrams, 2) the listing and sorting of summary statistics of required information in a country table view, 3) the listing and sorting of summary statistics of required information for a group of administrative units (e.g., villages) within the same broader administrative unit (called Kadaa), 4) the generation of a detailed wildfire profile including a full graphical report about each category of available data for each individual village, and 5) the generation of an annual country profile of fire statistics (based on field collected data previously entered in the database). In addition, the web-application allows further data entry through private access.

The user interface included an administrative map for each Mohafazat (administrative region) in Lebanon. These comprised Bekaa, Beirut, Nabatieh, North and Akkar, Mount Lebanon and South. The user has the possibility to select the Mohafazat of interest, visualize its coverage map and the name of each village, and select the village of interest. Accordingly, all data for the selected village can be visualized in form of tables and graphs. A full report of each village can be generated in a PDF format.

Overall, the application was not only viewed as a scientific tool, but also it was considered as a management and outreach mechanism. This is reflected in its capability of providing the public with the data needed at different levels, namely at the municipality, regional, and National levels. Also, the fact that the application allows further data entry in the system based on a specific data entry sheet, makes it a dynamic tool that incorporates new information with which to inform management.

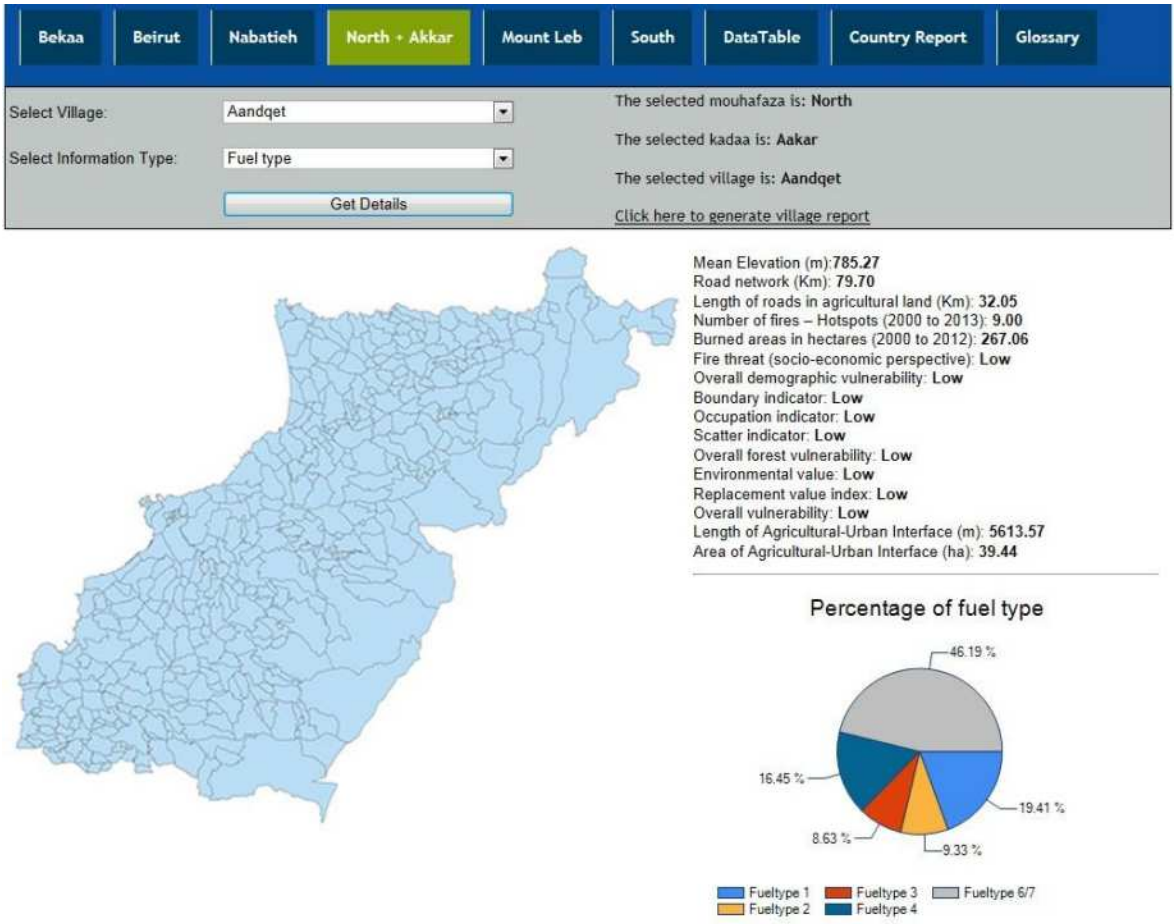

Figure 3. A screen shot of the main interface of the web-application

Conclusions

With projections for increased fire activity in Lebanon there is a critical need to provide spatially explicit wildfire data with which to assess fire risk and hazard at the village level. To address this need, we made fire data publicly available through an online web-application and within a framework where management decisions could easily be made. Additionally, we developed a structure where users can contribute to the development and dissemination of new knowledge, and to a more transparent and effective decision-making and policy assessment. Future work will involve collecting feedback from end-users on the use of such developed tool in order to evaluate its functionality and future improvement.

The weather circulation analysis over Adriatic region of Croatia in warm period 1981-2013

Marija Mokorić, Lovro Kalin

Meteorological and Hydrological Service of Croatia, Gric 3, Zagreb, mokoric@cirus.dhz.hr, kalin@cirus.dhz.hr

Abstract
The most frequent natural hazard in the Adriatic region are the forest fires, which are strongly affected by weather conditions. This is particularly stressed in the last two decades, when large fires occurred. Furthermore, the season has been expanded and large fires appeared also in early summer and early autumn, which was not so common before. In order to explain such a behaviour, an analysis of the atmospheric circulation patterns has been performed. The results reveal that the frequency of weather types conected to dry and warm conditions has been increased, and frequency of weather types with wet weather has been reduced. This is especially pronounced in June and September. Additionally, a change of number of days with precipitation has been observed, with less days with smaller precipitation and more days with larger precipitation. This can lead to additional drying of the fuel. The risk- and fire-managers should be aware of these trends in the future.

***Keywords**: forest fires, atmospheric circulation, weather types, climate change*

Introduction

Most frequent natural hazards on the Adriatic region are forest fires. They strongly depend upon weather conditions such as dry and warm periods, which are connected with weather types and atmospheric circulation.
A large number of forest fires appeared in 2000s. They occurred not only on the coast, but for the first time in the mountain region as well. Furthermore, since 2005 the most dangerous fires appeared at the end of August and first part of September, which was not common before. Recently – particularly in 2012 - fires became more frequent in interior parts also.
In order to find a possible explanation of such behaviour, an analysis of the upper atmosphere circulation was done for warm season for period 1981-2013.
Additionally, the analysis of mean monthly number of days with precipitation has been performed also.

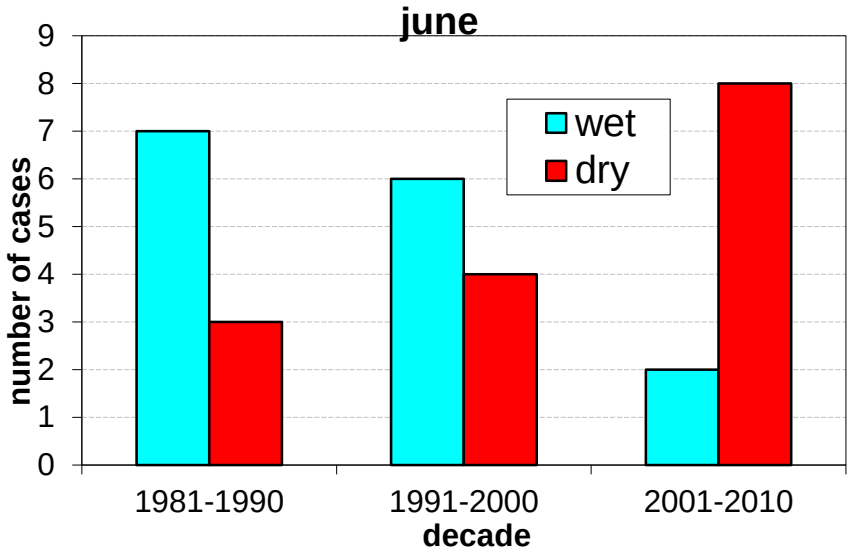
The atmospheric circulation

There are seven main atmospheric circulations patterns in upper atmosphere: upper atmospheric ridge (R), non-gradient field (NG), front side of the ridge (FR), upper through (TR), back side of the upper through or north-west stream (NW), west-stream (W), front side of upper through or south-west stream (SW).
First three types are associated with relatively dry and warm weather, which could be connected with an increased number of forest fires. North-west stream brings cold air with local showers or thunderstorms. West stream is characterized by moderate temperatures and precipitation, while south-west stream and upper through usually cause more precipitation.
The analysis is done for Adriatic coast for years 1981-2013 for period May to October. Charts of mean monthly circulation AT 500 hPa on the Northern hemisphere (Deutscher Wetterdienst and European Centre for Medium-Range Weather Forecast) were used. The weather pattern typing is done manually.

Results

Most frequent situations are north-west and west stream with relative frequency about 25%, the same as non-gradient field and the upper ridge (although the upper ridge is most common in July and August, and very rare - with only one case - in September). Frequency of upper through is about 15%, mostly in September. The southwest stream, which brings more rain, has the frequency 6%, and is most common in September. This distribution of weather circulation pattern is expected.

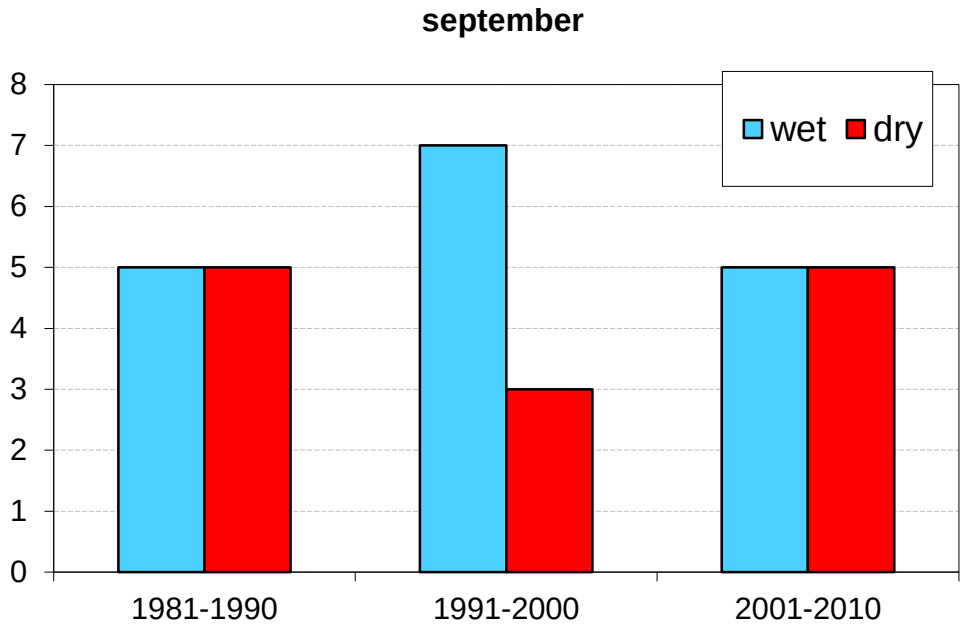
A further analysis showed that in May and June the non-gradient field and upper ridge mean monthly circulation has appeared more frequently since 2000. In July the distribution of patterns is dispersed. The west and north-west stream were most frequent in August, the west stream particularly in the first decade.



80’s	TR	NW	NW	W	W	SW	SW	W	NW	W
90’s	W	NG	W	R	TR	W	W	R	W	R
00’s	TR	R	FR	NW	NW	NW	W	NG	NW	NG

Figure 1. The frequency of relatively dry (filled red) and wet (filled blue) weather types in June, for period 1981-2010.

Finally, in September and October the most frequent types are north-west stream, upper through and - particularly in October - southwest stream. However, since 2005 non-gradient field appeared more often, characterized by less precipitation.



80's	W	NG	NW	SW	R	W	W	TR	NG	NW
90's	NW	W	W	TR	TR	TR	NW	W	NG	W
00's	TR	TR	TR	NW	SW	NG	W	NW	NG	NW

Figure 2. The frequency of relatively dry (filled red) and wet (filled blue) weather types in September, for period 1981-2010.

To estimate the potential influence of such a distribution to the precipitation regime on the Adriatic, an analysis of number of days with precipitation has been conducted also. The goal of such analysis is to provide the information about the distribution of precipitation events, and its possible trends.
A mean number of days with precipitation greater than 1mm, 10 mm, 20 mm and 50 mm is calculated for individual months (May, June, July, August, September and October). Data are based on 63 climatological stations on the Adriatic, for period 1981-2013.
A simple and preliminary analysis reveals that the number of days with smaller precipitation is generally found to be decreasing towards the end of the observed period. Meanwhile, number of days with larger precipitation thresholds is significantly increasing. This feature is observed for both June and September.

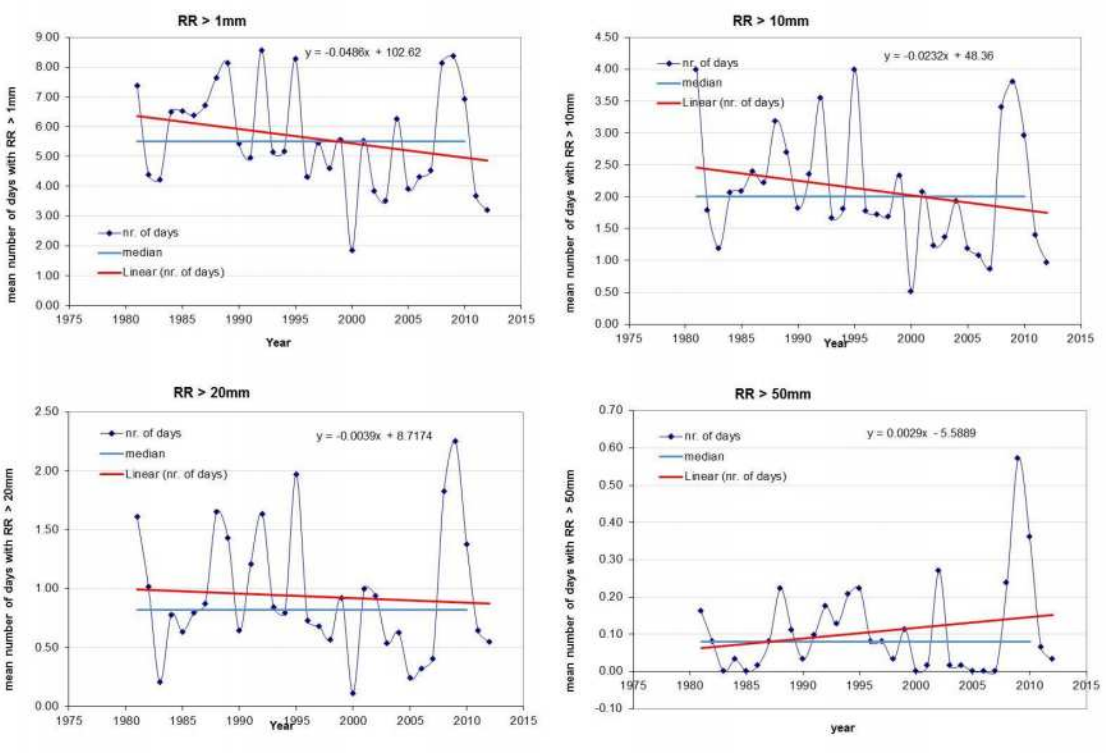


Figure 3.: Mean number of days with precipitation bigger than 1mm, 10 mm, 20 mm and 50 mm, for June (period 1981.-2013.), with corresponding linear trends.

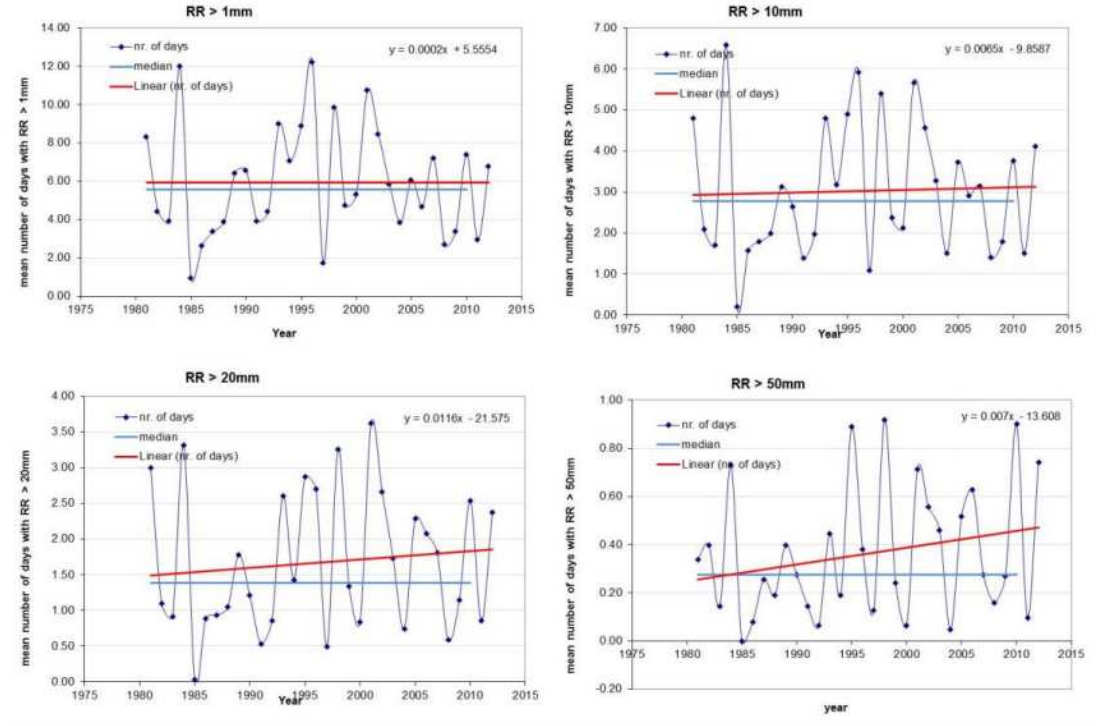

Figure 4.: Mean number of days with precipitation bigger than 1mm, 10 mm, 20 mm and 50 mm, for September (period 1981.-2013.), with corresponding linear trends.

Such trends, caused by changes of weather types, are not desired in hydrological and agrometeorological (silvometeorological) sense. Decrease of frequency of days with smaller precipitation and increase of frequency of days with larger (extreme) precipitation eventually leads to

prolonged dry spells on a wider area, and to the lack of water. This reflects significantly on the fuel condition.

Conclusions

To summarize, these possible changes of atmospheric circulation in the last decade can be connected to more frequent weather conditions associated with high forest fire risk, particularly in May, June and September. So, the risk- and fire-managers should be aware of more probable such weather circulation pattern in the Adriatic region in the future.

Understanding risk: representing fire danger using spatially explicit fire simulation ensembles

Abstract
Forest fires are periodic occurrences in many parts of the world. Where they coincide with human populations, they have the potential to have substantial impacts on human values. Consequently, strategies are adopted by land managers to reduce the probability of fire occurrence and, in the event of a fire, reduce subsequent impacts. One such strategy has involved the adoption of fire danger ratings. These are levels of alertness that are applied at a regional level on a daily basis. They are based on preceding and forecast weather and provide an indication of the potential severity of fire behaviour. Danger ratings are generally based on weather derived indices and have limited ability to represent the contribution of landscape attributes to potential impacts, including the properties of vegetation (fuels) and the amount and spatial configuration of vulnerable assets. We propose an alternative method for representing fire danger using fire simulation. An ensemble approach is demonstrated whereby thousands of virtual fires are ignited on a regular grid and simulated on a daily basis using forecast weather with the model PHOENIX RapidFire. Each fire is simulated in succession and burns for a specified period. Fire simulations integrate the contributions of local fuel, topography and weather to fire behaviour. The resultant fires can be aggregated to provide spatially explicit representations of potential spread patterns. These maps can be combined with asset registers to quantify potential impacts and assist with the prioritisation of response and protection measures.

Keywords*: bushfire; PHOENIX RapidFire; Monte-Carlo; risk; simulation; vulnerability; weather; wildfire*

Introduction

Fire danger ratings are used to influence the behaviour of the community at times of high fire risk. They are used to provide warnings, set preparedness levels and invoke regulations that reduce risky behaviour (Taylor and Alexander 2006). They are valuable tools to reduce the probability of fire occurrence and, in the event of a fire, enable the planning of effective responses to reduce subsequent impacts. As a consequence, they have been widely adopted throughout the world (Lin 2000). They provide an indication of the likelihood of a fire starting and for fires that do occur, an indication of the difficulty of suppression and potential damage.

In the context of this article, we define fire danger ratings as the descriptive classes used to communicate fire danger to the public. These danger ratings are typically based on quantitative indices of fire behaviour. Fire danger index systems are used worldwide, including the United States National Fire Danger Rating System (Cohen and Deeming 1985), the McArthur Fire Danger Index (FFDI) used in Australia (Noble *et al.* 1980) and the Canadian Forest Fire Weather Index used in a number of different countries (van Wagner 1974). Fire Danger Indices are calculated using models that are specific to broad landscape types (i.e. forest or grass) and are computed for specific points in space and time using preceding and forecast weather parameters (typically rainfall, temperature, wind speed and humidity (Fujioka *et al.* 2008; Matthews 2009)). To disseminate this information to the public, these indices are summarised on a regional basis using ordinal 'adjective classes' that describe increasing levels of potential fire behaviour (e.g. high, very high and extreme) (Hardy and Hardy

2007). While predominantly derived from fire danger indices, fire danger ratings can also incorporate some expert adjustment to account for additional considerations such as assets at risk, seasonal population movements and public holidays.
For communication purposes fire danger ratings are applied over defined regions, districts or management areas. As a consequence, large geographic areas can be given the same danger rating even though there can be substantial heterogeneity in the expected fire potential resulting from differing combinations of fuel (Duff *et al.* 2012), expected weather, topography (Schunk *et al.* 2013), ignition likelihood (Penman *et al.* 2013) and vulnerable assets (Cheney and Gould 1995; Bones *et al.* 2007). While the zoning of fire rating districts can be optimised to minimise within-district variation (Gouma and Chronopoulou-Sereli 1998), the dynamic nature of fuel and weather means that a single rating is unlikely to be representative of the entire mapped region it denotes (Cheney and Gould 1995). This may contribute to confusion in the community with regards to the intended meaning of danger ratings, or what the most appropriate action should be (Dawson 1988; Reid and Beilin 2013).
As fire danger indices are more quantitative, they can be more easily represented at higher spatial resolutions (e.g. Chowdhury & Hassan (2013)). However, as they were designed for informing land managers about fire spread potential and suppression difficulty, they are not necessarily suitable to provide to the public as information of fire hazard to the community (Cheney and Gould 1995). Current indices are generated from fixed (fuel and topography) and varying (weather) parameters, but are effectively point estimates. They have no way of incorporating landscape context related elements that can greatly contribute to expected fire impacts. These include predominant wind direction, changing patterns of weather throughout the day, the scale and relative position of fuels to assets and variation in the likelihood of human caused ignition. Furthermore, despite the use of the word 'danger' in the term 'fire danger index', there is no explicit evaluation of danger in the context of values at risk. As values in the landscape are unevenly distributed, two fires under similar weather conditions can have substantially different impacts. This can be seen in a recent study by Blanchi *et al* (2010), where high fire danger indices were clearly correlated with maximum house loss potential (extreme days had the potential to result in greater house loss) but only weakly associated with average house loss potential (fires under extreme conditions did not necessarily impact settlements).
We propose an alternative method for representing fire danger at a regional and local level utilising the ability of dynamic fire behaviour models to simulate of fire spread and characterise impacts. Such models have been used to estimate long term fire danger (e.g. Weise *et al* (2010)) however we suggest that ensembles of predictions can be effectively used as indications of daily fire danger potential. To do this, ensembles of fires can be ignited on a regional grid using each day's forecast weather to guide fire progression. Maps of the resulting fires impact characteristics can then be used to differentiate areas of varying fire danger. These maps can be combined with asset registers in order to quantify potential asset impacts and assist with the prioritisation of fire prevention and protection measures. Combined with ignition probability maps, hazard (combining likelihood and consequences) to specific assets can also be quantified. The process was demonstrated using the state of Victoria, Australia, as a test case with fires simulated from gridded weather forecasts using the simulator PHOENIX RapidFire (Tolhurst *et al.* 2008).

2. Methods

Method framework

Dynamic fire behaviour models have developed rapidly in recent years. Advances in computing power mean that fires can be rapidly simulated on a desktop computer. We propose that a parallel processing framework be used to simulate a large (>1000) ensemble of independent fires within the jurisdiction of interest using a regular ignition grid. These can be run on a daily basis using weather forecasts. The results of these simulations can then be combined to produce daily products that represent fire danger to particular assets of interest. The process is outlined in Fig 1.

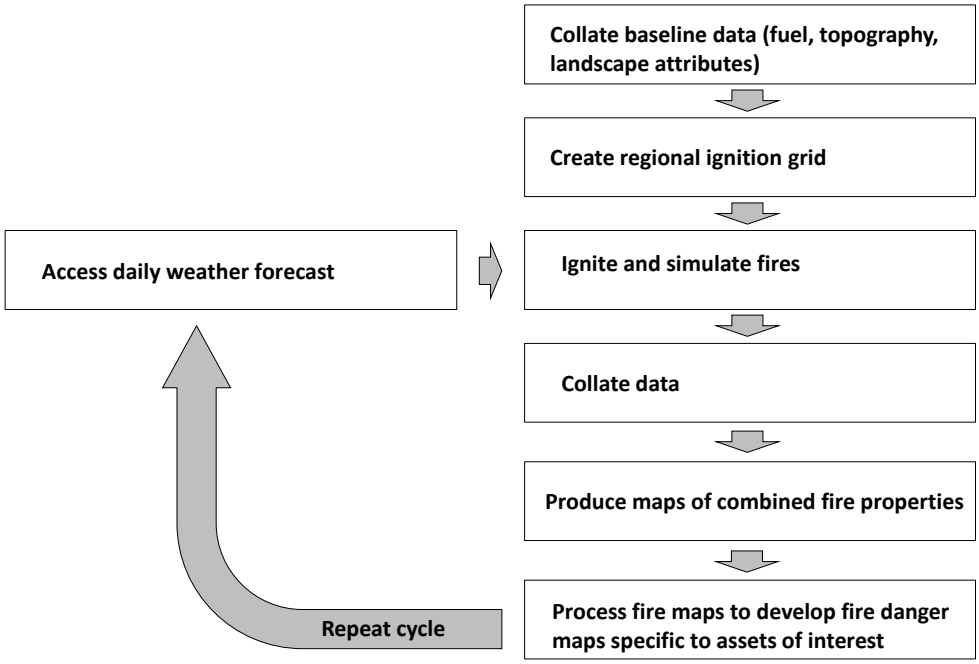

Figure 1. Framework methodology for producing simulation based fire hazard maps

Case study

We used the state of Victoria, Australia, to demonstrate the proposed methodology. Covering an area of 227 000 km^2, Victoria has a Mediterranean type climate and has been subject to a number of severe wildfires, including the Black Saturday fires of 2009.

To capture the spatially and temporally explicit nature of fire spread and resulting fire characteristics, we selected the model *PHOENIX RapidFire* (Tolhurst *et al.* 2008), a dynamic fire model developed explicitly for Australian conditions and used operationally by fire management agencies (Paterson and Chong 2011). The baseline data (fuel hazard, topography, roads, fuel barriers, fire history and wind modifiers) necessary to run simulations was sourced from the Department of Environment and Primary Industries (DEPI), Victoria.

Four days where total fire bans had been declared for the entire state of Victoria were selected from the 2013/2014 fire season. The dates and maximum temperatures at Melbourne Airport (a location of relatively central latitude in the state) are presented in Table 2. These days all had a similar level of alertness communicated to the public.

Table 1. State wide total fire ban days for 2013/2014 fire season showing a reference maximum daily temperature at Melbourne Airport (source Australian Bureau of Meteorology)

Total Fire Ban Date	Daily Max Temperature (ºC)	Total processing time (hrs)
15 January 2014	41.7	0.19
28 January 2014	42.0	0.30
8 February 2014	41.0	0.23
9 February 2014	40.4	0.82

Weather forecasts for the selected days were sourced from the Australian Bureau of Meteorology in the form of state wide NetCDF grids containing the required weather parameters for PHOENIX RapidFire. Inputs of wind speed and direction, temperature, relative humidity and cloud were supplied

at hourly intervals, whilst curing and drought factor were daily values. The NetCDF grids had a longitudinal resolution of 0.03 degrees (approximately 2.6 km) and a latitudinal resolution of 0.02 degrees (approximately 2.2 km). PHOENIX RapidFire continuously interrogates the forecast weather grids at all points along the modelled fire perimeter in order to capture the spatial and temporal variability of the weather across the landscape.

Daily fire potentially was evaluated by modelling ignitions on a regular 5 km grid across the entire state. For each day, ignitions times were calculated using a diurnal fuel moisture content derived FFDI as described by the Matthews fuel moisture model (Matthews 2006) and a nominal threshold FFDI value of 23 to capture the point at which fires become difficult to contain (Mason *et al.* 2011). Where the threshold value is not met, the peak FFDI value between 6am and 6am the following day is used. Ignitions are then modelled until 6am the following day. Grid ignition simulations were run with a nominal 'first attack' suppression allocation to reflect current operational practices. Each daily iteration consisted of a set of 9088 ignitions. The extent of each modelled fire is processed on completion, whereby they are aggregated to provide a state wide spatially explicit indication of the number of impacts affecting each point in the landscape. In addition, an expected house loss map was generated by combining the probability of house loss with the number of houses impacted in each fire (Tolhurst and Chong 2011). House loss results for each fire were represented at the ignition locations. Ignitions were processed in parallel using a 24 core, 2.7 GHz Xeon desktop running Windows 7 Professional with 64 GB of ram. Fires were modelled at 180m resolution which is the recommended resolution for operational use of PHOENIX RapidFire. This is also the reporting resolution for the aggregated results from all ignitions.

To contrast the method, we compare the ensemble generated maps with maps of the daily maximum FFDI sampled at the ignition grid points.

Results

All four days were processed in under an hour respectively, with the maximum ignition grid simulation time of .82 hours and the fastest day processed in 0.23 hours (Table 2).

Despite all four days being classified as total fire bans and the very similar maximum temperatures at Melbourne airport, all four days exhibited substantial spatial variation and range of fire impact values across the state.

The calculated maps showing peak FFDI display a large spatial variation of daily maximums across the state and within defined fire ban districts (Fig 2). Peak values range from the danger classes Low (<12) to Code Red (>100). There were substantial differences between days. In particular, the 9th of February had substantially elevated FFDI in the north and east of the state. The 28th of Janurary had substantially elevated FFDI In the west of the state.

The simulated burn frequency maps were generated for all days (Fig 3). In these, there were some key differences to the FDI maps. In particular, there were a number of parts of the state that had low impacts despite high FDIs (i.e. north-central, south and North West). There were also substantial differences in pattern between days. For example, the 9th of February shows an increased burn frequency in the east of the state.

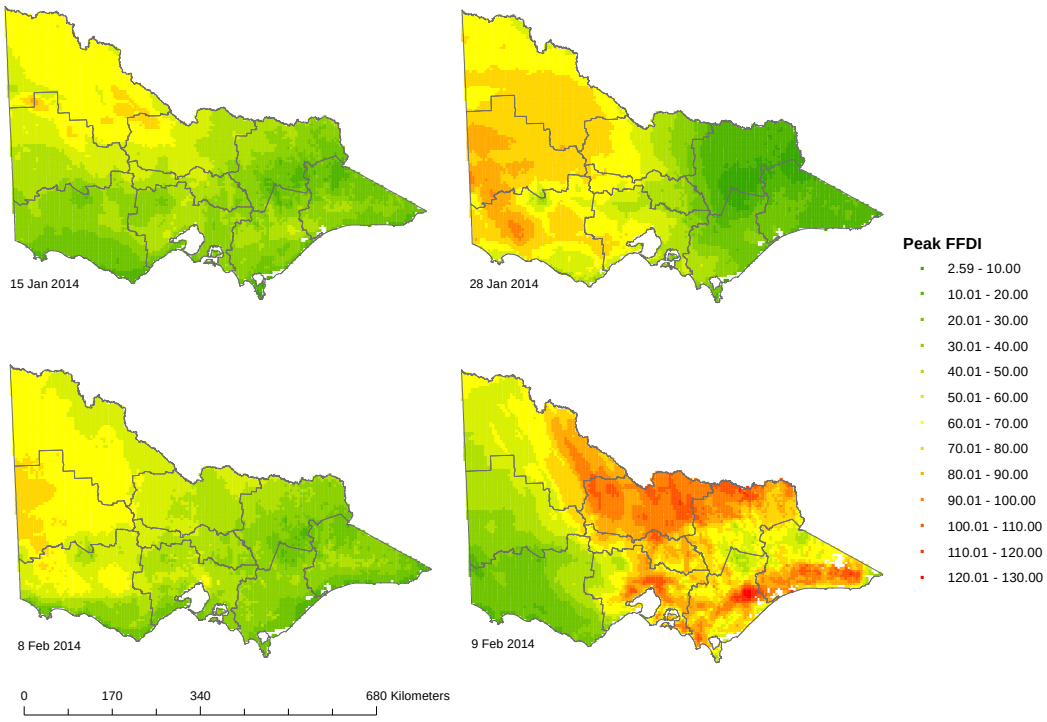

Figure 2. Calculated daily maximum Forest Fire Danger Index values for the state of Victoria, Australia

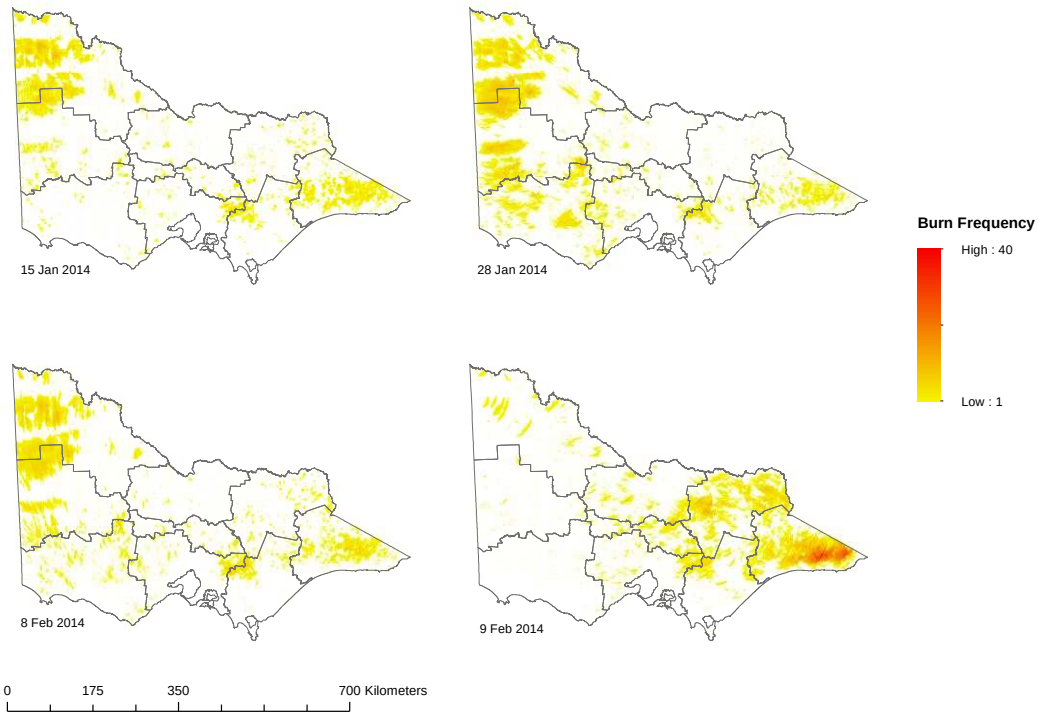

Figure 3– Cumulative burn simulated frequency for fires simulated from gridded ignitions in the state of Victoria, Australia

Resulting house loss values displayed against source ignition points (Fig 4) also show a large spatial variation in impacts across the landscape on each day. In contrast to FDI and burn frequency, there were proportionally higher expected house losses in the centre of the state.

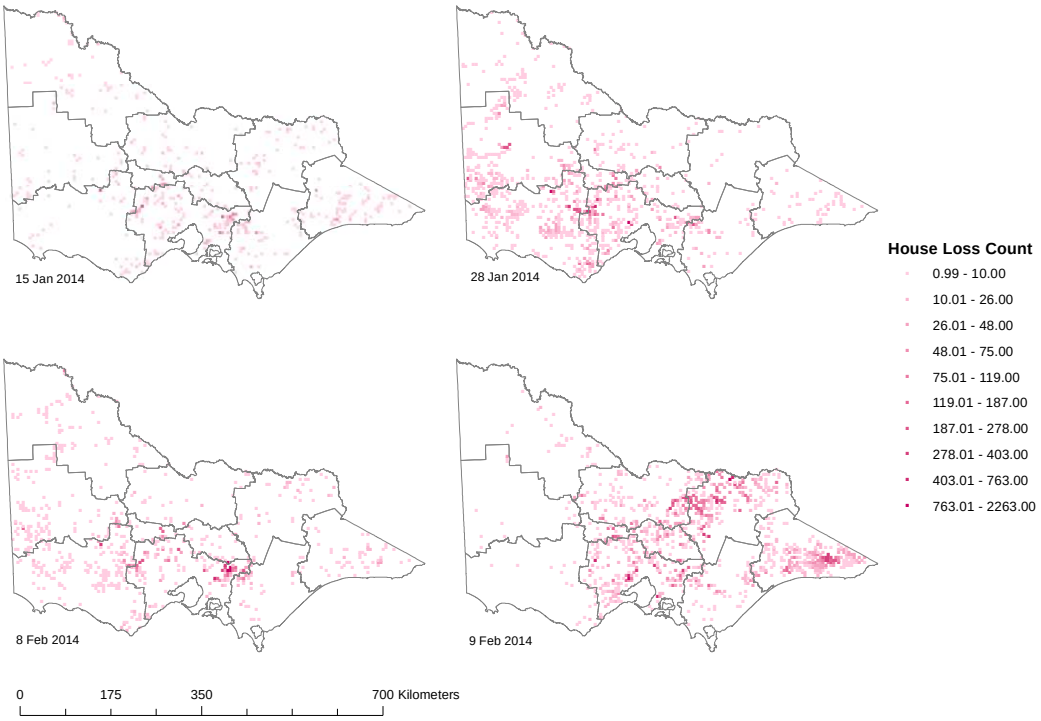

Figure 4– Modelled expected house loss for fires simulated from gridded ignitions in the state of Victoria, Australia

Closer examination of individual fires around the regional centre of Bendigo on the days of the 9th of February and the 28th of January show a clear difference in spread direction and area impacted (Fig 5).

Discussion

The ensemble fire prediction process was demonstrated to have the potential to produce forecasts of fire impacts in operationally useful timeframes. Forecasts of fire potential at operational resolutions for an entire state were all calculated on a desktop computer. As fires were processed in parallel, there is the potential to further decrease processing times with additional hardware.

Such simulation derived products of fire behaviour have substantial advantages over maps of fire danger indices. As they emulate the process of a spreading fire, they have much greater potential to consider temporal dynamics (such as the likely influences of weather fronts or wind changes influencing an area throughout the day) and spatial dynamics (such as the spatial context of varying fuel levels) in relation to values of interest. This means that fire simulations can provide more detail on likely fire behaviour and results will be more locally relevant than what can be produced by pure weather indices.

This is evident in Figure 3, where on all days there was low fire activity in the north-central part of the map due to grassland fuel types. The temporally dynamic nature of fire is evident in the map for the 9th of February, where there was limited fire behaviour in the north and west of the map despite declared total fire ban due to the wind change passing through early in the day bringing cooler conditions. In addition, In Figure 5, the orientations of the fires are markedly different on different days. This is due to the timing of the weather front moving from west to east throughout the day, a common fire weather pattern in South Eastern Australia (Long 2006). Wind changes that occur during fires can greatly effect on the size and overall impacts of a fire (Cheney *et al.* 2001). This means that in addition to the degree of fire threat that a point in the landscape faces, detailed information on the nature of the threat can also be obtained that can be used to guide daily readiness measures. Furthermore, while single day predictions were produced for case study purposes, the method can be validly applied to longer term outlooks. In localities where there is a 7 day weather forecast, there is the potential to produce equivalent fire behaviour forecast maps for each day of weather available. Fire behaviour forecasts could be automatically generated when weather forecasts become available (in Victoria, approximately 5am and 5pm daily).

An additional advantage of the use of ensemble simulations is that a wide variety of products that can be produced. In the example presented, we represent potential fire impacts as the number of fires impacting on a particular point in the landscape. However, other fire properties can also be represented; dynamic fire models can also produce a range of other outputs including fire intensities, cumulative ember loads, rates of spread and flame heights. Empirical data can be used to relate these to impacts on particular values of interest. By overlaying this information with other data sources, a single ensemble prediction can be processed to yield a wide range of information, including potential impacts to water resources, carbon storage, critical infrastructure, biodiversity, houses and human lives. In this study we demonstrated this by assessing the expected impact to houses of each fire (Fig 4). Of note are the higher expected house losses in the centre of the state in all cases. This phenomenon is due to the high concentration of houses in association with wildland fuels in this part of the state. This effect is also evident with the contrast between high FFDI forecasts, high fire impacts and low expected house loss in the north west of the state. While there is high fire potential in the north west, the housing density is very low, so the threat to the community is reduced. As simulation approaches are a way to integrate weather, the landscape, fire behaviour and impacts, they are an ideal way to get a clear idea of potential fire impacts on particular values.

The method presented here can be further extended by incorporating ignition probabilities. The maps presented here represent a regular grid of fires where each fire is given the same weighting. By weighting by ignition probability the likelihood of fires can be represented in the final output. By combining the likelihood of fires and empirically derived consequences (such as house loss in the example above) the method we present can be used to spatially represent fire hazard in a quantitative manner. This means that potential fires can be considered objectively and preparedness measures can

be efficiently designed to be proportional to expected impacts. In contrast, methods based purely on weather derived 'danger' indices cannot truly represent danger as there is no potential to objectively incorporate values at risk.

Ensemble derived maps are able to provide a more nuanced indication of fire risk to the public than regional fire danger ratings. This has the potential to reduce of type I 'false alarm' errors (Taylor and Alexander 2006). However, as sources of public information, weather forecast style fire danger outlooks may not be ideal for all uses. When weather conditions become extreme, members of the public may look for 'threshold' style indicators to spur them to undertake a particular response (Reid and Beilin 2013). Currently total fire bans and 'red alert' warnings used by agencies as unambiguous triggers for action. While the prediction ensemble products may assist in declaring fire bans, bans are likely to remain a valuable tool in fire management. As with fire danger ratings, fire bans are declared over particular regions. While our results have indicated that the regions are not representative of fire behaviour, by aggregating the results of many daily ensembles, there is the potential to use fire simulation to better redraw fire danger declaration regions to create districts with more homogenous expected fire behaviour (Gouma and Chronopoulou-Sereli 1998).

Conclusion

Our results indicate that there is substantial spatial heterogeneity in fire impact within fire danger rating districts. This means that the daily rating applied to a district is unlikely to relevant to all parts of that district. For a particular area, if fire danger ratings are commonly too high, complacency may result. Conversely if ratings are conservative, the residents may not understand the true level of threat. Our methods provide an alternative way to understand and represent fire danger that is more locally relevant. In addition, simulation approaches can give a greater indication of the nature of the fire threat that particular localities may face.

Abstract
The main aims of this work are to identify useful tools to determine potential impacts of expected climate change on dead fuel status in Mediterranean shrubland and, in particular, to estimate the effect of climate changes on the number of days characterized by critical values of dead fuel moisture. Measurements of dead fuel moisture content in Mediterranean shrubland were performed in North Western Sardinia (Italy) for six years by using humidity sensors. Meteorological variables were also recorded. Data were used to determine the accuracy of the Canadian Fine Fuel Moisture Code (FFM code) in modelling moisture dynamics of dead fuel in Mediterranean vegetation. Critical threshold values of FFM code for Mediterranean climate were identified by percentile analysis, and new fuel moisture code classes were also defined.
A stochastic weather generator (M&Rfi), linked to climate change scenarios derived from 17 available General Circulation Models (GCMs), was used to produce synthetic weather series, representing present and future climates, for the selected site located in North Western Sardinia, Italy. The number of days with critical FFM code values for present and future climate were calculated and the potential impact of future climate change was analysed.

***Keywords**: Forest fires, Mediterranean shrubs, Fine fuel moisture code, Downscaling techniques*

Introduction

The moisture content of dead fuel (FMC) is an important variable in fire ignition and fire propagation and is strongly affected by changes in atmospheric conditions. According to projections of future climate in Southern Europe, changes in temperature, precipitation and extreme events are expected (Christensen *et al*. 2007; Giannakopoulos *et al*. 2009; Giorgi *et al*. 2004). More prolonged drought seasons could influence fuel moisture content and, consequently, the number of days characterized by high ignition danger in Mediterranean ecosystems (Flannigan *et al*. 2009; Flannigan *et al*. 2013; Liu *et al*. 2013; Matthews *et al*. 2012; Westerling *et al*. 2006).
The low resolution of the climate data provided by the general circulation models (GCMs) represents a limitation for evaluating climate change impacts at local scale. For this reason, the climate research community has called to develop appropriate downscaling techniques. One of the downscaling approaches, which transforms the raw outputs from the climate models (GCMs or RCMs) into data with more realistic structure, is based on linking a stochastic weather generator with the climate model outputs. Weather generators linked to climate change scenarios can therefore be used to create synthetic weather series (air temperature and relative humidity, wind speed and precipitation) representing present and future climates at local scale.
Moisture exchange in dead materials is controlled by physical processes, and is clearly dependent on rapid atmospheric changes. Therefore, some meteorological danger indices can be used for modelling the moisture dynamics of dead fuel (Van Wagner 1977; Chandler *et al*. 1983; Van Wagner 1985; Wotton, 2009; Matthews, 2014).

The main aims of this work are to identify useful tools to determine potential impacts of expected climate change on dead fuel status in Mediterranean shrubland and, in particular, to estimate the effect of climate changes on the number of days characterized by critical values of dead fuel moisture

Materials and Methods

The study was carried out in in North Western Sardinia, Italy (40° 36' N; 8° 09' E, 30 m a.s.l.). Climate is Mediterranean with water deficit conditions occurring from May through September and precipitation mainly concentrated in autumn and winter. The mean annual rainfall is 640 mm and the mean annual air temperature is 16.8 °C. The experimental area is mainly covered by Mediterranean shrubs.

Figure 1. Experimental site location

The study was carried out in two different phases. In the first one, FMC values (1 hour and 10 hours fractions) were periodically determined during six consecutive years on three Mediterranean shrub species: *Cistus monspeliensis* L., *Pistacia lentiscus* L., and *Juniperus phoenicaea* L. During the same period meteorological variables and temporal patterns of moisture content, measured by using humidity sensors, were recorded. The relationships between direct field measurements and FMC values given by moisture sensor were analysed. Then, the Canadian Fine Fuel Moisture Code (FFM code) was calculated. Finally, FMC values obtained from fuel sensors were used to develop appropriate FFM code danger classes specific for Mediterranean climate.
In the second step the potential climate change impact on fuel status and ignition danger season in Mediterranean area was simulated. The weather generator M&Rfi (Dubrovsky *et al*. 2005, 2007) linked to climate change scenarios derived from 17 available General Circulation Models (GCMs), was used to produce synthetic weather series, representing present and future climate (2100) for the selected site (Table 1). The downscaling of future climate projections was made using three scenarios (A2, B1, and A1B) from the IPCC Special Report on Emission Scenarios (Nakicenovic *et al.* 2000) . The projected future climates were then used to calculate the FFM code of the Canadian Forest Fire Weather Index System (Van Wagner 1987) and to estimate possible impacts of climate change on dead fuel moisture content pattern.

Results

A highly significant relationship (R^2=0.82; p< 0.001) between direct measurements of FMC and values given by fuel moisture sensor was observed. Therefore, we used FMC values by sensor measurements to calibrate FFM code for Mediterranean species.

The range of values of FFM code (from 10 to 95) was divided into 35 classes of equal width (2.5). The frequencies of number of days characterized by values lower than 20% and 15% for each FFM code class were calculated. Figure 2 shows that most of days with moisture content lower than 20% and 15% are included in the FFM classes 87.5 and 90, respectively, and corresponded to 85th and 95th percentile of FFM series, respectively. Therefore, threshold values equal to 85th and 95th percentile of FFM code values calculated by synthetic weather series representing present and future climates were selected to identify days characterized by high (85th percentile) and extreme (95th percentile) fire danger.

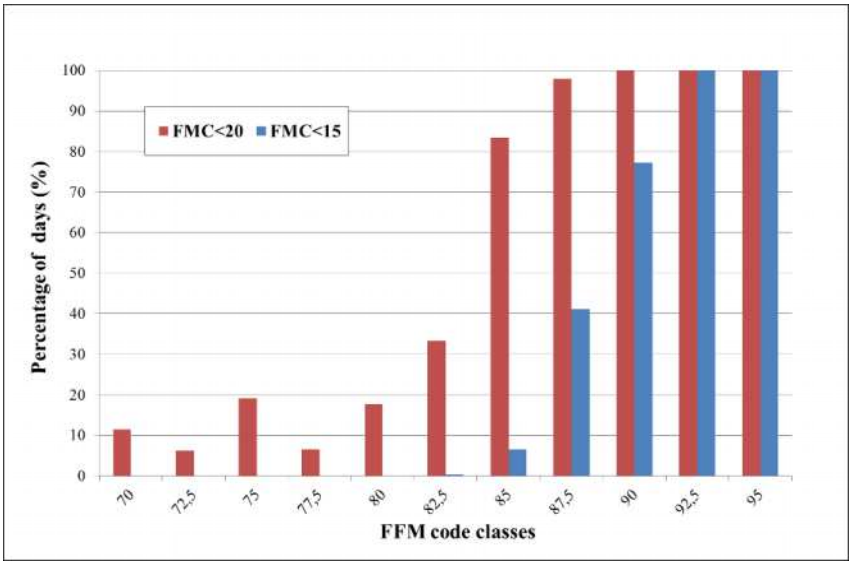

Figure 2. Frequency distribution (percentage) of days when dead fuel moisture content values (FMC) were less than 15% and 20% by FFM code classes (2007-2012)

Figures 3 and 4 show the forecasted total number of days characterized by high and extreme fire danger for each GCM and scenario (actual and 2100 projection) relative to April - October months.

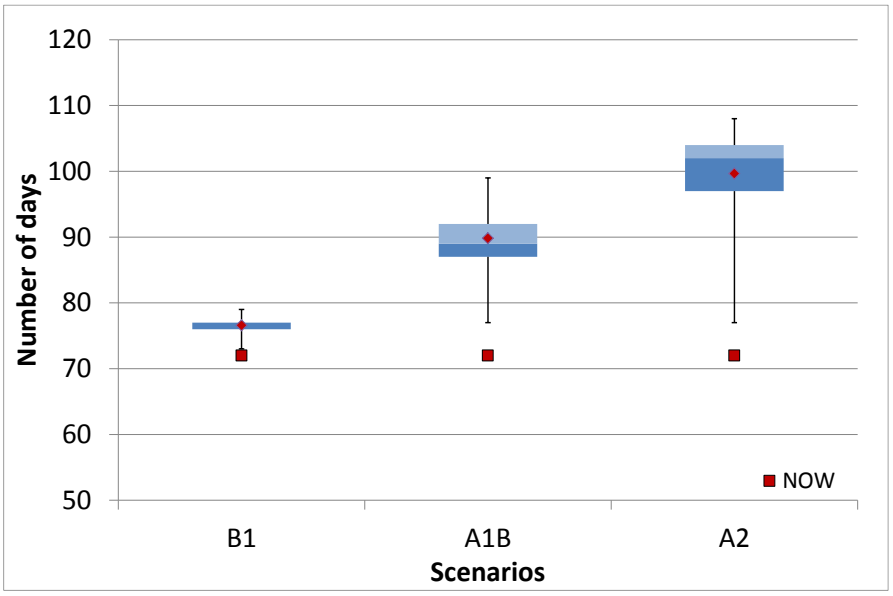

Figure 3. Boxplot of the actual and projected (blue) number of days characterized by high danger (85th percentile) relative to three climate change scenarios (B1, A1B, and A2). The chart shows the mean (red diamond), median, minimum and maximum values, and the lower and upper quartiles. The actual number of days characterized by high danger are indicated by the red squares (April - October period).

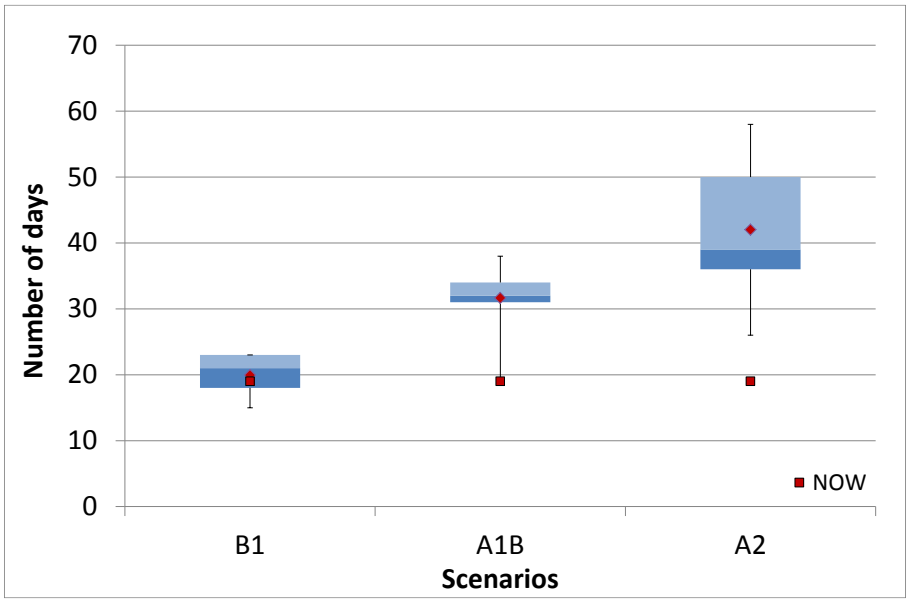

Figure 4. Boxplot of the actual and projected (blue) number of days characterized by extreme danger (95th percentile) relative to three climate change scenarios (B1, A1B, and A2). The chart show the mean (red diamond), median, minimum and maximum values, and the lower and upper quartiles. The actual number of days characterized by extreme danger are indicated by the red squares (April - October period).

No evident differences between baseline period and future were observed for B1 scenario especially regarding days characterized by extreme danger. More evident changes were observed for A1B and A2 scenarios. For A1B scenario the mean total number of high and extreme danger days is expected to increase by 18 and 12 days, respectively, compared to the present climate. The increase of high and extreme danger days reached 27 and 23 days in the case of A2 scenario.

Analysis of distribution of danger days throughout the April - October period shows that in general the increase of days characterized by high danger (85th percentile) is likely to occur during the second half of summer. For all three scenarios, in fact, the number of danger days increased in August and September. In addition, our results suggest that the fire season may end later than today (scenarios A1B and A2), although scenario A2 projections indicate a possible anticipation of the fire season.
With reference to extreme days (95th percentile), a general increase of number of critical days is likely to occur on the basis of A1B and A2 scenarios that are characterized by intermediate (A1B) and high (A2) anthropogenic greenhouse gas emissions.
In conclusion, this study confirms that an increase of number of days critical for fire occurrence and a longer fire season could be expected also in Mediterranean areas as a consequence of climate change projections.

Abstract

Accurate burned area information is required and of particular interest for the scientific communities dealing with land use and climate changes. Currently, due to the very broad spatial extent and the limited accessibility of some of the largest regions affected by fire, instruments on-board satellites provide the only available operational systems capable to collect cost-effective burned area data.

This paper presents the initial results of an algorithm for automatic extraction of burned area scars using Landsat TM and OLI imagery in the Cerrado (savannah) biome of Brazil. Development and validation tests were conducted for the "Jalapão" region, which has been intensely affected by fire in the last years; during the 2010 dry season, it accounted for 60% of all active fire pixels detected in the Cerrado.

A series of Landsat TM and /OLI 52 scenes (path/row: 221/067) covering the period of 2000 - 2013 was used. Input images were accepted only with cloud cover up to 10%, and the maximum period of time between consecutive scenes was up to 1 month. Composite images with differences in NDVI (dNDVI) and NBRL (dNBRL) of consecutive scenes were used to identify fire scars. The algorithm computes and filters the rate of change in dNDVI and dNBRL indexes, relative to the pre-fire condition. The value of the dNBRL change is then used in the calculation of the burned area mask.

Results of the automatic extraction were evaluated against maps of burned scar produced by visual photo interpretation of the composite images for the reference period of 2004 - 2010. Omission and commission errors were obtained, and the reliability of the algorithm and the burned area match levels were calculated for the image series. Omission Errors ranged from 4.8% to 21.0%, and Commission Errors from 2.3% to 24.1%. Reliability of the Algorithm and Burned Area Match varied from 75.8 % to 97.2%, and from 79 to 95.2%, respectively. These values are comparable to the best reported in the literature for other regions. Commission errors were associated mainly to clouds and their shadows in the images; agricultural practices were another source of error. Detailed error analysis and results are included in the text.

The algorithm developed is currently being implemented for operational and automatic generation of burned scar maps at a regional scale, particularly for conservation areas.

***Keywords**: fires, burned area, automatic extraction, Landsat, Cerrado*

Introduction

The Brazilian Cerrado extends over 2000000km^2, occupying almost a fourth of the country's territory, and is considered the most bio diverse Savannah of the world. Deforestation already reduced this biome to be at least 50%, and if degradation is also considered, this value increases significantly (Klink and Machado, 2005). Conservation areas account only for 8.2% of the Cerrado, and an additional 4.4% are preserved as indigenous territories (MMA, 2014a; Klink and Machado, 2005). The study area is located in the Jalapão region, at the northeast portion of central Brazil, comprising the largest and more important conservation areas of the Cerrado biome – see Figure 1. Its elevation ranges from 150 m to 950 m, and the climate in the region is hot semi-humid, with a pronounced drought season. Rains are concentrated in the October-to-April so-called summer season, with up to about 600 mm of average precipitation in the rainiest trimester, while winter, from May through September, may accumulate as little as 25 mm. Soils have a large proportion of quartz sands, almost 50%; vegetation types include

the main physiognomies of the Cerrado/Savannah, and the population density is below 2.5 inhabitants/km^2 [INMET, 2014, SEPLAN, 2013; Prado dos Santos *et al*, 2011].
Increasing efforts are being made by federal and state agencies in this region to control deforestation processes and anthropic vegetation fires [MMA, 2012; MMA, 2014b]. During the severe drought period of 2010, 60% of all fires in the Cerrado biome were detected in the Jalapão ecologic corridor. Remote sites and fire brigade's limited operational conditions contribute to an inefficient control of fires. The total fire pixel detections by Projeto Queimadas of INPE, Brazil [INPE, 2014], accounts for 83575 events in the period 2004-2013, with a mean annual value of 8357 [Candido 2014]; this value refers to multiple satellite platforms, when a unique fire event might have simultaneous detections from more than one satellite.
Mapping burned areas requires the development of methods to process massive mid-resolution (e.g. Landsat TM and OLI) image data bases to produce results of practical use; unfortunately, no reliable products are available on an operational basis. Remote sensing techniques are now recognized as the only cost-effective source of information for mapping burned areas from regional/national up to global scale [Stroppiana *et al* 2012]. Burned area mapping using mid-resolution sensors has been classically oriented toward local-scale studies, but the current availability of such images without costs allows their use in larger scales [Bastarrika *et al* 2011]. Our study area is contained in the Landsat TM/OLI scene path/row 221/067. Figure 1 shows the study area within the context of the South American continent.

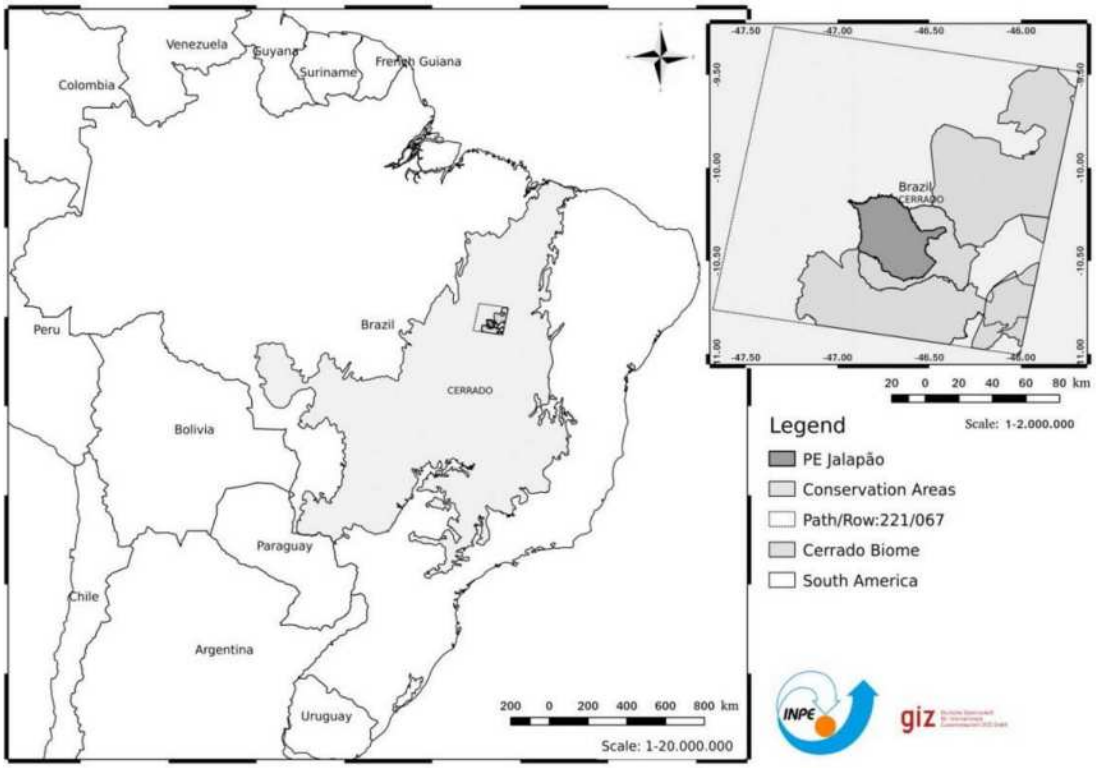

Figure 1. Location of the study area.

Landsat TM sensor images have been widely used for precise mapping due to its 30 meters spatial resolution in both visible and infrared channels [Stroppiana *et al*, 2012]. OLI sensor's images present strong improvements regarding the TM sensor, in both spectral and radiometric resolution. While temporal resolution might be adequate for multi-temporal mapping in ideal atmospheric conditions, the occasional presence of clouds and cloud shadows over the study region impair the regularity of the temporal series, even causing its interruption.

In this present work, the cloud content of any image used in the temporal series was limited up to 10% of total image special coverage. The amount of cloud cover was established by visual inspection. All images were downloaded from the USGS server [USGS, 2014]. The high quality of their geo-processing grants their use in automatic and operational processes.
The entire procedure for image processing was developed in the Python 2.7.4 programming language, using freely available function libraries like gdal, numpy, scipy, scikit, among others. Inter-operation among these libraries greatly simplifies the process work flow. The application developed allows the processing of raw image series, generating derived series as a result. Results from the sub-process stages like statistical information, objects mapped, thresholds used for classification, among other data, are logged in a file for further analysis.

Methods

Several processing routines were defined to process the Landsat TM/OLI images and obtain burned scar maps in a semi-automatic mode, file downloads and decompressing, generation of a layer stack, cropping, processing and comparisons with reference data.
Input data consisted of compressed Landsat TM and OLI imagery in the tar.gz format, downloaded from the USGS server [USGS, 2014]. Output data were the burned scar maps, in raster and vector file formats, reflectance images, and composite RGB files used for burned scar visual photo analysis [Candido, 2014]. The download process involved selecting, within the available images, those with less than 10% cloud cover. An automated routine was developed to handle the compressed data and generate the corresponding layer stacks of radiance images; it avoids compression tools and GIS systems to prepare data for processing, saving many hours per image set for the operators. Each uncompressed radiance stack layer obtained is accompanied by its metadata file for later reflectance conversion.
The next step in the process is the cropping stage, where radiance stack layers are cropped to a polygon vector file of the study area, using another specific automated routine developed for this purpose. The cropped layer stacks, with their corresponding metadata file, are the input for the main procedure.

Main procedure for burned area mapping

The main core of this classification procedure is based on calculations of the NDVI (Normalized Difference Vegetation Index) [Gitelson *et al*, 1996; Stroppiana *et al*, 2012] and the NBRL (Normalized Burn Ratio Long SWIR Variation) [Bastarrika *et al*, 2012; Key & Benson, 2006] indexes calculated from reflectance data. Conversion from sensor radiance to TOA reflectance was done following the work of Chander *et al*, 2009.
The detection and extraction of burned scars in the images is based on the concept that in conservation areas, the behaviour of the vegetation cover does not present sudden changes, and if they occur, they are very likely the result of fires. To evaluate this pattern change caused by fires, the variation in time of NDVI and NBRL, as described in equations 1 and 2, was evaluated in a similar way to the work of Miller and Thode (2007). In that work, they have used the positive square root of the absolute initial value divided by 1000. In this case, we directly used the absolute values. Considering two consecutive images of the same area with a maximum period between images of one month, the change rate for each index is defined by:

$$crndvi = \frac{ndvi(data1) - ndvi(data2)}{abs\big(ndvi(data1)\big)}$$

$$crnbrl = \frac{nbrl(data1) - nbrl(data2)}{abs(nbrl(data1))}$$

Outliers in ratio values may be found when a very low value (near zero) is present in data1. To avoid these extreme cases, a limitation threshold was used in the NBRL difference.

$$dnbrl = nbrl(data1) - nbrl(data2)$$

For each equation, a threshold was used to separate burned from unburned areas, where the complete masking procedure results as follows:

$$Bmask = (crnbrl \geq Tcnbrl) * (crndvi \geq Tcndvi) * (dnbrl > Tdnbrl)$$

Used thresholds were: *Tcrnbrl*= 0.5, *Tcrndvi*= 0.45 and *Tdnbrl*= 0.10, and they were obtained by qualitative comparisons. For OLI images, a different set of thresholds were used, and the NDVI threshold was lowered to 0.35, while *Tdnbrl* was lowered to 0.06.
The final operation is the vectorization, which is optional. To speed up the process, the vector file creation procedure can be cancelled. All these processes are straightforward using functions in the gdal, numpy and other python libraries. The complete work flow of the burned mapping process is presented in Figure 2.

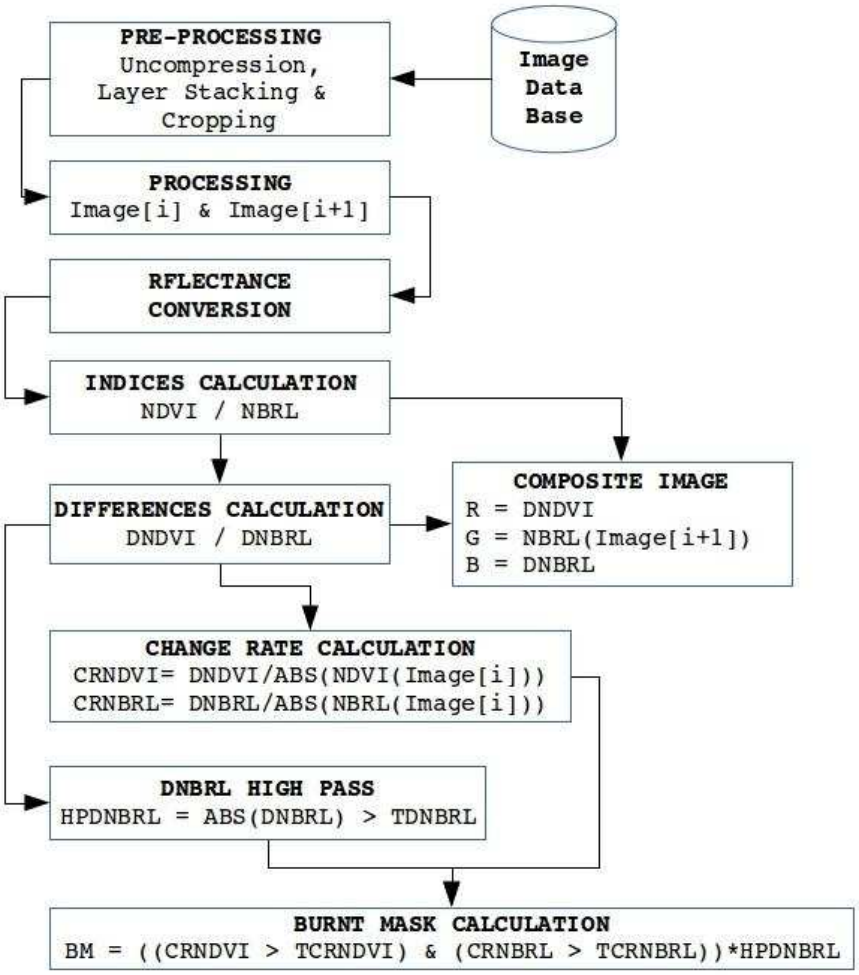

Figure 2. Flux diagram of developed process.

Evaluation of the algorithm's performance was made using burned area manually mapped from visual photo interpretation in the period 2004 – 2010 [Candido, 2014]. As mentioned by Congalton 1991, the accuracy of photointerpretation has been accepted as correct without any confirmation, and digital classifications are often assessed with reference to it leading to sometimes poor and unfair assessments. According to Blaschke *et al* (2008), visual photo interpretation is the ultimate benchmark for any classification and segmentation procedure. Omission and commission errors were obtained from image differencing between the reference data manually digitized and the algorithm's burned area (BA).

$$Omission\ Error = Reference - Algorithm's\ Burned\ Area$$

$$Commission\ Error = Algorithm's\ Burned\ Area - Reference$$

Burned Match (BM) and the Algorithm Reliability (AR) were obtained with the following formulas.

$$Burned\ Match = \frac{Algorithm's\ BA - CommissionError}{Algorithm's\ BA}$$

$$Algorithm\ Reliability = \frac{(Algorithm's\ BA - Commission\ Error)}{Reference}$$

Results

A total of 52 Landsat TM/OLI scenes from path/row 221/067 covering the period of 2000 – 2013 were processed. Over two thirds of the complete set was evaluated against visual photo interpretation of the burn scars, while the remaining 15 images were processed without a visual evaluation because this works was not yet available. For the 37 images in the 2004 – 2010 period, the obtained results are presented in the following tables.

Table 1. Scene date (day/month of the last image), algorithm burned area, reference burned area, commission error, omission error, burned match and reliability in percentages for year 2004.

2010	894723	892904	9.2	7.9	92.0	90.8	7
Mean	**426520**	**441884**	**8.2%**	**11.8%**	**88.6%**	**91.8%**	**Sum=37**

The mean burned Match for the whole 2004 – 2010 series was 88.6%, while the mean algorithm reliability was 91.8%. Mean commission error was 8.2%, while mean omission error was 11.8%. These results are considered excellent when one analyses similar studies found in the literature [Bastarrika, 2011], which normally indicate more limited classification skills; in addition, the study region is particularly difficult for mapping burned areas with mid-resolution imagery due to the low biomass volume and sparse vegetation in many locations. The results of the classification algorithm for the remaining 15 images of the series, without validation of the fire scars, are listed in Table 9, with total burned area for each year and the corresponding number of processed images.

Table 9. Year, algorithm burned area and number of scenes processed.

	2000	2001	2013	Mean	Total
Burned Area [ha]	472817	461377	401922	**445372**	
Scenes	3	5	7		**15**

The means for the Algorithm Reliability and Burned Match obtained for the other subset of 37 images can be also included, thus resulting in a mean annual burned area for the total period of 432175 ha. The figure with the accumulated burned pixels was obtained for the whole period 2000-2013, and as it can be seen on Figure 3, most of the area covered by the image was burned; from the total 30707018 pixels of our study area, 23021994 were burned at some occasion, or almost 75% of the pixels.

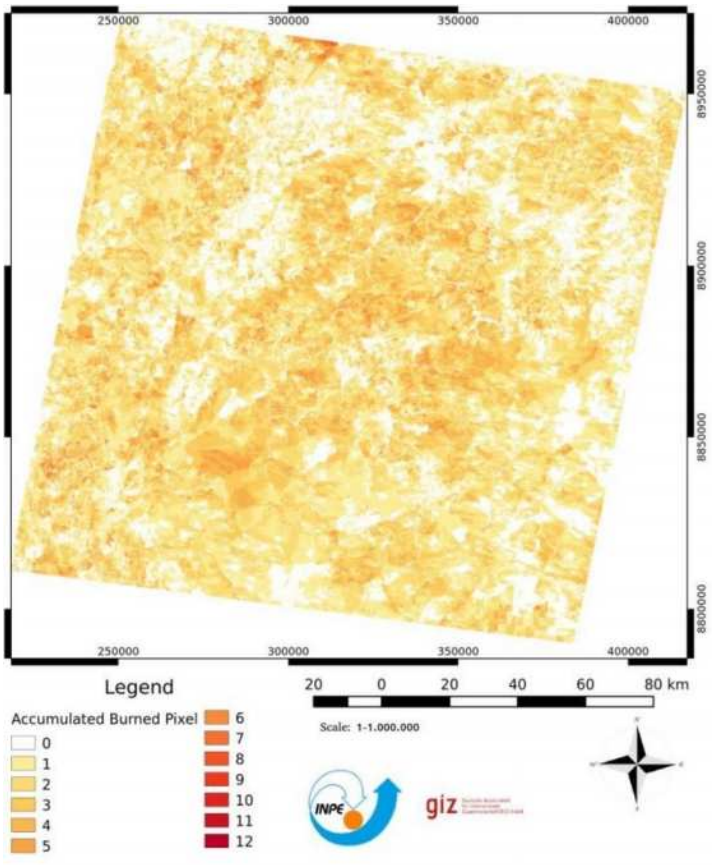

Figure 3. Cumulative burned pixels for the study area in the period of 2000-2013.

Conclusion

A relatively simple and reproducible concept for mapping burned area at the Cerrado-Jalapão region based on NDVI and NBR is presented. The Algorithm Reliability and Match coefficients suggest the usefulness of the tool developed and its application in other biomes. In particular, its use for conservation units could minimize the impact of land cover changes of anthropic origin.

Sudden changes in the spectral reflectance of the vegetation normally indicate perturbing events. The overlap of mapped burned scars with updated land use cover maps can identify the type of vegetation burned, allowing estimates of carbon and pollution emissions.

Agricultural land practices were a source of error in the mapping of fire scars, together with clouds and cloud shadows. Masking these three classes automatically will reduce the uncertainty of the process and improve the Burned Match; further work in this direction is currently in progress.

A reliable spatial reference is fundamental to validate a digital automatic process [Congalton 1991], but this condition is rarely found in the analysis of the results of algorithms to map burned area at regional and continental scales. The systematization of the processing stages herein proposed and their integration with a geographical data base engine could foster an operative system to process large image repositories. The implementation of software applications without proprietary libraries or closed systems grants the portability and free distribution of the developed tools, either in a dedicated system or as part of any processing chain.

Abstract
Firefighters (FF) have to deal in their routine with dangerous situations, exposing themselves to extreme environmental conditions, which can put their lives at risk. Extreme heat exposure, smoke inhalation and reduced visibility are among the most significant hazards to firefighters involved in the suppression of forest fires. In this sense, some new technologies were built addressing the monitoring of firefighters health in the field, mainly sport-oriented solutions adapted for both scientific studies and commercial solutions. However, none of those aim at the mitigation of the main reason for incidents involving firefighters: the exposure to dangerous concentrations of air pollutants.
Our purpose is the development of an integrated hardware and software solution that allows the online monitoring of vital and environmental parameters, helping the FF to preserve their personal health and safety. The system is composed of a specific hardware device attached to the helmet that measures several parameters of interest (e.g. elevation, air temperature, atmospheric pressure, luminosity, exposure to carbon monoxide and nitrogen dioxide), and a mobile application running in a smartphone, which processes information gathered by the helmet hardware to determine if the firefighter is at an acceptable level of exposure/danger and triggers an alarm, if necessary.
From an operational point of view, this work proposes a cost-effective solution to monitor FF smoke exposure in typical adverse scenarios such as forest fires, allowing the detection and mitigation of hypothetical intoxication incidents. The hardware component is easily integrated in standard firefighter's protection equipment and the mobile application can run in any "off-the-shelf" mobile computing device. Beyond the stand-alone firefighters monitoring perspective, this wearable technological solution opens several opportunities as a data source. In this sense, under development is the integration of the near real-time observations into a Decision Support System (DSS) aiming to provide knowledge-based aid to firefighters at critical decision-making situations, thus helping with the safe and successful management of fire fighting.

Keywords*: fire safety; smoke exposure; wearable sensor.*

Introduction

Firefighters (FF) have to deal, in their quotidian, with dangerous situations, exposing themselves to extreme environmental conditions, which put their lives at high risk. Extreme heat exposure, smoke inhalation and reduced visibility are among the most significant hazards to firefighters involved in the suppression of forest fires.
In this sense, there are some new technologies that enable the monitoring of some FF health parameters (e.g. heart rate, ventilation frequency, r-r interval) for commercial [Zephyr Technology, 2014] and scientific purposes [Heimburg *et al*., 2006]. However, these technologies are only partial solutions and mostly oriented to the offline analysis of physiological data, not taking into consideration the problem

of aiding the FF in the terrain nor the needed environmental data. Even the commercial solutions are actually adaptations of sport-oriented systems, and are not well suited for realistic operational conditions [Teie, 2005], letting important issues as ergonomic, needed monitoring variables or operational concerns out of their scope.

An illustrative example is the synergy between wearable technologies and mobile computing [Coimbra *et al*., 2012], in which FF were monitored by their own smartphone [Colunas *et al*., 2011] and using wearable sensors [Cunha *et al*., 2010, Cunha, 2012] (see Figure 1). In this previous work, physiological variables were nicely adapted to a wearable system that was specifically developed to FF requirements. Nevertheless, the needed environmental variables were not integrated.

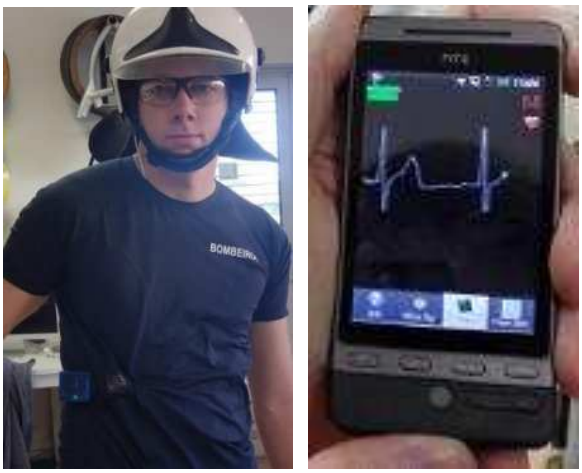

Figure 1. Vital Responder setup: wearable hardware (on the left) and the mobile application (on the right).

Recognising the power of mobile computing devices features (e.g. computational power, wireless networks) using wearable hardware as terrain sensors, our purpose is to contribute for mitigating one of the main reasons for incidents involving firefighters: the exposure to dangerous concentrations of air pollutants [Miranda *et al*., 2012]. The main goal of this research is the development of an integrated hardware and software solution that allows online monitoring of vital and environmental parameters that influence the firefighter's health and safety.

System Description

To achieve the referred goal, two technological paradigms were merged: wearable electronics development and mobile programming, as it is depicted in Figure 2.

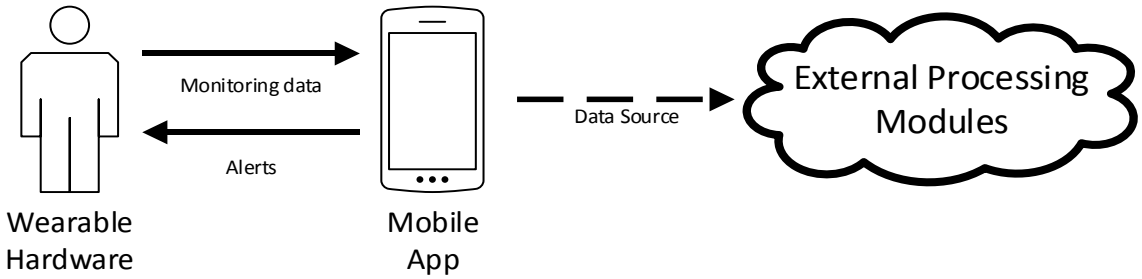

Figure 2. System interaction.

The wearable hardware consists on a sensored helmet unit (Figure 3) to be used by the firefighter. This device allows the measurement of elevation, air temperature, atmospheric pressure, as also the personal exposure to carbon monoxide (CO) and nitrogen dioxide (NO_2). These specific air pollutants are known to cause short term effects (e.g. headache, dizziness, nausea, dyspnea, loss of consciousness) [Treitman *et al*., 1980; Morrow, 1984; Sandstrom *et al*., 1990; Prockop *et al*., 2007] that can put a firefighter's life in immediate danger. In order to allow online processing of these variables, the hardware module transmits the information over a Bluetooth network that can be used by smartphones to receive and process the information.
The mobile application uses the information gathered to determine if the firefighter is at an acceptable level of exposure/danger and triggers an alarm, if necessary. Another potential feature of the mobile App is to add some information (e.g. GPS, fall detectors) to the hardware stream and relay it to some kind of superior monitoring platform over Wi-Fi networks. This information can then be used by the team leader to monitor his crew.

Hardware Modules

The hardware modules were developed in-house. The development process was based on the requirements identified based on the outcomes from two research projects:

- FUMEXP (PTDC/AMB/66707/2006), with special emphasis on sensors choice for a set of air pollutants of interest and corresponding typical ranges;
- VitalResponder (CMU/PT/CPS/0046/2008), due to the usability concerns and the technological possibilities already assessed.

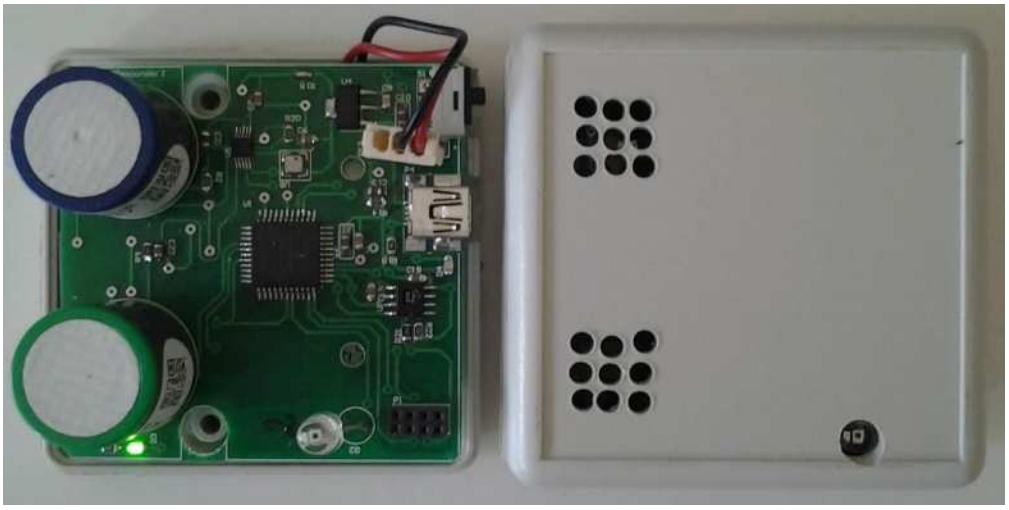

Figure 3. Helmet module prototype: hardware picture (on the left) and its integration on suitable box (on the right).

First of all, a requirement analysis was performed taking into consideration the state of the art on firefighters monitoring systems. It was concluded that the commercial solutions available for the monitoring of human exposure (usually in industrial environments) are not well suited to firefighting operational conditions due to their weight, discomfort and positioning. To mitigate these gaps, and after consulting stakeholders from several fire departments, a hardware device was designed with the objective of being placed on the firefighter's helmet. This approach presents several advantages, but the most representative are:

- ergonomy: with an approximate weight of just 150 g the device becomes imperceptible to the firefighter that is being monitored;
- proximity to the firefighter airways, allowing accurate measurement of the pollutants inhaled;

- usability: once the helmet is a part of the mandatory protection equipment, firefighters do not have to take extra concerns about the monitoring device;
- endurance: due to the environmental factors surrounding a wildfire scenario, it's very difficult to keep an electronic device working properly. For this reason, attaching the monitoring device on the helmet improves the hardware's safety and accuracy.

However, attaching a monitoring device on a firefighter helmet is not a trivial process due to its ratification standards (e.g. EN 443 for helmets hull, EN 16471 for wildland firefighting helmets). In order to surpass these constraints, an embedded helmet socket (Figure 4. left) was used to attach the monitoring hardware module (Figure 4. right). Originally, this socket was designed to support attachments as flash lights and fulfils the applied standards.

Figure 4. Helmet module prototype integration: original firefighter helmet (on the left) and helmet equipped with monitoring hardware (on the right).

Therefore, in order to build an electronic device small enough to be integrated on a firefighter helmet, we tried to achieve a suitable agreement between the technological possibilities and the most representative environmental variables to measure. Finding support on scientific studies [Ferreira *et al*., 2011], our helmet unit has sensors to monitor the data depicted on Table 1.

Table 1- Environmental data acquired by the Helmet module

Variable	Units
NO_2	ppm
CO	ppm
Atmo. Pressure	hPA
Elevation	m
Humidity	%
Temperature	ºC
Luminosity	%

Technologically, we developed a custom printed circuit board to support all the above mentioned sensors and the remaining necessary components:
- electronic front-ends to bridge all sensors with an Analog-to-Digital conversion
- a microcontroller (MCU) unit to gather and process data from all sensors;
- a bluetooth interface, in order to relay data frames processed by the MCU;
- a battery, providing an autonomy of 24 hours, approximately.

CO and NO_2 sensors were calibrated using a calibration gas with a known concentration (100 ppm for CO and 10 ppm for NO_2).

Mobile application

The mobile application is an evolution of the Android based DroidJacket system [Colunas *et al.*, 2011] with support to receive and process data from the helmet unit described on the above section. It can run in an off-the-shelve Android smartphone supporting bluetooth communication, or it can be integrated on a Wi-Fi network and relay data to any connected device.

To extend the DroidJackets physiological monitoring capabilities with the environmental data relayed by the new Helmet Unit we follow the application's original software architecture, replicating the functionalities implemented for VitalJacket®. This approach enables us to maintain all application features (e.g. visualization, persistence, danger alarms, network connection) on an already successful evaluation platform.

More specifically, pairing the smartphone with the Helmet Unit, the smartphone receives, displays (Figure 5), stores and relays all environmental data through a Wi-Fi network, if available.

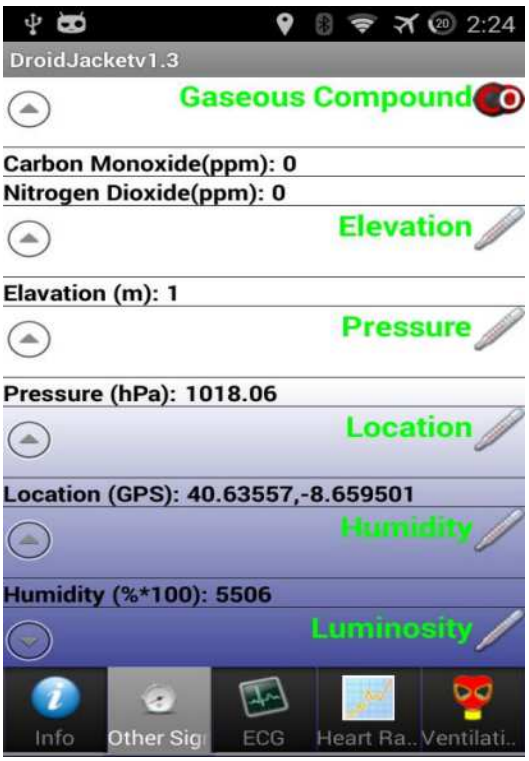

Figure 5 –Improved DroidJacket Version.

Besides the data provided by the Helmet Unit, and other external sensor (e.g. Vital Jacket), the application can use the smartphone's built-in sensors to provide additional information (e.g. GPS, accelerometers, battery).

Integrability and Scalability

The Hardware setup was built with the aim of integrating new sensors on an effortless manner, enhancing integrability and scalability of the overall solution of the Vital Responder project. In this case, we could integrate the previous physiological wearable platform [Coimbra and Cunha, 2012] with the environmental helmet monitoring unit and a GPS. In that sense, the main challenge was related with the sensors size and form-factor

At the software level, DroidJacket application was used and enhanced. It is an example of scalability, once it has been evolved over several iterations of the project with increasing new features [Marques *et al*. 2013]. At this point, the DroidJacket Android App can gather, in one smartphone, physiological data (ECG, heart rate and actigraphy, from VitalJacket®), environmental data (from Helmet Unit presented above) and GPS location. Furthermore, it enables to add more sensing devices up to the limit of the bluetooth connections (7 channels) or the smartphone processing capabilities.
Under development is an ad-hoc data networking technique that will allow the real-time data acquired in the terrain by several of these wearable monitoring equipments and its bridging to a cloud service that will allow numerical forecast that will enable projections of fire progression, smoke levels and critical exposure, aiming to permit safe and efficient positioning of crews.

2.4. System Evaluation

The whole system will be tested, on a stand-alone mode, during the summer of 2014. We will deploy the system on two fire departments, at two different operational zones. There will be firefighters equipped with our system and all monitored data will be stored on the smartphones, without connectivity between each other. Additionally, we will ask firefighters to produce mission reports to selectively tag relevant events (arrival to fire scene, approach a fire front, etc.) so that all collected data can be analysed for the intended evaluation.

Conclusions

Smoke exposure is identified as one of the most important cause of incidents among firefighters. Since the physiological monitoring of firemen has been already addressed, this work signifies one step ahead in this matter, pursuing not only the identification of high risk situations in the terrain, but also contributing to prevent them.
This work proposes a cost-effective solution to monitor firefighters smoke exposure in typical adverse scenarios such as forest fires, allowing the detection and mitigation of hypothetical intoxication incidents. The system is composed of a hardware component easily integrated in standard firefighter protection equipment and a mobile application that can run in any "off-the-shelve" mobile computing device.
Beyond the stand-alone firefighters monitoring perspective, this wearable technological solution opens several opportunities as a data source. In this sense, under development is the integration of the near real-time observations into a Decision Support System (DSS) aiming to provide knowledge-based aid to firefighters at critical decision-making situations, helping with the safe and successful management of fire.

Analysis of the effectiveness of fire detection systems in different dimensions

Agoston Restas

National University of Public Service, Budapest, Hungary, Restas.Agoston@uni-nke.hu

Abstract
Introduction: One of the key elements of the cheap but effective fire suppression is early fire detection and quick initial response. There are many ways of fire detection; in many cases taking an overview of the effectiveness is not useless. Methods: Firstly paper shows the basic principles of the economical effectiveness of the fire management. Afterwards, research turns to the different dimensions and basically counts with aerial flight patrol. Looking at the monitored forest as a flat area gives a 2 dimension analysis but as an articulated area gives a 3 dimension analysis. If research counts with the time scale, meaning the way weather condition changes, it gives a 4 dimension analysis. Results and discussion: Research says in the 2 dimension model the aerial flight patrol cannot be effective, a tower based fire detection system is required.
In case of 3 dimensions model the balance between the methods of aerial flight patrol or the tower based fire detection system depends on feature and rate of the area articulation. The 4 dimensions analysis says that the balance between the methods of aerial flight patrol or the tower based fire detection system can correlate to the fire weather index.

Keywords*: aerial patrol, UAS application, tower based fire detection system, dimension analysis*

Introduction

One of the key elements of the cheap but effective fire suppression is early fire detection and quick initial response. There are many ways of solutions for the fire detection, such as satellite in orbital equipped with special sensors, manned or unmanned aerial (UAV) flight patrol at different altitude, many kinds of tower based automatic fire detection systems, or mobile human surveillance. Each of them has operation costs, in many cases not negligible, therefore taking an overview of the effectiveness is not useless.
Satellite can be a very effective tool for fire detection but there are some problems with the application. Satellites at geostationary can monitor huge areas but the distance is too far from the Earth to detect hot spots in small size. Sensors with higher resolution could help to detect smaller size fire but there are other problems, like higher price or more false alarms (Pennypacker, 2013). Satellite with closer orbit than geostationary can be also a nice solution but keeping the distance from the Earth requires higher speed meaning that the same area can be monitored cyclically (Giglio at al., 2008). In this case we can count a *monitored time* and a *blind time*; latest means that area is not monitored continuously (Restas, 2012). This satellite can be a good solution at huge forested areas such as North and South America, Africa or Siberia.
Human surveillance is also a kind of fire detection method, however the effectiveness is many cases accidental. Closing out the human beings measuring the effectiveness of the human surveillance is more or less similar to tower based fire detection systems. Assuming continuous monitoring and taking into account the horizontal position of the "sensor" to the fire human surveillance can mean the one, on satellite installed sensor the other wings as extremes in the range of different fire detection solutions.
All method mentioned above belongs to strategic solutions for hot spot detection however at the beginning of the intervention managers also require tactical solutions. It can mean horizontal observation from the ground or human with special technical equipment like fire truck or UAS.

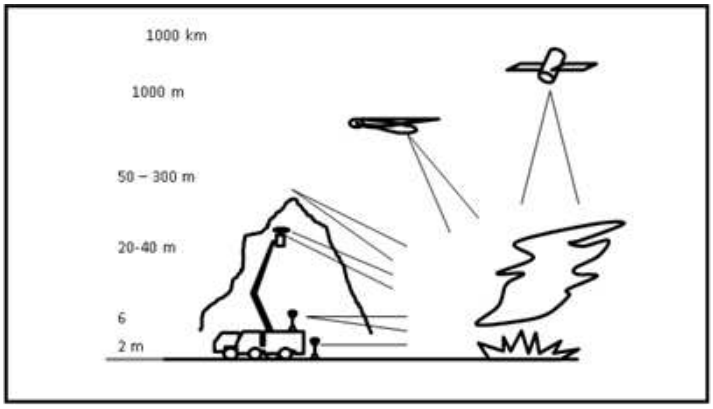

Figure 1. Different solutions for fire detection: from human on ground to on satellite installed sensors

Damage – time function analysis

When anybody assesses efficiency, it is usually the return on investment and the period of time required for such returns to be realized that we take into account. The concept of efficiency is applicable to firefighting as well, but the way it is applied differs from the traditional interpretation mentioned above. In the case of firefighting and other interventions, efficiency is measured either by the quantity of value saved or by the actual damage, which, of course, should be as small as possible.
The value of forest is not homogenous; it depends on variety, age, quality, etc. But forests have not only economical but a social, biological, goodwill, etc. value as well. The goodwill value is much higher than the simply economic value. It applies even more to national parks. Despite this statement this method basically takes into account only the economic value.
The value of saved forest is also not homogenous, neither in time nor in field. Usually it doesn't take into account the total price of the forest. Destruction depends on the age of the forest, the type of the trees, the combustible materials and weather parameters. They are separated not in a discrete value but a complex continuities function.
On the other hand, there are years when the risk is very high, the value of destruction is extreme and in other years much less. Let us look at this curve in the case of a forest fire. The damage-time function gives an exponential curve that diverges to infinity.

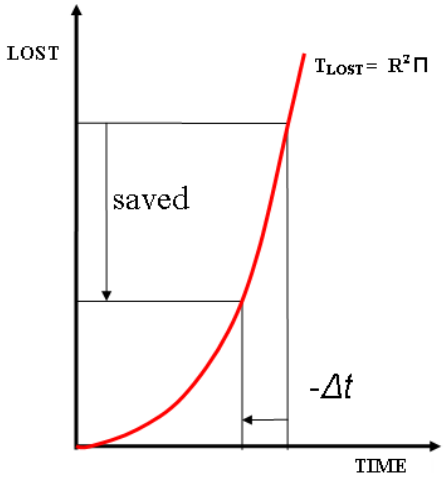

Figure 2. Damage-time function. Basic shape at uncontrolled forest fire

It is easy to recognise if for any period Δt is reduced, the area burnt and thereby the damage caused is reduced exponentially. The smaller the area affected by the fire, the smaller the quantity of resources to extinguish it.

Aerial patrol for hot spot detection – 2 dimensions analysis

Basic elements of the effectiveness

The basic assumption is that by using aerial patrol the fire service can save forest of more value than without it. The economic efficiency will materialize if the saved forest is more than the all expenditure of fire service regarding using aerial surveillance. At the strategical level, author means a bigger scale, let's say at a government level, we have to take into account all the expenditure of aerial surveillance and all the saved forest of the country.
Aerial patrol can detect hot spots very quickly and it is able to give the first fire report to fire brigades; it can reduce the time of first attack.

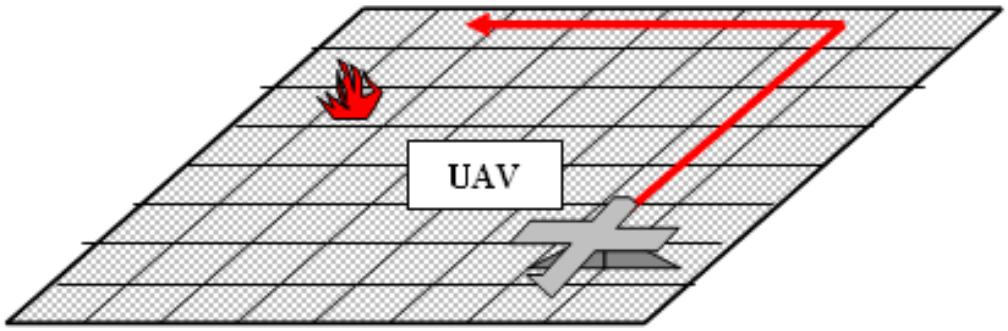

Figure 3. Aerial surveillance e.g. using UAV for hot spot detection

For hot spot detection spotter makes a patrol following the pre-programmed flight path usually as routine task. Obviously, the average delay of the aerial fire report must be less than the average delay of the civil report. This condition is necessary even if not sufficient for satisfying the requirements of economic efficiency of aerial surveillance, in this example UAV flight.
From the ignition (fire starts) till the aerial based fire report takes different time depending on the position of the UAV and the position of the ignited fire crossed by planned flight path. Obviously large number of fire detection (statistical data base) gives for the time of average fire report as a half time of the UAV patrol time. This statement can be accepted also by logical conclusion.

$$\bar{t}_{UAV\_report} = \frac{1}{2} t_{UAV\_patrol} \qquad (1)$$

$$\bar{t}_{UAV\_report} < \bar{t}_{Civil\_report} \qquad (2)$$

- t_{UAV_patrol} - full time of a flight patrol, made by UAV;
- t_{UAV_report} - average time of fire report given by UAV, making fire patrol;
- t_{Civil_report} - average time of fire report, given by civilians.

The other criteria for satisfying the economically efficiency is that based on aerial surveillance (e.g. UAV use) fire service must save forest of more value than the costs of the surveillance (aerial patrol).

A quick fire report results in quick answer; short uncontrolled fire means less damages but more saved value.
If the intervention starts very soon after ignition, the savings will come not just from the saved forest but also from a shorter use of the special equipment required to suppress the fire (figure 4).

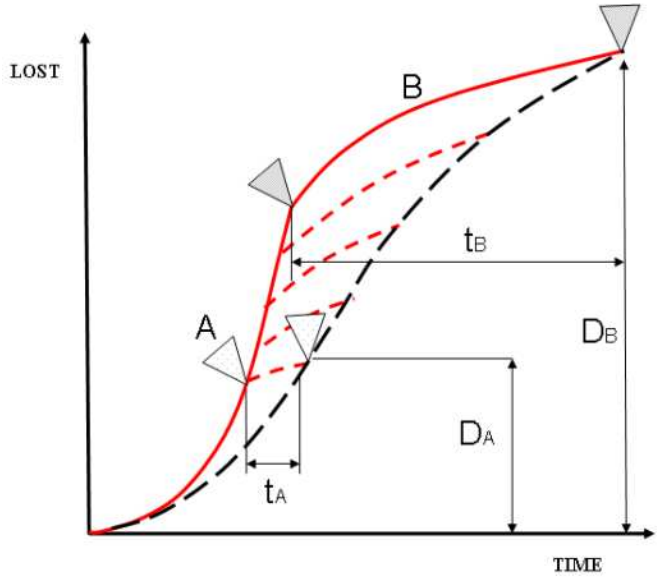

Figure 4. Structure of damage – time functions taking into account the quick fire report

Modelling the extinguishing of the fire by the damage – time functions the beginning of the response will break the fire curve (figure 2 → figure 4). The intensity and the length of the modified fire curve will depend on the time between the ignition and the beginning of the response. In case of A the time is shorter than in case of B therefore in case of A the intensity is lower and the length is shorter of the modified fire curve than in case of B (figure 4). The response in case of A results in lower damage (lost) and shorter time of intervention; this latest one results also in lower costs of the intervention. The shorter the time is between the ignition and the beginning of the response, the lower the intensity and the shorter the modified fire curve is. The above criteria can be expressed also by the next formulas:

$$S \Rightarrow D\left[\bar{t}_{Civil\_report} - \frac{1}{2}t_{UAV\_patrol}\right] > \Sigma C_{UAV\_patrol} \qquad (3)$$

$$\int_{\frac{1}{2}t_{UAV\_patrol}}^{\bar{t}_{Civil\_report}} D \; > \Sigma C_{UAV\_patrol} \qquad (4)$$

- S (D) - damages between the average term of civil report and aerial report;
- A - characteristic of suppression using UAV support;
- B - characteristic of suppression without UAV support.

Till the above formulas are valid the criterion of the economically based efficiency is satisfied at UAV patrol based fire management.

3.2. Moving to higher effectiveness – flight speed analysis

Since the efficiency obviously depends on the difference of the civil based and aerial supplied report's time, the question spontaneously arises, how can we make longer term between these reports? Based on the above formulas the delay of civil report is relatively stable, while the aerial based hot spot detection depends mainly on flight regimes. Therefore, making the aerial based hot spot detection more efficient we must face fly parameters. Logically we can test the flight speed, the altitude and the visual or camera (UAV) focus. During the analysis idealistic circumstances are supposed: there is no wind, it counts just with one hot spot, price of the technical elements, like camera does not change, weather does not limit the visibility, area is flat, etc. This latest one, the flat area means that we monitor 2 dimensions extension.

The purpose of reducing the average detection time requires the flight speed rise. With this process the flight path will not change but the time of aerial patrol will reduce. In case of a 24 km x 24 km area, with about a 180 kmh^{-1} flight speed and about a 3 km x 3 km monitored (camera) pixel in a moment (e.g. UAV) the monitored time for 1 pixel is 1 minute then 63 minutes are blind; the rate of monitored and blind area is 1:63. Raising the speed the cycle will reduce but the rate of the monitored and blind area will not. The problem is that the flight speed rise is objectively limited.

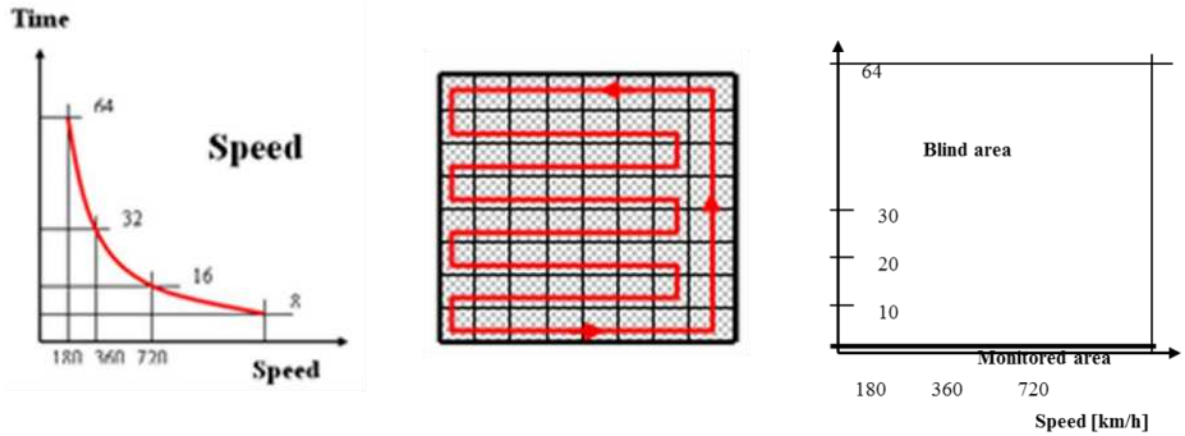

Figure 5– Example for moving towards the higher effectiveness of the fire detection. Raising the flight speed neither the flight path nor the rate of monitored and blind area do not change

3.3. Moving to higher effectiveness – camera focus and altitude analysis

The analyses of camera focus and altitude gives a little bit different results. Rising the altitude the on board installed camera monitors larger area (pixel). If the frame of the supervised area remains but the monitored pixel is larger than earlier, it means that the flight path can change; obviously it will be shorter. The flight path will move to the center of the area. Step by step continuing this process it reaches the end values when the flight path will concentrate at the middle point of the supervised area. It means our aerial means hangs on the central point of the area without flight speed! Logically the end value doesn't require the manned or unmanned flight; in this case a tower based camera system can be an alternative solution with the same effectiveness.

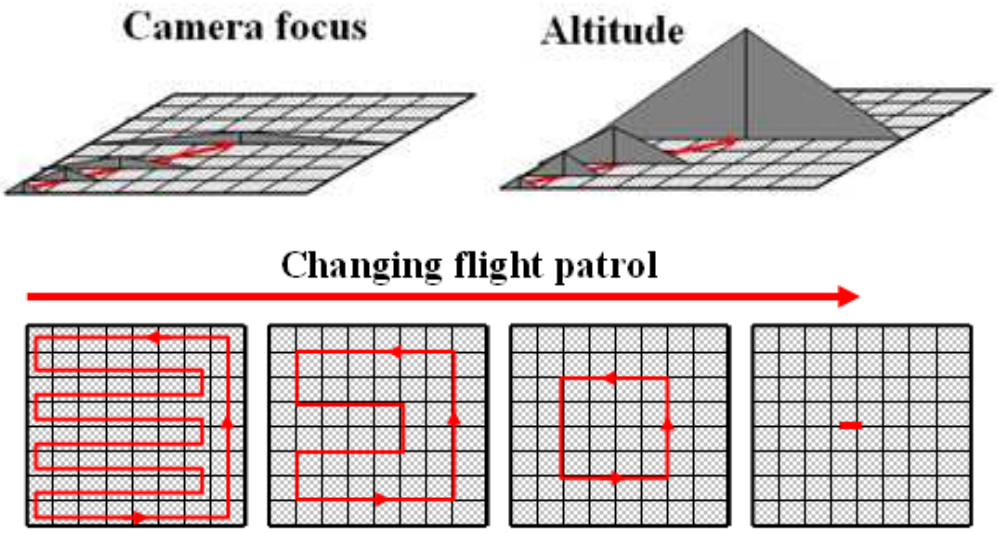

Figure 6– Example for moving towards the higher effectiveness of the fire detection. Raising the angle of camera focus or the altitude the flight path changes; it moves to the centre of the monitored area

Without deeper explanation it can be accepted the analysis of camera focus with similar way as above gives the same results. In this case there is no or insignificant difference between the altitude of aerial "surveillance" –hanging on the center point of the area – and tower based fire detection system.
In both cases the rate of the monitored and blind area also changes; it drastically turns beneficially. At the end of the process the rate is 1:0; which means all area is monitored continuously. Even if the effectiveness of both systems – aerial surveillance and tower based fire detection system – can be similar that is not sure in case of efficiency. If all the costs of using tower based fire detection system and the aerial surveillance are similar the efficiencies are also similar. In the assumptions we took into account same technical parameters – it means camera installed on board or tower too – therefore, the difference of the efficiency generates from the all costs of using the systems. This is true in case of UAV use too, even if it is supposed to be a cheaper solution than manned aircraft. In this case the tipping point – meaning the balanced costs – can be lower.

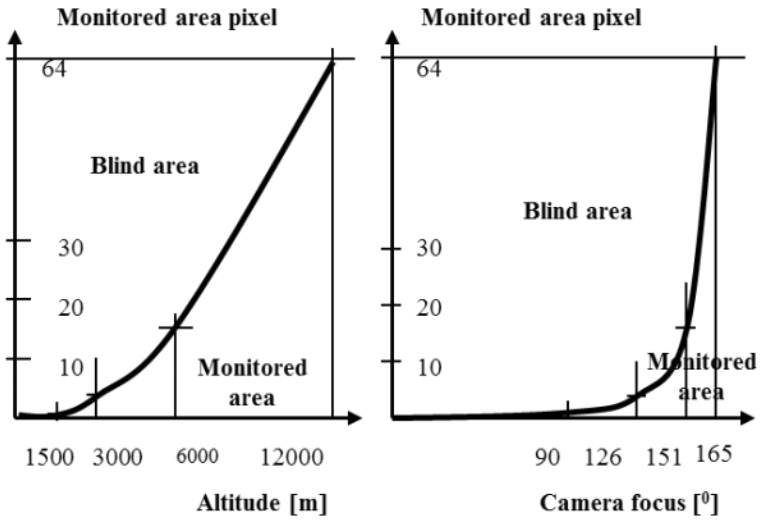

Figure 7– The rate of the monitored and blind area changes drastically positive

Geographically high articulated area – 3 dimensions analysis

Based on the above using tower based fire detection system in case of flat area – 2 dimensions extension – is more effective. The question is that in what or when the higher efficiency can be limited. As a first step, author extended flat – 2 dimensions – area to geographically high articulated – 3 dimensions – area.
In case of flat area tower based fire detection system can detect hot spots by direct way; it means there is no natural or manmade barrier to "see" the hot spots by the camera or sensor. In case of articulated areas the way for fire detection can be different. If the ignition is at the valley or at the bottom of the slope it can be in shadow of the hills, therefore, tower based fire detection system can detect fire in many cases only by indirect way; it means fire is in the shadow of the hill, camera or sensor cannot detect the fire but the smoke column or plum of it.
Naturally the smoke column in indirect way can be detected later than fire in direct way. Depending on different circumstances – wind power and direction, inversion, fire intensity, rate and way of the articulation, etc. – the detection of smoke column can delay significantly. It means that not just the effectiveness of the tower based fire detection system reduces but also the efficiency of it. The rate of reduction naturally depends on the rate and way of articulation; this is a circumstance that does not change in time. In case of high articulation reduction of effectiveness is surely higher; however, the rate of correlation between them requires advanced research. Moreover, the way of articulation is also important.

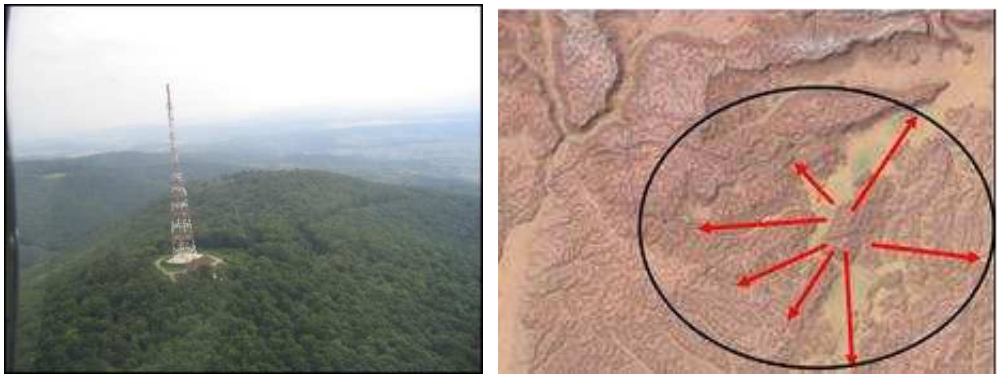

Figure 8– Example for a geographically good positioned tower based fire detection system. Aggtelek National Park - Szendro Fire Department, Hungary, Installation: 2005

There is an example where tower based fire detection system was installed in such an advantageous way that the valley's position looks like radiation spread from it (Restas, 2006). Positioning this kind of system is very important; it basically determines its potential of both effectiveness and efficiency. Good positioning – even if just a limited way, but – can reduce the shadow effect of hills.
When positioning of the system cannot be advantageous but the area is high articulated the rate of direct detection and indirect detection can be also very bad. The smoke emission from the valley stand ignited fire can be detected only with such delay so the advantages of low yearly costs evaporate.
Obviously the mission costs of aerial surveillance do not depend or just to a limited extent on the rate of area articulation. On the other hand, during flight patrol the shadow effect of hills can be relevant only for that pixel where the aircraft flies above. Naturally this effect is much lower in this case than in case of tower based fire detection system. Since the effectiveness and efficiency correlate to each other, the higher costs of aerial surveillance can be balanced by the lower effectiveness of the tower based system. It can be explained by other words too; the rate of catching hot spots in time by aerial surveillance is higher than in case of tower based system. The disadvantageous rate of monitored and

blind area is balanced by higher rate of quick fire report regarding shadow area. The above criterion can be expressed by formula (1) and (5) too.

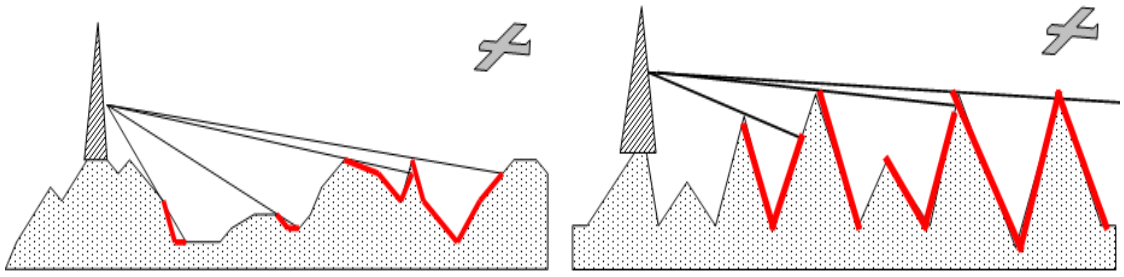

Figure 9– High articulated area: direct detection versus indirect detection (red colored slopes).

Aerial surveillance versus tower based fire detection system

$$\bar{t}_{UAV\_report} = \frac{1}{2} t_{UAV\_patrol} \qquad (1)$$

$$\bar{t}_{UAV\_report} < \bar{t}_{delay\_tower\_report} \qquad (5)$$

- $t_{delay\_tower\_report}$ -average delay of fire report, given by tower based fire detection system.

As the formulas (1) and (3) are logically same at time factor, formula (3) and (6) also have logical similarity in costs factor.

$$S \Rightarrow D\left[\bar{t}_{delay\_tower\_report} - \frac{1}{2} t_{UAV\_patrol}\right] > \Sigma C_{UAV\_patrol} \qquad (6)$$

It means also that it must satisfy other basic criterion too, as quicker average fire report than report of civilians. Till the above formulas are valid the criterion of the economically based efficiency is satisfied at aerial surveillance versus tower based fire detection system.

Extremely High Fire Weather Index – 4 dimensions analysis

Analysis above focused on physical extension of the given area; 2 dimensions counted as flat area, 3 dimensions as articulated area. In any case, there is no difference in time range; it takes into account time range as standard condition, however areas are threatened by fire risk usually cyclically so-called fire seasons. If the fire risk is cyclic, the question arises spontaneously, can it be even cyclic or not monitoring the area? If we take into account the cyclic – fire seasons – as time factor, it can mean as 4 dimensions analysis.
It is known, fire seasons strongly correlate to weather conditions; for measuring it different type of index – fire weather index (FWI) – were created, e.g. Canada: McArthur FWI (Dowdy at al., 2010), Germany: Waldbrandgefahrenindex WBI (König, 2007). That is obvious, area monitoring is the more required the higher the fire risk; in this case probability of matching hot spots is higher, which is shown by FWI. Therefore, it is practical to find correlation between FWI and effectiveness of fire detection.

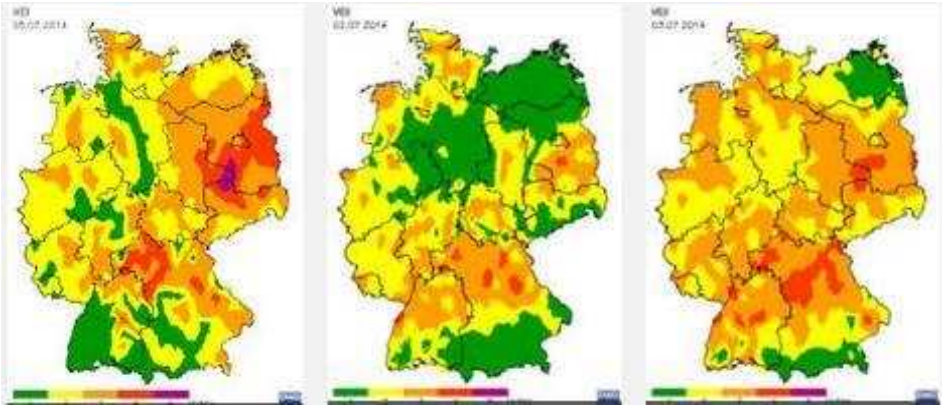

Figure 10. Examples for Waldbrandgefahrenindex, July 2014, Germany

Following the correlation, FWI based planning of applied system for fire detection does not require area monitoring all year round. This condition is not relevant for tower based fire detection system because its installation fix and it is able to work during all year. It means we need count with its all year costs. In case of aerial surveillance we have to count with costs only for that period when it is occasionally demanded.

There are some options for analyzing the efficiency: areas extension can be taken as 2 dimensions or 3 dimensions, however the essence of both results must be similar.

In case of same effectiveness – the average rate of fire detection is equal – the cheaper solution takes the higher efficiency, however this possibility has low chance. The other situation is when there are differences between both the average rates of the fire detection and the costs of using the different systems; obviously the higher costs of the aerial fire detection are suspected. In case of same efficiency the higher costs of aerial fire detection must be balanced by the higher rate of matching hot spots; it is the tipping point. Above this threshold – taking into account fix price for the flight hour – aerial fire detection is more efficient, otherwise not.

Otherwise, if there is difference in match of hot spot detection we have to calculate the rate of the difference between the saved forest and costs. In basic situation the criterion can be expressed by the next formula:

$$\Sigma C_{UAV\_occasionally} < \Sigma C_{Tower\_yearly\_costs} \quad (7)$$

$\sum C_{UAV\_occasionally}$ - occasional costs of UAV, used it at extremely high FWI;
$\sum C_{Tower\_yearly\_costs}$ - yearly costs of the tower based fire detection system.

Till the above formula is valid the criterion of the economically based efficiency is satisfied at extremely high FWI term.

It can be seen, this latest analysis contains the most vulnerable elements. Therefore, this paper just shows some directions for further research, exact definition of the tipping point as well as determines the correlation between the higher rate of matching hot spots and the efficiency requiring more study.

Summarizing

There is no doubt one of the key elements of the cheap but effective fire suppression is the early fire detection and quick initial response. There are many solutions for the fire detection however in many cases taking an overview of the effectiveness is not useless.

This paper firstly described the basic principles of the economical effectiveness of the fire management. Afterwards, research turned to the different dimensions and basically counts with aerial

flight patrol. Looking at the monitored forest as a flat area, it gives 2 dimensions analysis but as an articulated area it gives 3 dimensions analysis. Research counted also with the time scale, meaning that weather conditions can change; it gave the 4 dimensions analysis.
Based on the research in the 2 dimension model the aerial flight patrol cannot be effective, a tower based fire detection system is required. In case of 3 dimensions model the balance between the methods of aerial flight patrol or the tower based fire detection system depends on feature and rate of the area articulation. The 4 dimensions analysis says that the balance between the methods of aerial flight patrol or the tower based fire detection system can correlate to the fire weather index.
Research pointed out that applied analysis contains many vulnerable elements. Therefore, this paper just shows some directions for further research, exact definition of the tipping point as well as determines the correlation between the higher rate of matching hot spots and the efficiency requiring more study.

Analysis of the thermophysiological response to cooling techniques in firefighters

R. Marcelo Abreu, António M. Raimundo* and Divo A. Quintela

ADAI-LAETA, Department of Mechanical Engineering, University of Coimbra - Pólo II, Rua Luís Reis Santos, 3030-788 Coimbra, Portugal. antonio.raimundo@dem.uc.pt; +351.239790738

Abstract
Firefighting has often been compared to a fight against an enemy capable of both material and lives' loss. It is a physical activity that requires a rare combination of strength, flexibility, endurance and intelligence to survive under extreme conditions. When it comes to firefighting, men fighting fires are potential victims of heat stress because they go through long periods of hard work in hot environments. The present work's target is the analysis of firefighters' thermophysiological reactions to heat stress situations caused by hyperthermia. Using a *software* that simulates the human body's thermophysiological behavior, several aspects, such as the fire intensity's influence on the thermal state of the firefighter, the exposure time and the body cooling technique used to attenuate heat stress, are highlighted. With the goal of embracing the most possible situations, three intensity levels of impinging radiation that come from the fire and affect men fighting fires are analyzed: low; medium; and high. Three alternative body cooling techniques are considered: the traditional one; by immersion of forearms and hands in water at 20ºC; and by immersion of forearms and hands in 10ºC water. Normal ingestion of water during recovering breaks (matching the cooling times) was also in focus in the simulations.

Keywords*: Safety firefighting; Human thermophysiological response; Body cooling techniques*

Introduction

Firefighting has often been compared to a fight against an enemy capable of both material and lives' loss. It is a physical activity that requires a combination of strength, flexibility, endurance and intelligence. Men fighting fires are potential victims of heat stress because they go through long periods of hard work in very hot environments (Barr *et al.*, 2009).
Heat stress is defined as the amount of heat that needs to be dissipated or produced in order to maintain the body in a safety thermal balance (WHO, 1969). When the thermoregulatory system is unable to compensate the overload of heat imposed to the human body, the system gets unbalanced and the individual begins to suffer from hot heat stress. This kind of thermal stress occurs due to internal factors, such as the metabolic heat and individual differences, due to the person activity intensity and the garments that uses, and due to the surrounding thermal environment (Sharkey, 1999; McLellan & Selkirk, 2005). Any job or task that may cause an increase in the body core temperature elevates the risk of hyperthermia (heat stress caused by over accumulated heat in the body). Operations involving high air temperatures, high level of moisture, impinging radiation from heat sources, direct physical contact with hot objects, or very intense physical activities have a high potential risk of hyperthermia. Firefighters on duty are potential victims of numerous pathologies related with excess of heat and the consequent increase in body core temperature. These heat-related illnesses are introversion (violent sweating, misleading, amnesia, etc.), heat-stroke (fainting and eventually stop of sweating, central nervous system alteration, etc.), superficial skin damages (pain and first-degree burns), and permanent injuries (second-degree burns or higher, brain damage or, in more serious cases, death).
In order to satisfy all the demands of the firefighting activity, it might be necessary to use recovery strategies for physical recuperation and for body cooling as a way of thermal stress attenuation (Barr *et al.*, 2009). The purpose of the body cooling process after the firefighting activity is to restore the

thermophysiological balance of the body in the shortest time possible and thus avoid harmful effects to health trying at the same time help the recovery of the individual for any subsequent activity.
Body cooling techniques can be passive or active. Passive cooling methodologies are much simpler to implement then the active ones. Normally, passive cooling is implemented by the moving of the firefighter to a secluded area far from the fire front, if possible shaded, and removing some of his personal protective ensemble. Active body cooling techniques requires the same actions as the passive ones and an additional cooling process, for instance forced air convection, immersion of body segments in water, etc. The drinking of water (preferably moderately cold) is also fundamental, but for body hydration as its effect on body cooling is only marginal.
The body cooling by forced air convection is based on the use of fans in order to impose a strong air speed (Carter *et al.*, 1999). This technique is reasonable effective but somehow unpractical to improve. By other hand, the techniques based on immersion of body parts in cold water have good efficacy if applied to areas with a high concentration of arteriovenous anastomoses, as the case of hands, forearms and legs (Magalhães *et al*., 2001; Barr *et al*., 2009). This technique is simple and easy to implement due to the availability of water supply from wells or rivers, which is usually at temperatures of the order of 15 to 20°C, making this technique often used. Studies have shown that for an individual who is in a state of hyperthermia the water temperature should be not lower than 10ºC in order not compromising vasodilation (Selkirk *et al*. 2004; Carter *et al.*, 2007; Barr *et al*., 2009). In the case of immersing the forearms and the hands in water, the highest cooling rates occur when the water temperature is 10°C (Giesbrecht *et al.*, 2007; Barr *et al*, 2009).
The main objective of this work is the establishment of secure protocols to fight high intensity fires. The emphasis will be given to the identification and analysis of the effectiveness of body cooling techniques capable to mitigate the risk of heat stress by hyperthermia. It also aims to determine the influence of the intensity of the fire on the risk of incidents related with hot heat stress, as well as the maximum exposure times of firefighting to prevent any body thermal conditions that may constitute a hazard.
Three intensity levels of radiation are considered: low, medium and high. As alternative body cooling techniques, applied during regular time-breaks, attention was given to the most traditional passive method (the firefighter goes away from the fire front to rest in a shaded location) and to the immersion of forearms and hands in water at 20ºC and at 10ºC. During these periods the firefighter is dressed with his personal protective ensemble, but without the helmet, the balaclava, the coat, and the gloves. The normal ingestion of water was also taken into account.

2. Calculation Tool

To obtain the results presented in this study, a computer program implemented by the authors (Raimundo and Figueiredo, 2009; Raimundo *et al*. 2008 and 2012) is used for the simulation of heat and mass transfer and thermophysiological response of a male firefighter exposed to extreme environmental conditions, such as those occurring in the proximity of a high intensity fire front. This program is composed by nine modules. However, for present purposes are used only the ones for the calculation of (*i*) person thermophysiological response, (*ii*) heat and water transport through the clothing, (*iii*) heat (by conduction, convection and radiation) and mass exchange between the external surface of clothing (or skin) and the environment and surroundings, (*iv*) start and evolution of skin injuries (pain and burn) and (*v*) detection of specific incidents within the human being.
The simulation of man thermophysiological response is based on the Stolwijk (1971) thermoregulation model, improved with knowledge found in the literature (e.g., Henriques, 1947; Weaver and Stoll, 1969; Konz *et al*., 1977; Wissler, 1985; Huizenga *et al.*, 1999; Fiala *et al*., 1999; Tanabe *et al.*, 2002). This enhanced 89-node model considers the human body divided in 22 segments (face, scalp, neck, chest, abdomen, upper back, lower back, pelvis, left shoulder, right shoulder, left arm, right arm, left forearm, right forearm, left hand, right hand, left thigh, right thigh, left leg, right leg, left foot and right

foot). Each body segment is composed of 4 layers (core, muscle, fat and skin), the 89th node being the central blood compartment. The model was implemented for an average man of 1.72 m tall, weighing 74.43 kg and with 14% of body fat (1.869 m^2 of skin). For other anthropometric data, the appropriated coefficients are proportionally changed in function of the body weight, skin area and body fat. Nevertheless, the model does not take into account the influence of barometric pressure and hydration status of the subject, because there is a lack of information in the literature about the relationship between these physical and physiological parameters and the human thermophysiological response.
The simulation of heat and water transport through the clothing is based on the formulation purposed by Havenith *et al*. (2002). The calculations are made for each specific human body segment. Then, individual values of the local clothing parameters (intrinsic insolation, mass, specific heat, vapour permeability and radiation emissivity) must be specified for each of the 22 human body segments considered. Each section is either completely clothed or nude.
The modeling of skin burn process implemented in the software is based on Henriques' theory (Henriques, 1947; Weaver and Stoll, 1969), which represents the skin thermal damage as chemical rate phenomena. As they don't start at same instant, the prediction of the skin pain threshold is also useful. This is important because, as reported by Stoll and Greene (1959), when the pain is felt, it is often too late to avoid a 2nd degree skin burn or, in some extreme situations, a heat stroke or even death. Empirical correlations have been developed that allow the prediction of the time until pain is felt, some of them reported in Wenger (1988), SFPE guide (2000) and Gagnon (2000). In the present program, the onset of skin pain is marked when epidermis-dermis interface temperature (T_{edi}) reaches 45ºC (Havenith and Heus, 2000) or when Henriques (1947) integral injury parameter (Ω) equals 0.53, depending on what occurs first (generally, T_{edi} = 45ºC).
In order to understand the significance of the calculated body temperatures, it is necessary to identify the values for which there is the probability of occurrence of specific incidents in the human body. Normally, the rectal temperature is used to identify the risk of thermal injuries. Nevertheless, the temperature of blood reaching the hypothalamus is regarded as a major afferent stimulus for the intensity of the effective response of sweating, vasomotor activity and shivering. Then, a better relationship may be expected between hypothalamus temperature (T_{hyp}) and the various physiological and sensory states (Pascoe *et al*., 1994; Kenney *et al*., 2004, Raimundo and Figueiredo, 2009; Raimundo *et al*., 2012). In the module of the program for the detection of specific incidents, the temperature limits are set as function of the hypothalamus temperature (T_{hyp}) following the Pascoe *et al*. (1994) scale: $\leq$ 25ºC → death, $\leq$ 28ºC → ventricular fibrillation, $\leq$ 30ºC → stop shivering and fainting, $\leq$ 34ºC → introversion and violent shivering, 34 < T_{hyp} < 39ºC → normal thermoregulation, $\geq$ 39ºC → introversion and violent sweating, $\geq$ 41ºC → heat stroke (stop sweating and fainting), $\geq$ 42ºC → brain damage (permanent injuries) and $\geq$ 44ºC → death.

Problem Description

It is assumed that the firefighter in question has a physique corresponding to the average of worldwide adult male population. This corresponds to 1.72 m tall, 74.43 kg of weight and 14.5% of body fat (Tanabe *et al*., 2002; Raimundo and Figueiredo, 2009).
The protocol adopted in this study submits the firefighter to several phases. Each firefighting period is followed by a time break where a body cooling technique is applied and a normal ingestion of water is also taken into account.
Three alternative body cooling techniques were analyzed: the most traditional method (the firefighter goes away from the fire front to rest in a shaded location) and the immersion of forearms and hands in water at 20ºC and at 10ºC. With the aim to determine how long it took until the manifested of the various heat stress related pathologies, simulations were also performed without the application of any cooling technique.

In order to verify the usefulness of each body cooling technique, simulations were made taking into account three levels of fire intensity: low, medium and high. The corresponding impinging radiation fluxes are quantified in the Table 1.

Table 1. Characterization of the impinging radiation fluxes for the various fire intensities.

Radiation from / Intensity	Impinging radiation fluxes [W/m^2]		
	Low	Medium	High
North	3 000	6 000	9 000
South	60	120	180
East	1 200	2 400	3 600
West	1 200	2 400	3 600
Top	120	240	360
Ground	60	120	180

The following phase sequence was assumed: neutral (stabilization), pre-firefighting, firefighting, time break with cooling, firefighting, time break with cooling, firefighting, time break with cooling.
The neutral phase is foreseen to ensure that all firefighters submitted to this protocol start equally in a state of thermal neutrality. It should be noted that at this stage it is considered that the firefighter is nude.
During pre-firefighting the firefighter is moving towards the scene of the fire or making preparations for firefighting in this vicinity. At this stage the firefighter is dressed with a shirt, pants of protective clothing and boots.
The firefighting phase is when the firefighter is in front of the fire to fight it. It is assumed that the firefighter is facing the fire and thus exposed to incident radiation from the flame which varies according to the intensity of the fire (see Table 1). At this stage the firefighter is equipped with all parts of his personal protective ensemble.
The cooling phase aims to lower the core temperature of the firefighter in order to prevent the harm caused by heat exposure and to recover him in the shortest time possible. The firefighter is dressed with protective clothing but without: the helmet, the balaclava, the coat, and the gloves.
The simulation process requires a complete characterization of each phase. Namely, it must be defined the firefighter parameters (activity intensity, posture, orientation relatively to the fire, garment and food or water intake), the description of the thermal environment (temperatures, impinging radiation, relative humidity, etc.) and several calculation controlling parameters. A short of the required parameters is summarized in Table 2.

Table 2. Summary of the parameters required for the simulation of each phase.

Parameter	Neutral phase	Pre-firefighting phase	Fire fighting phase			Time break and cooling phase
			Low intensity	Medium intensity	High intensity	
Duration	120 min	30 min	20 min	15 min	10 min	15 min
Activity level	0.8 met	1.5 met	3.0 met	3.0 met	3.0 met	1.0 met
Man posture	Sitting	Standing	Standing	Standing	Standing	Sitting
Man orientation	North	North	North	North	North	North
Mass of food ingested	0	0.66 kg	0	0	0	0.66 kg
Temperature of food	0	15ºC	0	0	0	15ºC

Specific heat of food	0	4 186 J/(kg ºC)	0	0	0	4 186 J/(kg.ºC)
Clothing global intrinsic insolation	0.00 clo	1.53 clo	2.45 clo	2.45 clo	2.45 clo	1.53 clo
Total mass of clothing (including the helmet and the boots)	0.0 kg	2.8 kg	5.3 kg	5.3 kg	5.3 kg	2.8 kg
Clothing specific heat	1 000 J/(kg.ºC)	1 000 J/(kg.ºC)	1 000 J/(kg.ºC)	1 000 J/(kg.ºC)	1 000 J/(kg.ºC)	1 000 J/(kg.ºC)
Clothing global vapour permeability	1.00	0.42	0.22	0.22	0.22	0.42
Clothing global external surface emissivity	0.93	0.91	0.90	0.90	0.90	0.91
Air temperature	29ºC	35ºC	35ºC	35ºC	35ºC	35ºC
Surrounding temperature	29ºC	30ºC	40ºC	40ºC	40ºC	30ºC
Air relative humidity	50%	40%	40%	40%	40%	40%
Air velocity	0.1 m/s	3.0 m/s	5.0 m/s	5.0 m/s	5.0 m/s	3.0 m/s
Impinging radiation	0	0	Values from Table 1			0

Results and Discussion

As far as safety is concerned, the most important indicators seem to be the times delays for the starting of heat stroke (fainting) and of skin pain, mainly the first one. These and other pathologies can occur, but only for continuous firefighting circumstances (without time breaks). This aspect is remarked in Table 3, where the instants for the beginning of skin pain, introversion, heat stroke, brain damage and lethal conditions, are represented as functions of the intensity of the radiation that impinges the firefighter.

Table 3. Time delay (after firefighting start) for the occurrence of undesired pathologies with the man for continuous firefighting circumstances.

Time delay [minutes] for	Impinging radiation intensity		
	Low	Medium	High
Skin pain	130	74	50
Introversion	23	15	12
Heat stroke	45	29	21
Brain damage	64	39	28
Death	128	74	50

As stated in Table 3, undesired pathologies can occur with the man if no time breaks are applied. The threshold for introversion is a good indicator for exposure limits that must not be exceeded. However, even for low incident radiation flux, this pathology and worst can occur for a continuous firefighting. Skin pain situation is reached only after death. Then no pain is felt by the firefighter, which can be a trap. This fact was also reported in the bibliography (e.g. Stoll and Greene, 1959; Raimundo and Figueiredo, 2009). This is perhaps one of the reasons why many experienced firefighters refuse to wear protective clothing in some body parts (ears, hands, neck, etc.). Traditionally the ears were used by firefighters as in indicator of dangerously high temperatures. A good clothing insolation protects against the incoming of external heal but also can allow a firefighter to stay in dangerously hot places, and remain there for unsafe times without any warning.

To avoid the undesired pathologies the firefighter must stay enough away from the fire to be exposed to impinging radiant fluxes lower than the specified in Table 1. If it is not possible, then the firefighting period must be of limited duration and followed by recovering periods. It is recommended the application of a body cooling technique during these time breaks, which is the main subject of this work.

In the analysis of the results for firefighting following the protocol defined in previous section (with recovering body cooling periods), the emphasis is given to the hypothalamus, rectal and skin temperatures and to the maximum variation of the heat stored by the body over time. This is due to the fact that these variables are considered to be the most important to characterize the evolution of the thermal state of the human body. The main conclusions will be drawn about the relationship between these factors and the intensity of impinging radiation on the firefighter and of the recovery technique used.

In Figures 1, 2 and 3 are represented the results obtained with the simulations for the evolution of the thermophysiological state of the firefighter during the protocol adopted, assuming that the firefighter keeps a distance from the fire front from which results a low intensity of incident radiation and for the three cooling techniques considered.

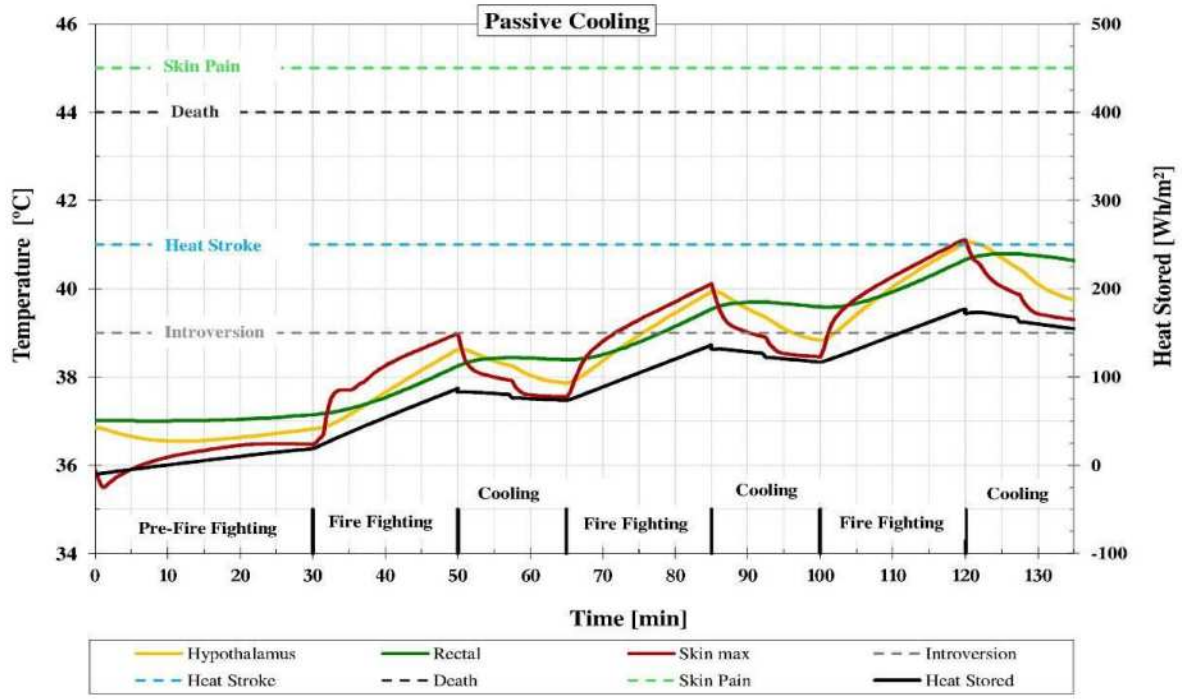

Figure 1. Evolution of firefighter thermophysiological state for low intensity incident radiation and passive cooling recovery.

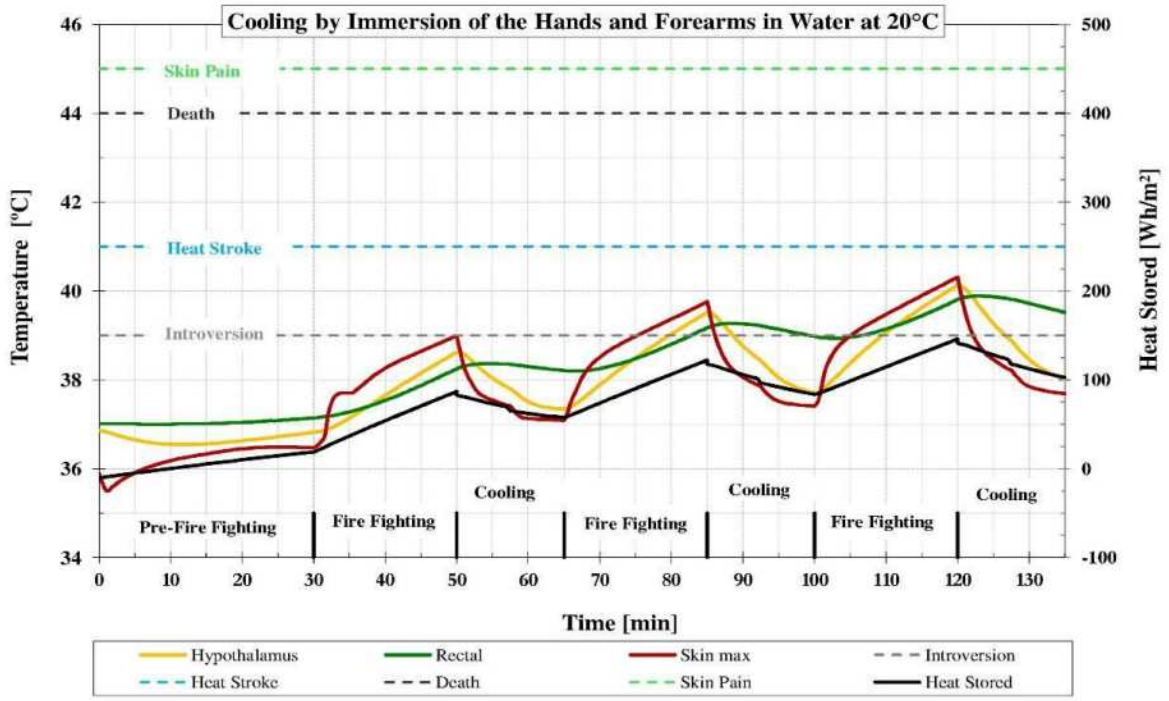

Figure 2. Evolution of firefighter thermophysiological state for low intensity incident radiation and cooling by immersion of the hands and forearms in water at 20°C.

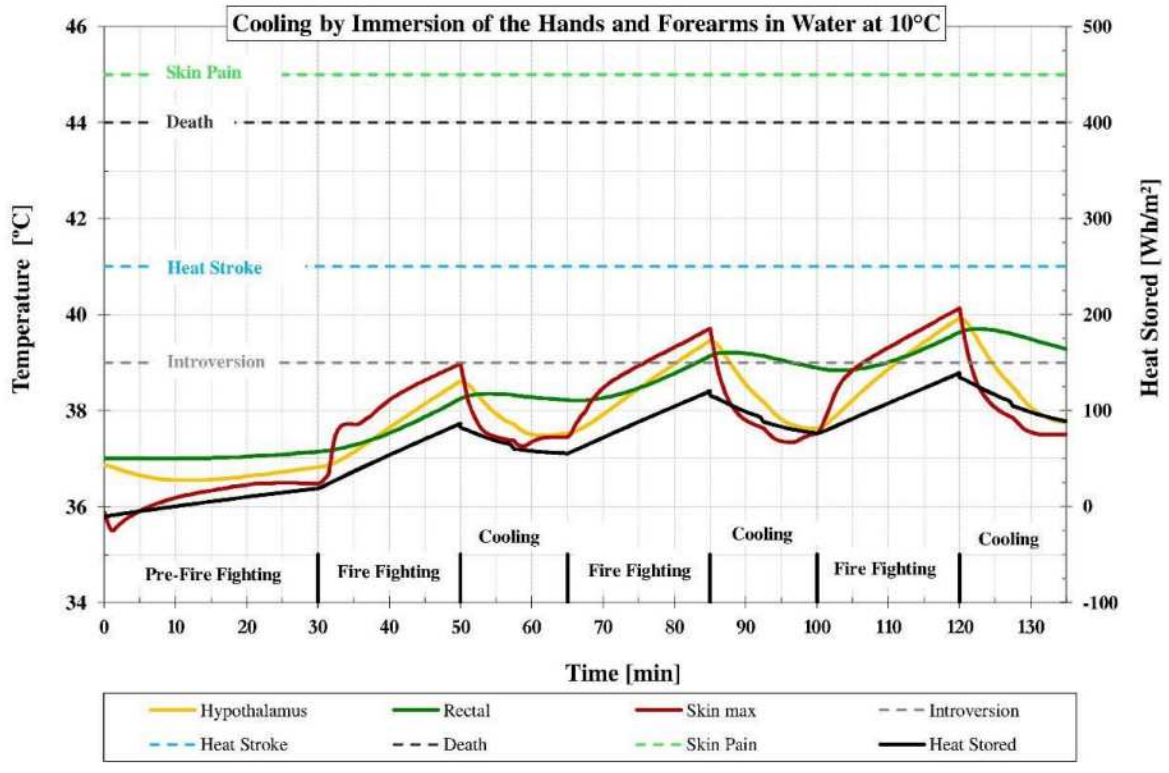

Figure 3. Evolution of firefighter thermophysiological state for low intensity incident radiation and cooling by immersion of the hands and forearms in water at 10°C.

As it can be seen in Figures 1 to 3, passive cooling for the conditions defined in this case proves to be a recovery strategy with a reduced efficacy when compared with the techniques of immersion of the

hands and forearms in cold water. The strategy of passive cooling (Figure 1) attenuates the heat stress felt by the firefighter but is not enough to prevent the rising of the hypothalamus temperature causing a decompensation to the thermoregulatory system, thus increasing the possibility of firefighter to come into introversion and even faint.

The cooling techniques by immersion of the hands and forearms have a greater efficacy and it would be expected that the lower the water temperature the higher the cooling produced, but it didn´t happened in an obvious manner. In some cases the cooling effects are higher when the water is at 20°C (Figure 2) than 10ºC (Figure 3). This is due to the fact that the temperature of the hypothalamus may not be high enough (slight degree of hyperthermia), thus the immersion of hands and forearms in water at 10ºC promotes the appearance of cold signals, then leading to the occurrence of vasoconstriction and shivering. The vasoconstriction reduces the body cooling rate and the shivering increases the internal heat production.

By other hand, the values of the rectal temperature and of the heat stored were lower and the cooling rate (ºC/min) is higher by applying the cooling technique of hands and forearms immersion in water at 10 ºC. So it can be stated that this is the most effective cooling technique for heat stress reduction on fighting fires where low radiation intensity impinges the firefighter.

Similarly to the previous case, Figures 4, 5 and 6 summarize the results previewed by the simulations for the evolution of the thermophysiological state of the firefighter during the protocol adopted, but now assuming he keeps a distance from the fire front resulting in a medium intensity of incident radiation and for the three cooling techniques considered.

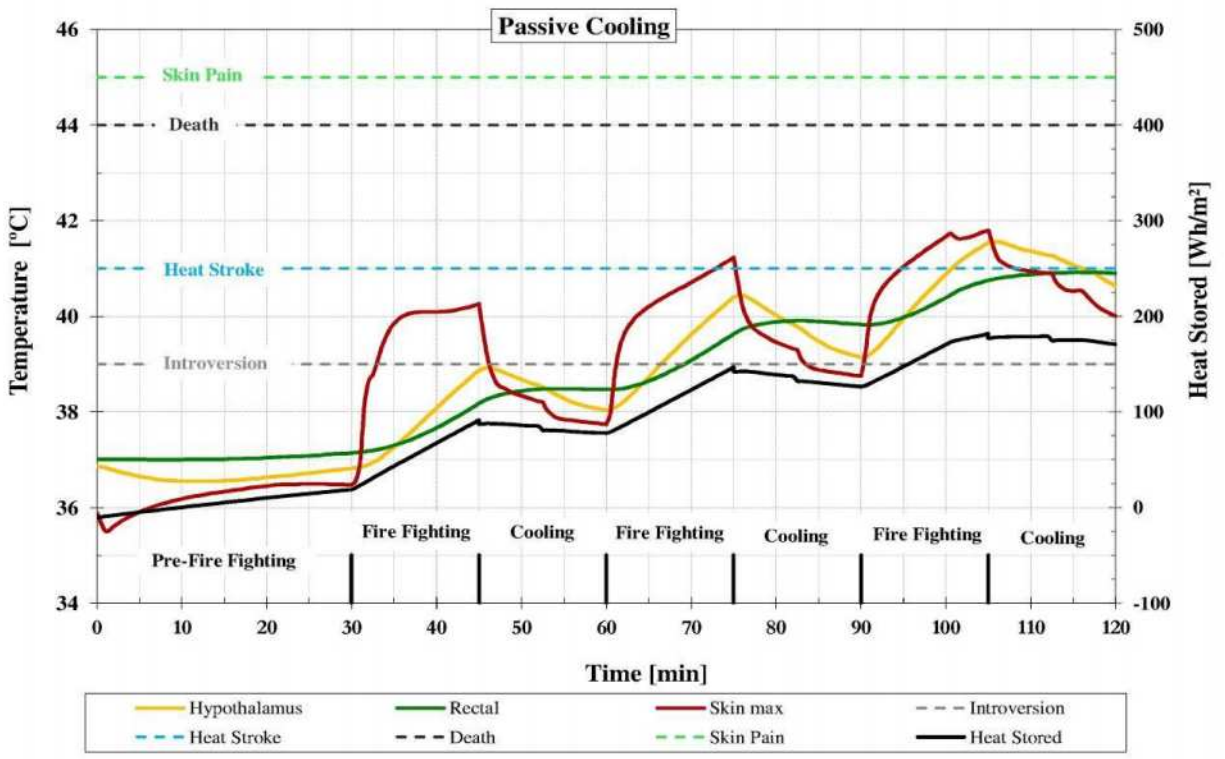

Figure 4. Evolution of firefighter thermophysiological state for medium intensity incident radiation and passive cooling recovery.

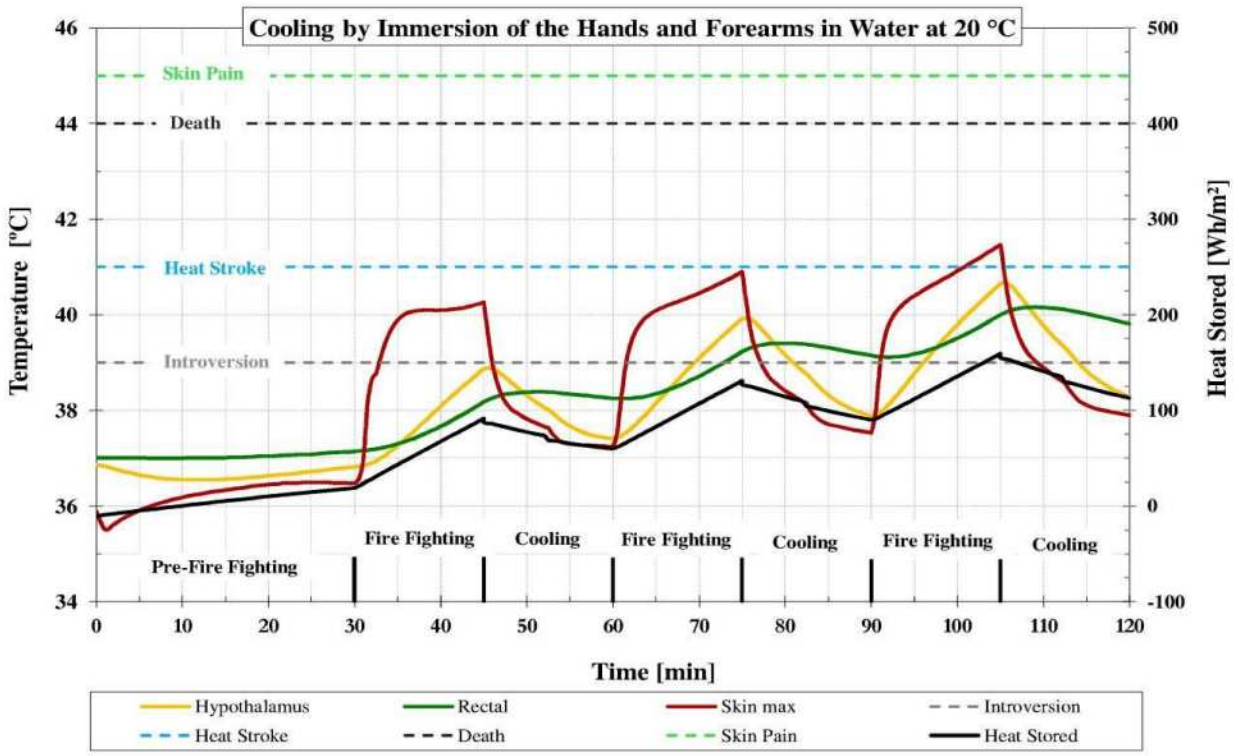

***Figure 5. Evolution of firefighter thermophysiological state for medium intensity incident radiation and cooling by** immersion of the hands and forearms in water at 20°C.*

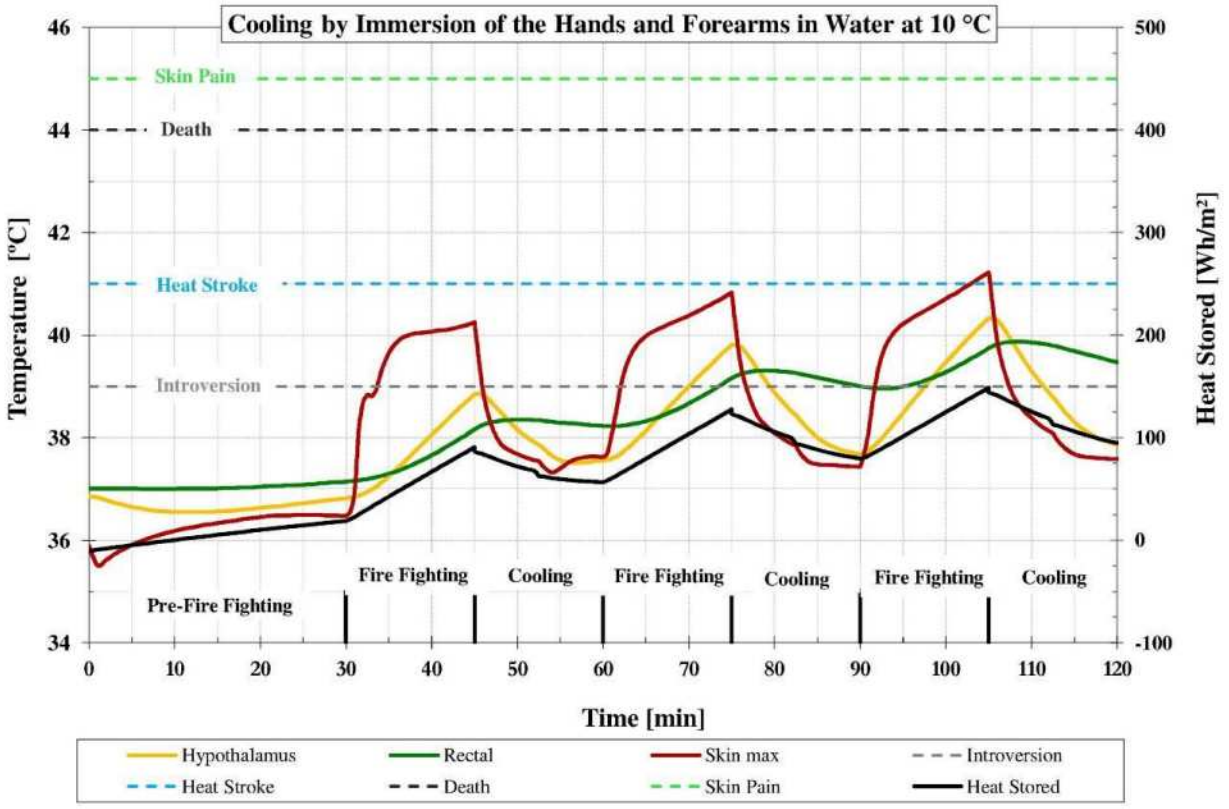

***Figure 6. Evolution of firefighter thermophysiological state for medium intensity incident radiation and cooling by** immersion of the hands and forearms in water at 10°C.*

Just like what happened in the previous case, the passive cooling (Figure 4) does not show results that allow us to state that this is an efficient solution for the attenuation of heat stress. This intensity of fire causes the hypothalamus temperature to rise 2°C for every 15 minutes of firefighting while the passive cooling technique can only lower this temperature 1°C for every 15 minutes of cooling. This generates a decompensation of the thermoregulatory system thus increasing the possibility of the firefighter to be affected by introversion or even by a heat stroke, which, if occurs, prevents the firefighter of getting out of the way of fire by himself.

The cooling techniques by immersion of members in cold water (Figure 5 and Figure 6) proved to be more efficient since they can provide a greater and faster reduction of hypothalamus temperature. After the entry of the firefighter in the state of introversion, they always succeeded to recover and restore the hypothalamus temperature within the range where thermoregulation occurs normally. Following the same trend previously verified the cooling technique with the immersion of hands and forearms in water at 10ºC (Figure 5) is the more efficient, even in spite of the occurrence of vasoconstriction in a first cooling phase. This is the body cooling technique which promotes the lower values for the temperatures (hypothalamus, rectal, skin max, etc.) and for the heat stored and guaranties the higher cooling rates (ºC/min). Then, also for the case of fire with a medium intensity of incident radiation this is the most effective technique in the attenuation of the heat stress.

Figures 7, 8 and 9 shown the results obtained with the simulations for the evolution of the thermophysiological state of the firefighter in the case when he is kept at a distance from the fire front leading to a high intensity of incident radiation.

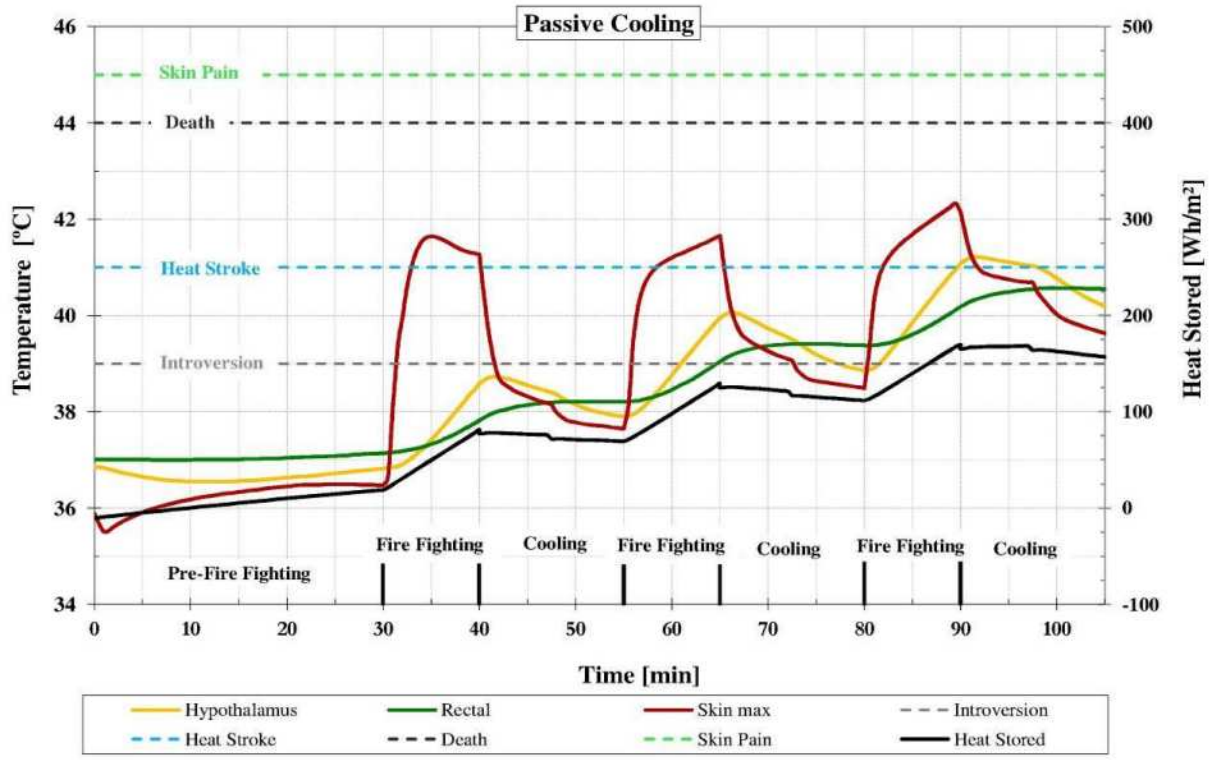

Figure 7. Evolution of firefighter thermophysiological state for high intensity incident radiation and passive cooling recovery.

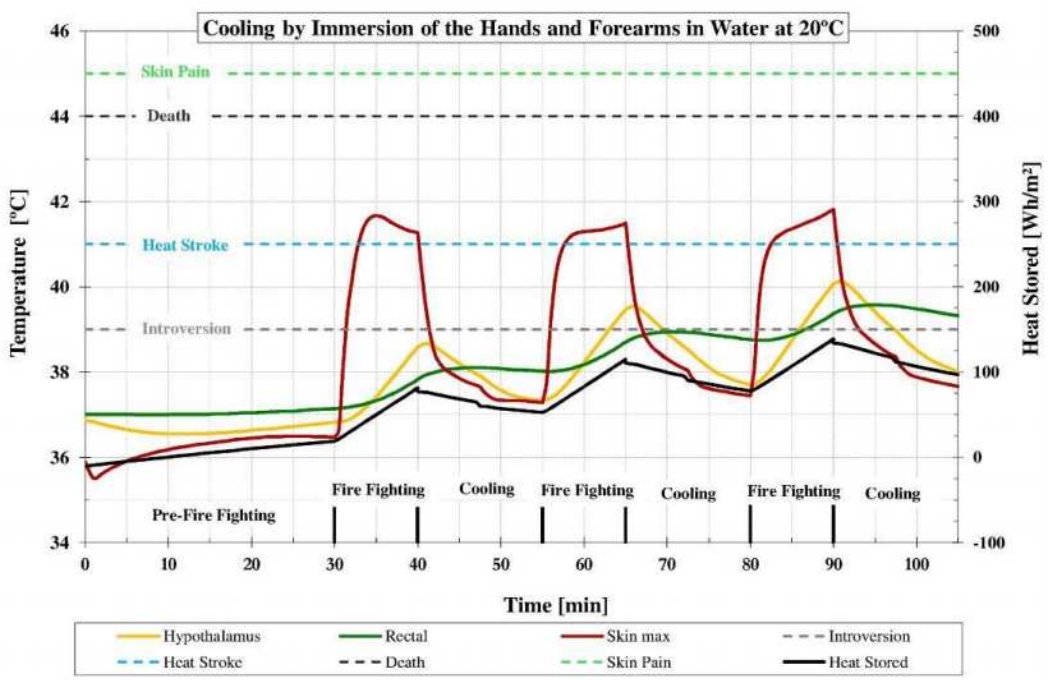

Figure 8. Evolution of firefighter thermophysiological state for high intensity incident radiation and cooling by immersion of the hands and forearms in water at 20°C.

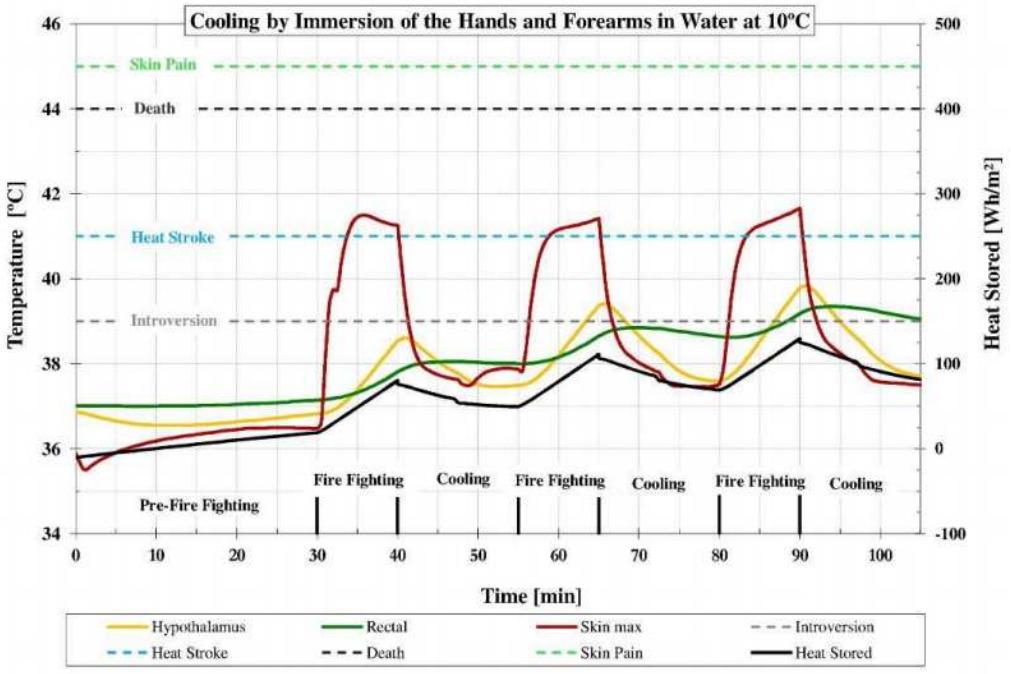

Figure 9. Evolution of firefighter thermophysiological state for high intensity incident radiation and cooling by immersion of the hands and forearms in water at 10°C.

Following the example in the analysis of the results obtained with the two types of fires previously seen, the technique of passive cooling (Figure 7) presents a decrease of hypothalamus temperature lower than those obtained through the cooling techniques by immersion of members in cold water. Otherwise, even if vasoconstriction occurred in the first cooling phase with water at 10 °C, this

technique turned out to be the most effective one in attenuating the heat stress for the same reason mentioned above in the other two cases.
In short, among the tested, the cooling technique of immersion of the hands and of the forearms in cold water at 10ºC proved to be the more efficient, even in spite of the occurrence of vasoconstriction (and in some cases shivering) in the first cooling phase. This is the body cooling technique which promotes the lower values for the temperatures (hypothalamus, rectal, skin max, etc.) and for the heat stored and guaranties the higher cooling rates (ºC/min).

Conclusions

During this work several aspects related to the activity of fighting fires, including the intensity of the impinging radiation on the firefighters, exposure time, pathologies related with heat stress and recovery strategies (active and passive) were explored.
The intensity of the incident radiation on the firefighters during the specific fighting phase, as well as the time of heat exposure are crucial for the occurrence of heat stress.
Among the simulated cases, it can be stated that the exposure time without affecting the physical integrity of the firefighter (hypothalamus temperature lower than 39ºC), decreases with the increasing of the intensity of the incident radiation in the fighting phase.
In relation to the cooling techniques, it was found that the body cooling by immersion of the hands and of the forearms in cold water is much more efficient than the passive air cooling, which is in good agreement with other results available in the literature.
In spite of causing vasoconstriction, and in some cases shivering, when the degree of hyperthermia is high, the strategy of body cooling by immersion of the hands and of the forearms in cold water at 10 ºC provides the best results in the attenuation of heat stress. Among the three body cooling techniques tested this was the one with the highest cooling rate (°C/min) and the lower values for the temperatures and for the heat stored in the human body. Then, this is the one that sustains the firefighter effectiveness during more time.

Consideration of an Empirical Model for Wildland Firefighter Safety Zones

B. Butler

USDA Forest Service, Rocky Mountain Research Station, Fire Sciences Laboratory 5775 W US Highway 10 Missoula MT 59808, USA bwbutler@fs.fed.us t:406 329 4801

Abstract
The term safety zone was first introduced into the official literature in 1957 in the aftermath of the Inaja fire that killed 11 firefighters. Since then identification of safety zones has been a primary duty of all wildland firefighters. Unfortunately, information regarding what constitutes an adequate safety zone is not well defined. Measurements of energy release from wildland fires have been used to develop an empirically based safety zone guideline. The proposed model is compared against past fire entrapments in North America. The comparison indicates that the empirical model does provide an extra margin of safety over most entrapments that are associated with injury or fatalities but it seems to underpredict the separation distance needed to meet the full definition of a safety zone.

***Keywords**: Fire behavior, prescribed fire, firefighter safety*

Introduction

Wildland firefighting by its nature is inherently dangerous. 699 wildland firefighters died in fire related accidents between 1910 and 1996 in the United States, 384 of those were directly related to fire entrapments (National Wildfire Coodinating Group 1997). Wildland firefighters must consider the risks to themselves and others when approaching, suppressing, and managing wildland fire and take action to minimize those risks (National Wildfire Coodinating Group 2004). The identification of suitable safety zones for firefighters during daily fire management operations is perhaps one of the most critical decisions made on wildland fires.
All wildland firefighters in the United States are required to identify safety zones when working on or near fire. Until1998 the regulatory agencies responsible for wildland fire management in North America did not provide any quantitative information about safety zone characteristics other than that proposed by Butler and Cohen (1998) which was subsequently included in the Fireline Handbook (National Wildfire Coodinating Group 2004). The safety zone guidelines are based on the assumption that the fire and safety zone were located on flat terrain. The minimum safe distance for a firefighter to be from a flame was calculated as that corresponding to a radiant incident energy flux level of 7.0 kW-m-2. This was determined to be the level at which exposed human skin will develop a 2nd degree burn in less than 90 seconds. An approximate correlation was derived from this model that indicated a minimum separation between the firefighter and fire should be equal to four times the flame height. For a circular safety zone this would be equal to the safety zone radius. When fires are burning on flat terrain, convective energy transfer is primarily upward in the plume while radiant energy transfer occurs out ahead of the fire front. Current firefighter safety guidelines are based on the assumption that radiant energy transfer is the dominant energy transfer mode. Measurements have verified the accuracy of this assumption but have also indicated that when fires are burning on slopes or under the influence of wind convective energy transfer ahead of the fire front can be significant. Intuition, professional observations, and experimental measurements indicate that when fires are located on slopes or ridges or are burning with a strong wind convective energy transfer may reach distances two to four or more flame lengths ahead of the fire front. This implies that the current safety zone guidelines may be invalid in some situations. It is also clear from site visits to designated safety zones on

numerous wildland fire incidents that considerable ambiguity exists regarding identification or creation of true 'safety zones,' versus 'deployment zones.'
Measurements of energy release from fires have been gathered from a range of ecosystem and vegetation types. The data were used to calculate the distribution of energy in and around those flames (Frankman *et al*. 2012a). Measurements and analysis of fires and safety zones on flat terrain showed that the current safety zone guidelines were adequate with the assumption that both the fire and safety zone were on flat terrain. Additional guidelines were developed that related safety zone size in acres to flame height in feet and to account for changes in safety zone size necessary to accommodate equipment and multiple personnel. When the influence of slope on fire intensity and spread is considered, the current safety zone guidelines that were designed for flat terrain and low wind clearly become inadequate. With this need in mind efforts have focused on measuring energy release from fires burning in natural conditions. While a very small subset of the data collected corresponds to fire on slopes, the data suggest a potential safety zone rule that encompasses all terrain and weather conditions as a function of vegetation type. These measurements are analysed to propose an empirically based firefighter safety zone rule.

Methods – Energy Measurements

Definition of a firefighter safety zone requires determination of the fire energy source strength; calculation of burn injury as a function of heating magnitude and duration; and estimation of safe separation distance (SSD) from the fire to prevent injury.
Energy is transported from wildland fires primarily by two heating modes: 1) radiative energy transport (Albini 1986; Viskanta 2008) and 2) convective energy transport (Yedinak *et al*. 2006; Anderson *et al*. 2010). Some cases exist where radiation dominates fire energy transport, for example a fire spreading through grass in the absence of wind would seem to be driven by radiant heating ahead of the flaming front, or a large crown fire with minimal ambient wind would also be characterized by primarily radiant heating although in both cases it is difficult to separate the radiant heating from the advective influence of lofting and ignition from burning embers that act as ignition pilot sources (Albini 1986). Logically, convective heating should also play a critical role in fire spread, for example a fire burning through grass in the presence of a very strong ambient wind where the wind causes the flames to reach ahead of the burning front preheating vegetation far in advance of the fire through direct contact between the flames and unignited fuels. In this case convective energy transport would dominate energy transport and fire spread. Recent measurements support this (Yedinak *et al*. 2010; Frankman *et al*. 2012a).
Safety zone studies have assumed that radiative heating is the primary heating mode (Butler and Cohen 1998; Zarate *et al*. 2008; Rossi *et al*. 2011). Various methods have been used to measure radiant energy release from wildland flames. Butler (1993) describes a simple radiometer. Packham and Pompe (1971) measured radiative heat flux from a fire in Australian forest lands. Heating reached 100 kW m-2 when the flame was adjacent to the sensor and 57 kW m-2 when the sensor was a distance 7.6 m from the flame (King 1961), no description of flame dimensions were provided. Butler *et al*. (2004) presented temporally resolved irradiance measurements in a boreal forest crown fire burning primarily in jack pine (Pinus banksiana) with an understory of black spruce (Picea mariana). Irradiance values reached 290 kW m-2, flames were 25 m tall, and fire spread rates were nominally 1 m s-1. Morandini *et al*. (2006) measured time-resolved irradiance values from flames burning in 2.5 m tall Mediterranean shrubs (Olea europea, Quercus ilex, arbustus unedo, Cistus Monspeliensis and Cytisus triflorus). Radiative heat fluxes peaked at 1, 2.2 and 7.8 kW m-2for distances to flames of 15, 10 and 5 m respectively. Silvani and Morandini (2009) measured time-resolved radiative and total heat fluxes incident on the sensor in fires burning in pine needles and oak branches. For the burn conducted on a slope of 36% with flame heights of 5.6 m the peak radiative and total heating at the sensor were 51 kW m-2 and 112 kW m-2 respectively, implying that convective heating was nominally of the order

of the radiative heating. Frankman *et al*. (2012a) report measurements from fires burning in a variety of vegetation and terrain. Irradiance from two crown fires burning in lodgepole pine (Pinus contorta) peaked at 200 and 300 kW m-2 respectively with flames reaching 30 m, convective fluxes were 15 to 20% of the peak radiative fluxes. Peak irradiance associated with fires in grasses and leaf and pine needle litter in southern longleaf pine (Pinus palustris) reached 100 kW m-2 with a mean value of 70 kW m-2 for flames nominally 2 m tall, convective heating were equal to or greater than the radiative flux. Fires burning in sagebrush (Artemisia tridentata subsp. Wyomingensis) dominated ecosystems generated peak radiant energy fluxes of 132 kW m-2 with a mean value of 127 kW m-2 for flames less than 3 m tall, peak convective heating was 20 to 70% of the radiative heating magnitudes on slopes of 10 to 30%. Napier and Roopchand (1986) report an average incident radiant flux of 7.5 kW m-2 159 m away from LNG flames 80 m tall and 31 m in diameter. Measurements incidate that flame increases nearly monotonically with approach of the flame front and declines exponentially with its passage. Irradiance beneath crown fires peaks at 300 kW m-2, peak irradiance associated with fires in surface fuels reaches 100 kW m-2 with a mean value of 70 kW m-2; the peak for fires burning in shrub fuels was 132 kW m-2 with a mean value of 127 kW m-2.

Recent measurements of convective energy transport have shown that instantaneous peak convective energy fluxes inside flames may significantly exceed the radiant fluxes although convective heating based on 2 s moving averages are nominally 70% of similarly averaged radiant heating values (Frankman *et al*. 2012b). Measurements of flame geometry ahead of a spreading fire front suggest as slope exceeds nominally 30% flames begin to attach to the surface and high temperature gases are convected along the slope (Viegas 2004). Crown fires in lodgepole pine (Pinus contorta) resulted in 2 second averaged convective fluxes from 15 to 20% of the peak radiative fluxes. However, fires in surface fuels characteristic of a southern longleaf pine (Pinus palustris) ecosystem showed convective heating equal to or greater than the radiative flux. Fires burning in sagebrush (Artemisia tridentata subsp. Wyomingensis) or similar shrub dominated ecosystems produced peak convective heating 20 to 70% of the radiative heating magnitudes.

Results

It is commonly believed that radiant energy decays as the inverse of the square of the distance away from the source. This is based on energy transport theory and ideally holds true. While it is somewhat arbitrary, the data collected as part of this study were grouped according to the vegetation and fire type (i.e. grass, brush, moderate intensity crown and high intensity crown). Measurements of total incident heating are plotted below and compared to the ideal decay model (Figure 1). Clearly the correlation is not entirely accurate. It appears that "real" wildland flames do not necessarily represent ideal flame models. Logically departure from theoretical flame behavior can be attributed to three primary factors: 1) absorption of energy by water vapor and carbon dioxide in the atmosphere, 2) convective energy transport away from the fire, and 3) varying temperature and emissivity of the flame. The implications from these data are that the 1/r2 rule (which theoretically applies to radiative heating) does not seem to apply to total energy transfer from fires suggesting that convective energy transport extends the distance over which heating from the flames occurs. In the context of firefighter safety zones, these results suggest that convective heating can be a significant contributor to energy transfer from fires.

Figure 2 presents energy levels as a function of vegetation type which is intended to be a surrogate for fire intensity. The burn injury threshold of 7 kW m-2 is displayed in both graphs. Based on these groupings, the decay in intensity with distance can be simulated using a model of the form q=m/rn where (q) is incident heating level at distance (r) from the flame, (m) is a constant, and the exponent (n) is 0.75 for these data. The values for (m) scale nominally with the observed peak total heating values measured in each grouping, the exponents (n) were held constant. The largest discrepancy between this model and the data occurs for the moderate intensity crown fire data. These data are based on measurements over a range of topographical and vegetation types. Also the arbitrary nature of the

grouping could alter the results. However, there is some intuitive comfort derived from the correlation between peak total heating values and the constant multiplier values.

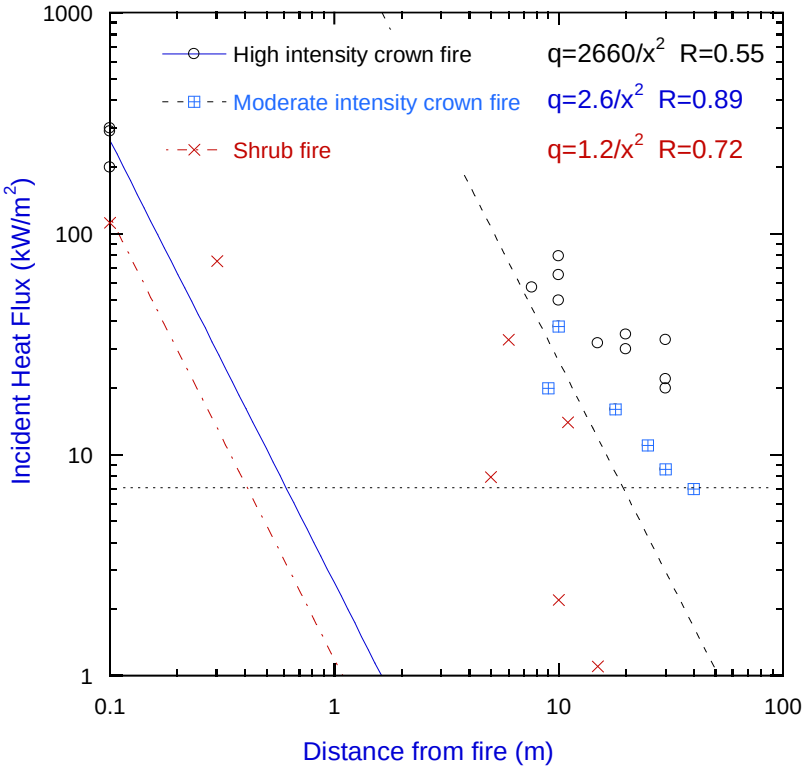

Figure 1—Comparison of measurements to inverse squared law.

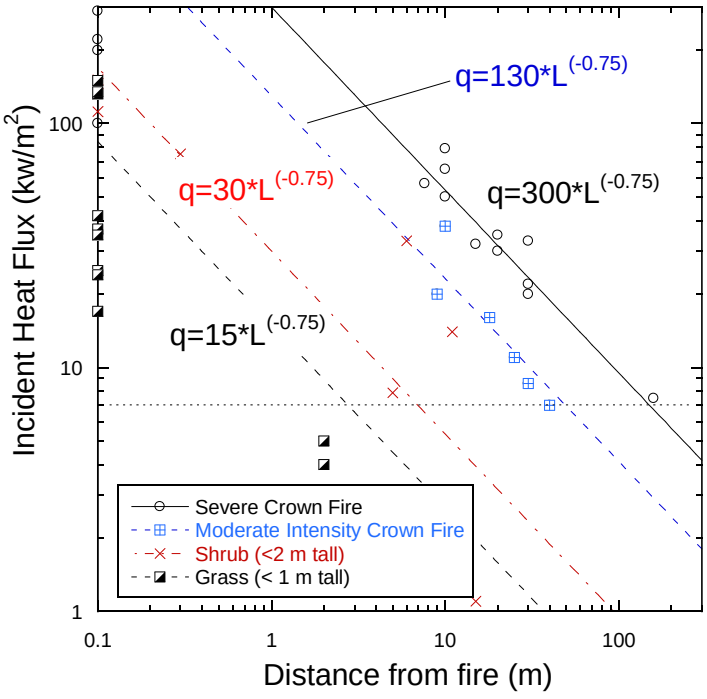

Figure 2-- Exponent based models for energy decay with distance for wildland fires.

Four heating regimes are identified for these data. The lowest being that associated with fire in grass vegetation (nominally less than 1 m tall). The measurements are best fit by a line defined as q=15/L0.75 where L is the distance between the receptor and the fire. The next highest heating level is associated with shrub vegetation similar to sage brush. Nominally 1 to 2 m tall. The best fit for heating level as function of distance from flame is q = 30 / L0.75. For taller shrubs (e.g. gamble oak or other shrubs 2 to 5 m tall) or low intensity crown fires the fit is q = 130 / L0.75. Finally when considering the most intense fires such as those typically associated with forest crowns the best fit is q = 300 / L0.75. The horizontal dashed line represents the level at which second degree burn injury will occur in roughly 30 to 60 seconds. Logically the point at which the best fit for energy distribution crosses the burn injury limit would represent the minimum distance required from a fire in the particular vegetation type to prevent injury. Based on these data a rule for SSD that is dependent only on vegetation type is proposed. The rule is based on extrapolating vertically downward from the intersection of the line corresponding to each fire (or vegetation) type and the burn injury limit of 7 kW m-2 to the horizontal axis. The intersection with the horizontal axis would be the distance from the fire necessary to maintain an exposure below the burn injury limit. Thus for the highest intensity crown fires nominally 105 m is required, for moderate intensity crown fires or fire in 2 to 5 m tall shrubs the minimum distance is 60 m, for fires in 1 to 2 m tall shrubs or tall grass the minimum distance is 8 m and for fires in grass less than 1 m tall the minimum separation distance is 3 m. This approach includes wind and slope implicitly in the data set. There is no direct accounting for steep slopes or strong winds. Additionally only a few data points were collected in steep terrain or windy conditions, thus this empirical model does not have a strong slope or wind component.

Butler (2014) evaluates safety zones for selected firefighter entrapments over the past 70 years in the United States. Figure 3 compares entrapment data presented in that study as well as a few other entrapments in the context of the empirical SSD model for the entrapments. Table 1 summarizes the entrapment incident details. The data indicate that for all but two fire incidents the empirical model suggests a larger SSD is required. In most cases the difference between the actual SSD and the suggested SSD is significant (for example consider the Mann Gulch, Inaja, Dude, Thirtymile, Cramer, and Yarnell Hill fires). The suggested SSD is significantly larger than the actual SSD. All of these are associated with fatal entrapments. However the Blackwater, Butte, South Canyon-II deployment are fires where firefighters deployed fire shelters, or in the case of the Blackwater fire took evasive action and survived, albeit in some cases very uncomfortably. The Butte fire and South Canyon-II entrapments had actual SSD greater than that specified from the empirical model. In the Butte fire incident, firefighters deployed aluminium fire shelters in a prepared safety zone. They had to move from one side of the clearing to the other as the fire burned around the area. In the South Canyon-II entrapment, 8 firefighters deployed on a rocky ridge nominally 160 m from the primary vegetation (Gambel Oak). At no time did they feel threatened in their shelters and some indicated they believe they would have been safe without the shelters. These two incidents suggest that the empirical model seems to underpredict the minimum distance needed.

The empirical model is attractive from the standpoint that it is simple to memorize and apply, it does not require that the firefighter visualize the fire behaviour, and can be applied quickly. But it does not consider slope or wind both of which are considered shortcomings in the present safety zone rule applied in the United States. These shortcomings might be the reason why there are some fires where the proposed SSD was lower than the actual SSD (i.e. Butte, and South Canyon-II).

Table 1—Fire incident details

Incident	Fatalities	Injuries	Vegetation	Vegetation Ht (m)	Flame Ht (m)	Actual SSD (m)	Actual SSD/Flame Ht	Empirical SSD/Flame Ht
Blackwater		36	Timber	25	80	30	0.37	1.3
Mann Gulch	13	1	Timber	20	10	13	1.3	10
Inaja	11		Shrub	8	12	5	0.42	3.3
Loop	10	12	Brush	6	10	15	1.5	5.0
Battlement Mesa	3	1	Brush	5	14	5	0.36	3.6
Butte		73	Timber	30	70	125	1.8	1.4
Dude	6		Timber	15	50	5	0.10	2.0
So Can-I	14		Brush	5	29	2	0.069	1.7
So Can-II		8	Brush	5	29	160	5.5	1.7
30-mile	4	12	Timber	25	50	5	0.10	2.0
Cramer	2		Timber	20	30	3	0.10	3.3
Esperanza	5		Brush	5	20	10	0.50	2.5
Yarnell Hill	19		Brush	5	30	5	0.17	1.7

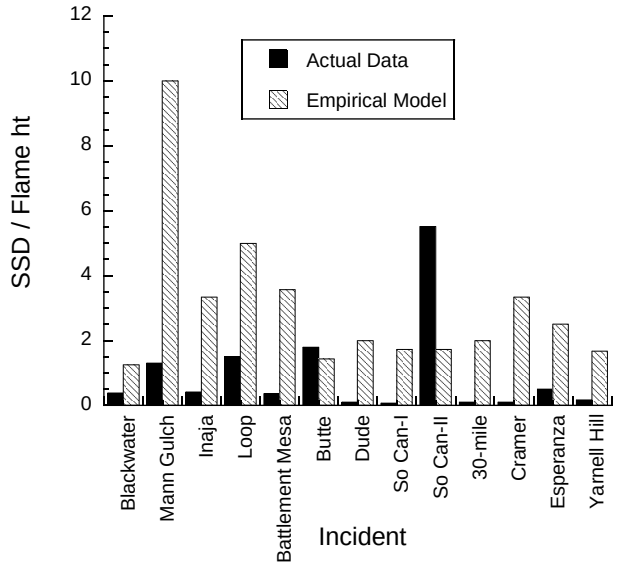

Figure 3—Comparison of actual entrapments and empirical safety zone SSD model.

Conclusions

Many questions remain regarding how energy is generated and released from wildland flames and the implications of energy distribution on safety zone effectiveness. It is only recently that measurements have identified the range of heating magnitudes that can be expected from wildland flames. The prediction of fire behaviour, especially during dynamic fire operations can be very difficult even with access to sophisticated computer models and hardware. Current studies suggest that heating levels of 6 to 7 kW m-2 generally represent burn injury limits, however a more appropriate metric is thermal dosage unit that includes both heating magnitude and exposure time (Butler 2014). Comparison between a selected set of fire entrapments and the empirical model derived from the data presented here suggests that the empirical model suggests SSD on the order of the current guideline based on earlier work (Butler and Cohen 1998). Intuition, professional observations, and the few experimental measurements that have been reported indicate that when fires are located on or adjacent to slopes or

ridges or are exposed to winds convective energy transfer may reach distances equal to 2 to 3 or more flame lengths ahead of the fire front (Frankman *et al*. 2012a). This implies that the empirical model may underestimate SSD in some situations. This conclusion is supported by the comparison to fire entrapments. Recent measurements suggest that in the context of wildland firefighter safety zones on slopes an accurate accounting of energy transport requires consideration of both convective and radiative heating. The inclusion of convective heating implies that slope steepness, ambient wind, and safety zone geometrical location relative to terrain slope are all relevant.

Acknowledgements

This work could not have been accomplished without the financial support provided by the Joint Fire Sciences Program, as well as support from fire managers in the Bureau of Land Management and the National Park Service when we were deploying sensors in and around fires. We also acknowledge the enthusiastic support from many fire crews, as well as forest service district, and forest staff.

Abstract
Eruptive fires are one of the main causes of human losses in forest fire fighting. This phenomenon is fairly rare, unpredictable and thus extremely dangerous for firefighters (or civilians). Many casualties result from several accidents identified in the last fifty years around the world. Indeed, people involved in fire fighting activities are not prepared for facing such an unpredictable phenomenon. Very few literature is available to support either modelling or occurrence prediction for this phenomenon. Eruptive fire behaviour usually describes an extreme case of dynamic fire behaviour in which a sudden increase of the fire front rate of spread (ROS) in a short lapse of time is observed. So the question of predicting an eruption's occurrence is a crucial point for the fire fighters' safety. In this study, it is assumed that the eruption is due to physical considerations. The mechanism responsible for this erratic behaviour is the pioneering interpretation proposed by Viegas (2005) which consists in a feedback between the ROS and a convective air flow created by the fire itself. A physical modelling for this "induced wind" is given and is coupled with a simplified physical propagation model for surface fires. If the solution of the coupled system usually converges, it may diverge under certain conditions, leading to a fire eruption. It is then possible to obtain a physical condition which gives the impossibility (or not) for a fire to turn into an eruptive fire and the model is able to predict the occurrence of a fire eruption according to the triangle of fire. The model is tested by comparing its numerical results on the one hand to a set of experiments carried out at laboratory scale and on the other hand to an outdoor wildfire (Kornati accident).

Keywords*: Eruptive fire, fire spread, physical model, prevention, eruption's occurrence*

Introduction

The term 'blowup' used in wildland fires by Butler *et al*. (1998) indicates a rapid change from a low intensity surface fire to a high fire burning through the whole vegetation complex, from surface to canopy and demonstrates dramatically larger flame heights, higher energy release rates and rates of spread that are faster than usual fires. As this work focuses on the acceleration of surface fires, the designation of fire eruption proposed by Viegas (2005) is used and describes the sudden change in rate of spread of the head fire and in energy release within a very short lapse of time. Viegas and Simeoni (2011) reviewed the mechanisms (physical or chemical considerations, variation of external conditions, etc…) that are described in literature to explain the onset and development of fire eruptions. The major part of these diagnoses are refuted by examples of real fires occurred in the past. Among all these explanations, the pioneering interpretation proposed by Viegas (2005) must be highlighted. Actually, it is based on the coupling of the own properties of the spreading fire with other conditions (wind, topography) and consists in a feedback effect caused by the convective flow induced by the fire in the presence of wind or/and a positive slope. The fire creates an 'induced wind' which transports oxygen to the reaction zone which intensifies the combustion process and consequently flame length and ROS. So the reaction needs more and more ambient air. This feedback process will increase continuously and the ROS could reach very important values if it is not inhibited by some external mechanisms. This strong air flow movement was proved at the laboratory scale by Viegas and Pita

(2004) and observed at the field scale (Viegas *et al*. 2002). Moreover, the testimony of the one fire fighter who survives the Kornati fire accident (Stipanicev and Viegas, 2009), the meteorological measures of the wind speed during the freixo accident (Viegas 2005) are clear evidences of the importance and the relevance of the induced wind. Viegas (2005) suggested a mathematical model (constituted by a non linear differential equation) that predicts the fast increasing of the ROS. One can also cite the model developed by Dold *et al*. (2011) in which the phenomenon is the result of a flow attachment and the ROS is assumed to vary as a power-law of the fireline intensity. If these empirical models can reproduce the fire behaviour during the eruption, they do not predict the eruption's onset and to our knowledge, such a model does not exist.
This work focuses on the existence of a condition for predicting either extreme or usual fire behaviour. A physical modelling of the induced wind is coupled with the simplified physical propagation model for surface fires developed at the University of Corsica (Balbi *et al*. 2007, 2009, 2010). In some cases, this coupling can diverge, leading to a fire eruption's onset.

Equations of the simplified physical propagation model

As some authors (*e.g*. Albini 1985, Telisin 1974, Van Wagner 1967) assumed that radiation was the dominant process in the contribution of heat to unburnt fuel, the propagation model developed at the University of Corsica (Balbi *et al.* 2007) was only based on radiation. It was elaborated to be as complete as possible with regard to the equations that govern fires, whilst also being computationally cheap. To this end, the use of partial differential equations was avoided because of their associated long calculation times and also because of the difficulty of making a sensitive study of the fire behaviour with respect to the different parameters involved (e.g. environmental, topographic, or fuel bed properties). This model was later improved and successfully confronted to sets of experiments at the laboratory scale with aligned slope and wind and at the field scale (Balbi *et al.* 2009) or confronted to the set of experiments conducted by Viegas (2004a) where slope and wind are not aligned. The improvements brought by Chatelon *et al.* (2010) or Marcelli *et al.* (2011) have changed the propagation model into a complete fire behaviour model in which rate of spread (ROS), flame tilt angle, flame temperature, flame length, radiant fraction and vertical velocity due to buoyancy are given.
The two main algebraic equations of the model are the following:

$$\tan\gamma = \tan\alpha + \frac{U}{u_0} \quad (1)$$

$$R = R_b + R_f \quad (2)$$

Equation (1) gives the flame tilt angle γ depending on the slope angle α, the normal component of the wind velocity U and the upward gas velocity u_0. Equation (2) provides the ROS R as a function of the two radiative contributions from the flame (R_f) and from the burning fuel bed (R_b). These contributions are obtained by considering the flame and the base of the flame as grey radiant panels:

$$R_b = \frac{e}{\sigma}\,\frac{B\,{T_b}^4}{C_p\Delta T + m\Delta h} \quad (3)$$

$$R_f = A\,R\,\frac{1+\sin\gamma-\cos\gamma}{1+\frac{R\cos\gamma}{r_0}} \quad (4)$$

where C_p denotes the specific heat of the vegetative fuel, B the Stefan-Boltzmann constant, m the fuel moisture content, Δh the heat of latent evaporation, σ the fuel load, e the fuel bed depth, T_b the fuel burning particles temperature and $\Delta T = T_i - T_a$ the difference between ignition temperature and ambient

air temperature. The coefficient r_0 is a ROS factor that can be expressed as a function of the surface area to volume ratio of the fuel elements (Chatelon *et al.* 2010).
The coefficient *A* in equation (4) involves flame radiation. It represents the magnitude of the flame radiation related to the ignition energy. Its expression given in equation (5) depends on the heat of combustion of the pyrolysis gases ΔH, a radiant factor χ_0, the absorption coefficient ν and a corrective term *Y* to the view factor introduced by Koo *et al.* (2005) in order to improve Pagni and Peterson's model (Pagni and Peterson 1973). This term *Y* depends on dynamic fire parameters (ratio between fire front width *W* and flame length *l*).

$$A = \nu \frac{\chi_0 \, \Delta H}{4\left(C_p \Delta T + m \Delta h\right)} \, Y \qquad (5)$$

This model was successfully used to model several laboratory experiments (e.g. Guijarro *et al.* 1997, Mendes-Lopes *et al.* 2003, Viegas 2004b) and applied to some field-scale fires (e.g. McArthur 1969, Cheney and Gould 1995, Fernandes 2001). As this model is a steady-state model, it cannot reproduce a fire eruption which is an unsteady phenomenon (Viegas 2005, Dold and Zinoviev 2009). Thus a sub-model which describes the effect of the induced wind defined by Viegas (2005) has to be added.

Induced wind modelling

Under slope and weak wind conditions, the fire creates an induced airflow U_i in order to compensate the draught caused by the hot gases moving upwards. Considering a positive slope, the airflow comes from both sides of the fire front but only the airflow coming from the burned zone enters the flame. Indeed, the flame geometry causes an important deviation of the trajectory of the fresh air stream coming from the unburnt zone. So, the induced wind velocity under the flame is assumed to be practically zero. Consequently, there is no indraft at the fire front. On the other hand, the airflow coming from the burned zone is only slightly deviated, particularly near the ground, as it gets into the flame and supplies the reaction zone with oxygen.
Viegas and Pita (2004) clearly showed the presence of induced wind at the laboratory scale. Their experiments consisted in measuring the fire spread in canyons, using a combustion table with two inclined faces in order to create a canyon geometry. A first set of experiments in opened canyons showed a very fast spreading fire, which can be considered as eruptive. When the induced-wind was inhibited by a plate placed across the base of the canyon, the spread was much slower and the fire never showed an eruptive nature.
At the field scale, the Freixo de Espada-a-Cinta accident reported by Viegas (2004c) is a good example of the presence of an induced wind. Indeed, when the fire reached the base of a canyon, it was given as practically extinguished and the wind was blowing from the northwest in a downslope direction with a velocity on the order of 15 km/h. Suddenly, the wind turned to south-southwest, which is approximately the upslope direction and rose to 65 km/h 30 minutes later, with gusts up to 96 km/h. These data were retrieved by a meteorological station located on top of the ridge that was located in the spreading direction of the fire front. They clearly showed the impact of the induced wind because no other atmospheric phenomenon can explain this eruption.
The induced wind formulation is derived from a simplified mass balance based on the geometrical flame characteristics between the top of the vegetal stratum and the mid-height flame. The equality between inflow and outflow can be written as:

$$\rho_a \, \frac{H}{2} \, U_i = \rho \, \frac{L}{2} \, u \, \cos\alpha \qquad (6)$$

where U_i is the self induced wind, ρ is the combustion gases density, ρ_a is the ambient air density, *L* is the flame depth, *H* is the flame height and *u is* the upward gases velocity with slope (see Figure 1).

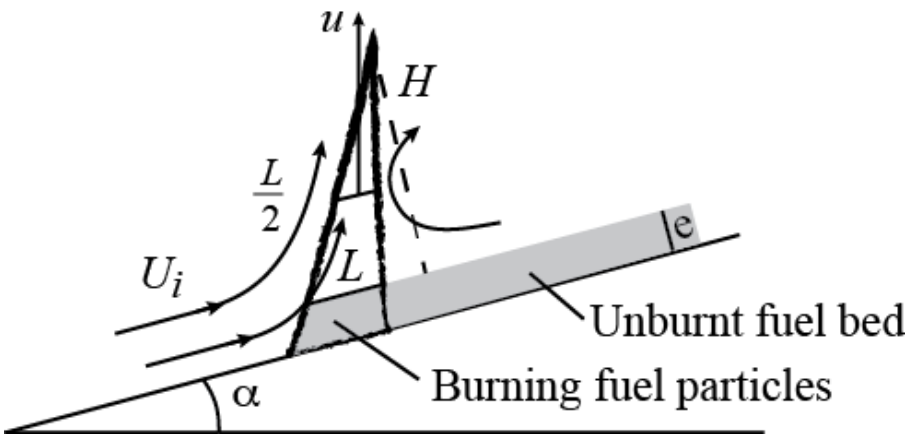

Figure 1. Qualitative description of the flame geometry.

Using the relationship $u = \frac{u_0}{\cos\alpha}$ (Balbi *et al.* 2009), the ratio between induced wind (U_i) and upward gases velocity at mid-height flame (u_0) is

$$\frac{U_i}{u_0} = \frac{\rho}{\rho_a}\frac{L}{H} = \frac{\rho}{\rho_a}\frac{R\,\tau}{H} = \frac{R}{p} \tag{7}$$

where τ is the flame residence time and

$$p = \frac{T}{T_a}\frac{H}{\tau} = 2\,\frac{\chi_0\,\Delta H\,\rho_v\,v\,r_0}{B\,T_a\,T^3\,\tau_0} \tag{8}$$

with the flame height given by Marcelli *et al.* (2011)

$$H = \frac{2\chi_0\Delta H\,\rho_v v r_{00}}{BT^4} \tag{9}$$

The flame residence time τ in equation (8) is expressed by using the relationship provided by Anderson (1969): $\tau = \tau_0 / s$ with τ_0 = 75591 m^{-1}·s. This time is inversely proportional to the fuel surface area to volume ratio *s*. Notice that this relationship is currently used in BEHAVE (Andrews 1986) in operational conditions. Using equation (7), the relationship (1) is changed in

$$\tan\gamma = \tan\alpha + \frac{R}{p} \tag{10}$$

Finally the fire spread behaviour taking into account the self-induced wind, is obtained by solving the following system:

$$R = p(\tan\gamma - \tan\alpha) \tag{11}$$

$$R = R_b + A\,R\,\frac{1+\sin\gamma-\cos\gamma}{1+\frac{R\cos\gamma}{r_0}} \tag{12}$$

The safety condition

In the coordinate system (tan γ, *R*), the steady solutions of the model are defined as the intersection of the growing function given by equation (12) and the straight line given by equation (11). Chatelon *et*

al. (2010) have showed that equation (12) exhibits two different behaviours for the ROS depending on the value of the coefficient *A*. Indeed the ROS *R* given by equation (12) is always a growing function which presents an horizontal asymptote when *A* is smaller than ½ and an affine asymptote (whose slope denoted by p_∞ is equal to $r_0(2A\text{-}1)$) otherwise (see figure 2).

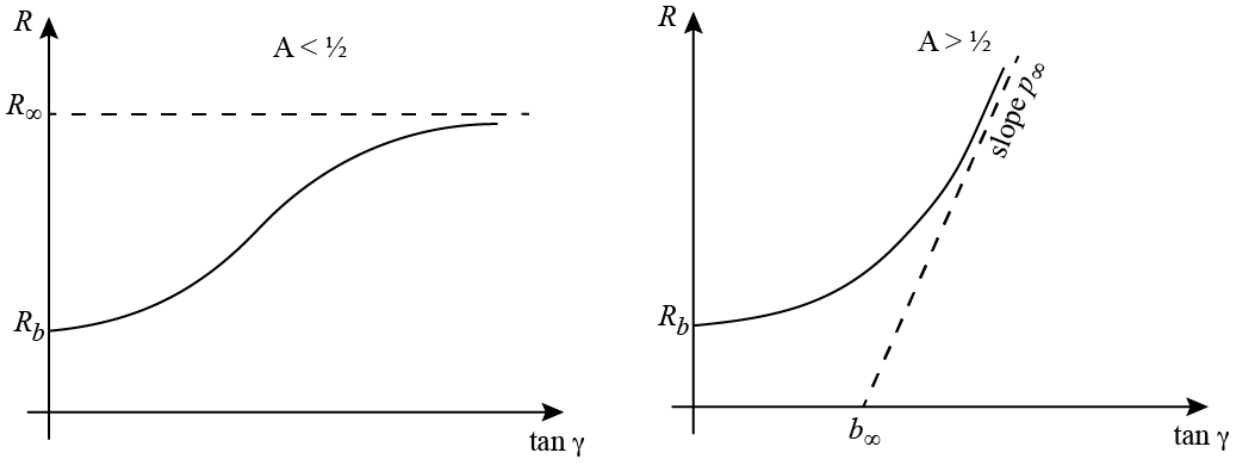

Figure 2. Qualitative illustration of the different rate of spread behaviours as a function of the flame tilt angle according to the value of the coefficient A.

A qualitative graphic analysis leads to several different cases, according to the values of the slope angle and the coefficients *A* and *p*:

- When $A < ½$, at least one solution of the system (11-12) always exists and is finite due to the horizontal asymptote exhibited by the ROS given by equation (12). So a fire eruption is impossible because the ROS cannot go to infinity. (see left side of figure 3)
- When $A > ½$, if *p* is greater than p_∞, the intersection of the ROS given respectively by equations (11) and (12) always exists. Its value may be great (when the slope is steep) but is always finite. So the fire never erupts (right side of figure 3).
- When $A > ½$, if *p* is smaller than p_∞, a fire eruption is possible but not sure. It depends on the value of the terrain slope angle. When α is greater enough, fire inevitably erupts.

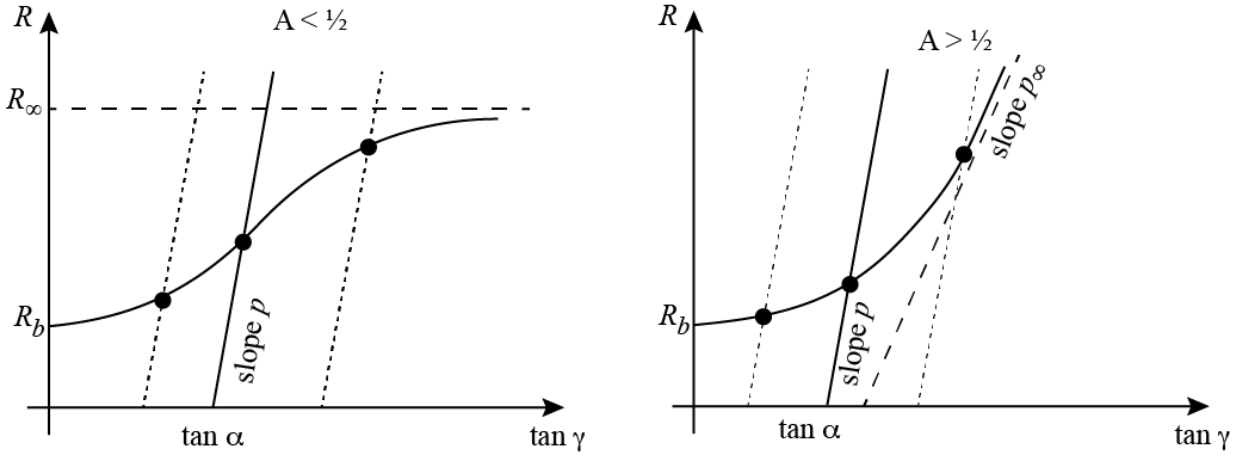

Figure 3. Qualitative illustration of the intersection of equations (11-12) when coefficient A is smaller than ½ (left side) and when A is greater than ½ (right side).

Consequently, two safety conditions with regard to fire eruptions can be expressed. The first one, i.e. $A < ½$ is usually obtained when the fuel bed arrangement is well ordered (e.g. with vertically-oriented fuel particles at the laboratory scale) or when the number of gaps in the vegetal stratum is very important (at the field scale). This condition is rarely satisfied when facing an eruptive fire.
Using equations (5), (7) and the expression of p_∞ previously given, the second condition i.e. $A > ½$, $p > p_\infty$ leads to the following ratio

$$\left(\frac{p}{p_\infty} = \frac{\rho_v}{\tau_0\, B\, T_a\, T^3\left[\frac{Y}{4(C_p\,\Delta T + m\Delta h)} - \frac{1}{2\,\nu\,\chi_0\,\Delta H}\right]}\right) > 1 \qquad (13)$$

where T_a is the ambient temperature, T the flame temperature, τ_0, B and χ_0 are constant values.
When the inequality (13) is satisfied, a fire eruption cannot occur. As soon as the ratio p/ p_∞ is smaller than 1, a fire eruption becomes possible but not sure. In fact the lower the value of the ratio p/ p_∞ the more the fire eruption risk grows.
Several factors contribute to reduce the value of the ratio p/ p_∞:

- Fuel bed properties
  - A low density vegetation with small specific heat, where its density ρ_v and the specific heat of vegetative fuel C_p are small.
  - A vegetative fuel with a light ligneous component. Indeed, the heat of combustion of the pyrolysis gases can be written as $\Delta H = (1\text{-}c)\ \Delta H_T - c\ \Delta H_c$, where ΔH_T is the heat of combustion of fuel ($\Delta H_T \approx 1.8\times10^7$ J·kg^{-1}), c the percentage of char and ΔH_c the heat of combustion of the char (Leroy *et al.* 2009). So, low char contents induce high values for ΔH, and then the ratio given by equation (13) decreases. Furthermore, the cubic flame temperature T^3 strongly increases with ΔH.
  - A sufficient fuel load. Coefficient ν must be as great as possible (ν=1 is the perfect situation for an eruption). As $\nu = \min(1, S/4)$, the leaf area S must be greater than 4. Moreover, as $S = \frac{s\,\sigma}{\rho_v}$, a low buoyancy (low density) and thin (important surface area to volume ratio) fuel satisfies this condition with a minimal fuel load of $\frac{4\,\rho_v}{s}$.
  - A dry vegetal stratum. Indeed, the moisture content m is lower than the moisture content of a living vegetal stratum and the greater m, the smaller the ratio p/p_∞.
- Environmental factors
  - A high ambient temperature. T_a plays a direct part in equation (13) but also through $\Delta T = T_i - T_a$ and through the flame temperature T (Balbi *et al.* 2009). Note that a specific work (Chetehouna *et al.* 2009) shows that if summer temperatures are extreme (≈ 40°C), some volatile organic compounds are probably emitted in a sufficient quantity to burn at a temperature lower than the usual temperature given for T_i (around 550 K). This issue deserves to be deepened and it would be useful to have a law for ΔT as a function of T_a.
  - Assuming a homogeneous fuel bed (or a dead fuel bed), a low relative air humidity induces a low fuel moisture content (Ascoli and Bovio 2010).
- Factors related to fire dynamics
  - A strong coefficient Y (close to 1). This coefficient depends on the fire front width/flame length ratio. When the fire front width is large compared to the flame length, the coefficient Y is close to 1 (*e.g.* in field scale configurations).

To summarize, the required conditions to increase the fire eruption risk are:

- A low buoyancy vegetation, weakly ligneous, with a sufficient fuel load,
- Bad meteorological conditions (high ambient temperature, low relative humidity),
- A large fire front.

Dold and Zinoviev (2009) emphasized the impossibility to describe an eruption phenomenon with a steady-state model for the ROS. In our case, the steady state propagation model is only used to obtain the safety condition (13) because the danger condition represents its limit case. The expression of the ROS and consequently the fire behaviour during the eruption is obviously obtained using the unsteady version of the propagation model but this aspect is not studied in this work which only focuses on the eruption's occurring.
When the condition (13) is no longer satisfied, a fire eruption is probable but does not inevitably occur. The eruption's onset depends on the value of the slope angle. One can note that the safety condition (13) does not depend on the slope angle. If the slope angle is greater than a threshold value α_c, fire will erupt. It is not possible to obtain an analytic expression of this threshold but only a numerical value which is found at any precision by solving the coupled model (11-12) with a fixed-point method.
One can also note that the model (11-12) can be used when a fire spreads downslope (*i.e.* for negative slope angle values) or on flat ground (as the eruptive fire occurred without wind and slope in the Saint-Génis Des Fontaines' local site in the south of France in 2005). But in these cases, the value of the ratio p/p_∞ has to be very small in order to obtain an eruption.

Confrontation with laboratory experiments and a real accident

Sets of data describing an eruptive behaviour are very rare in literature. So, testing the proposed approach is a difficult task. Two sets of laboratory scale experiments and a wildland fire that occurred on Kornati Island in 2007 were selected.
The first set of experiments was carried out by Viegas (2004b). Notice that the main goal of that set of experiments was only to observe fire propagations on slope.
The experimental bench (DV2 inclination table) had a useful 3m x 3m area that could be inclined at any desired angle α between 0° and 40°. The fuel bed used was made with dead pine needles (Pinus pinaster). The average fuel load was 0.8 kg m^{-2}. The average moisture content was about 10-11%.
No eruptions were observed, even with the steepest slopes (30° to 40°). This is due to the intrinsic properties of the pinus pinaster needles and to a pointed head of the fire front, leading to a fast decrease of the fire front width, especially with steep slopes and then to a weak ratio fire front width/flame length W/l. The flame length is approximately 1 m. The greatest width of the fire front (3 m wide) leads to a value of the coefficient Y equal to 0.75. In this "worst" case, the value of coefficient A is greater than ½ ($A = 0.91$) and the value of the ratio p/p_∞ is much greater than 1 ($p/p_\infty = 1.73$). So the model does not predict any eruption even for a 40° slope angle.
The second set of laboratory experiments was conducted by the CEIF (Centro de Estudos sobre Incêndios Florestais) laboratory of ADAI (Association for the Development of Industrial Aerodynamics) for Dold (2010) in which eruptions are observed for slope angles greater or equal than 30°.
The experiments consist in five trench fire experiments at 15°, 20°, 25°, 30° and 35° slope angles. For the three lower slopes, the fire spreads in a usual way, but a very fast spread is observed for the two higher slopes. So eruption happens between 25° and 30°.
The characteristics of the fuel bed (straw) that were used lead a lot more easily to a fire eruption than pinus pinaster's ones. Indeed, the great surface area to volume ratio ($s = 10000$ m^{-1}) or the small density of the vegetal particles ($\rho_v = 450$ kg.m^{-3}) involve a smaller value of the ratio $\boldsymbol{p/p_\infty}$ than the one obtained for pinus pinaster needles.

Moreover, vertical walls are located on the sides of the inclination table. According to Catchpole *et al.* (1998), the role of these walls is to mimic a wider fire front by preventing indraft into the combustion zone and by reflecting some of the radiation.
The model provides a value of 1.21 for coefficient *A* and a ratio p/p_∞ smaller than 1 ($p/p_\infty = 0.76$). Then a fire eruption is possible. The value of the threshold slope angle is obtained in solving the equations (11-12). A 26° slope angle is found which means that the fire eruption will occur only if the slope angle is greater than 26°. This threshold value is in accordance with the observed results.
The model was also confronted to a real fire that happened on the Kornati Islands, Croatia in 2007. This fire led to a dramatic fire-fighting accident causing the death of 12 fire fighters and severe burns for another one. The full description of this accident is detailed in Viegas *et al.* (2008) and Stipanicev *et al.* (2008).
The accident took place in the island of Kornat (the largest of 365 islands in Croatia's Kornati National Park). The fire started 6.6 km from the accident, which occurred in a small canyon (500 m long). The fuel load was low and made of sparse vegetation, mostly grass of approximately 30 cm with a few small isolated trees and bushes. The fuel load ranged from 0.561 $kg \cdot m^{-2}$ to 0.837 $kg \cdot m^{-2}$ and the average vegetation low heating value was estimated to be 1.8×10^7 $J \cdot kg^{-1}$. The moisture content of the fine fuel mass was equal to 10-12%. The canyon's main axis was directed to the north with a 15% (about 9°) average slope. A camera was found at the location of the accident. A large fire front (of about 50 m) was clearly seen on a photo from this camera (Stipanicev and Viegas 2009), with small flame lengths (below 1 m). So the parameter Y is close to 1 in this case ($Y = 0.98$).
On the Kornat Island, the fire was pushed by a S-E wind (about 40 km/h at 10 m height). According to the only fire-fighter who survived the accident of Kornati, the important fact was the very strong wind. In the canyon, the wind changed its direction to become parallel to the main canyon axis and the fire front was spreading at very high speed, maybe 6 or 7 $m \cdot s^{-1}$. His words are confirmed by the melted particles of a fire-fighter belt buckle found on a stone behind the place where his body was laying, which prove that the wind generated by the fire was very strong and coming from the south. The fire-induced wind, which grew to be stronger than the S-E wind and changed its direction, had clearly a key role in the occurrence of the eruption. Note that the few trees here have not been burnt. That means that flames were very slanted (in agreement with the flame attachment assumption).
The simulation results with Y = 0.98 and an average fuel load (0.7 kg·m-2) give the initiation of eruption for a slope angle $\alpha = 8°$, which is in accordance with the average slope of the canyon. Indeed, the value of coefficient *A* is equal to 1.24 and the ratio $\boldsymbol{p}/\boldsymbol{p}_\infty$ is smaller than 1 ($\boldsymbol{p}/\boldsymbol{p}_\infty = 0.86$).

Conclusion

If a few works about modeling of a fire ROS during an eruption can be found in the literature (e.g. Viegas 2005, Dold *et al*. 2011), to our knowledge none of them are able to predict the eruption's onset. This work focuses on a physical safety condition which means that a fire cannot erupt if this condition is satisfied. Otherwise, an eruption is either possible or certain. The physical model proposed in this work consists mainly of one propagation equation and one equation providing the induced wind created by the fire.
The explanation of the eruption phenomenon is the following: if the slope angle is sufficient enough, the combustion of the pyrolysis gases creates an indraft proportional to the flow of these gases that is related to the fire front depth and then to the ROS. So, there is a coupling between ROS and induced wind that created a feedback effect leading to unsteady growing propagation. Note that this interpretation was given by Viegas (2005).
Usually this unsteady phase converges to a steady phase, but under some conditions, this unsteady phase grows exponentially and a fire eruption occurs.
The specific conditions leading to certain eruption ($p < p\infty$ and $\alpha > \alpha c$) are obtained with:

- Dry summer conditions (weak humidity, great ambient temperature),

- Low density vegetation, slightly ligneous (e.g. grass),
- View factor of the fire front close to 1,
- Slope angle important enough.

The two last conditions are usually contradictory: it is well known that if the slope is steep, the fire front presents a 'pointed' effect with a narrow fire head. Then, the coefficient *Y* is small and the condition $p < p_\infty$ is satisfied with difficulty. This pointed effect is due to the induced wind, which reduces the view factor on the edges of the fire front. The ROS at the edges of the fire front is then close to the backward ROS.

The right situation for a fire eruption is obtained when this induced wind downslope does not exist. This can happen when:

- The inclined plane is lined with 'walls', i.e. a trench effect or corridor topography. The nature of this topographic concavity may be geological (rocks) or constituted by a vegetation stratum (e.g. hillside lined with forests). So, in order to obtain a Y coefficient close to 1, the fire front width must be much greater than the flame length. The eruption can only develop in long corridors that let the positive feedback happen before the fire reaches any topographic limits. The trench effect defined by Sharples *et al*. (2010), especially the King Cross underground disaster, is part of this first case.
- Vegetation made of two different layers – a lower stratum and a higher stratum, such as shrubs and trees – is covering a hill. If the lower layer is burning and the induced wind is strong enough, the flames will not reach the canopy and the fire will remain a surface fire. The induced wind coming upslope can enter the flame front from the burned area but vegetation slows down the induced wind coming downslope and the pointed head effect will not appear. So, the fire front width may be much greater than the flame length and then, $Y \propto 1$. For example, the Canberra fire in 2003, or the black Saturday fires in 2009, may be part of this second case.

In these two cases (corridor and bi-strata), the Y coefficient is close to 1. If the moisture content is of the order of 10%, a fuel bed with averaged properties (surface area to volume ratio, density, specific heat, height, fuel load) will give the following results: $p_\infty = 2p$, $\alpha_c = 15°$, $R = 6.4\ m \cdot s^{-1}$ after 60 s and L = 128 m. This example corresponds to the blow up phenomenon described by the fire-fighters.

Apart from these two cases, the decrease in coefficient Y will not provide a fire eruption faced to topographies as inclined plateau or hill with convex shape.

Extended abstract

A major consequence of large wildfires is the budgetary impact on public agencies tasked with wildfire management and suppression efforts. In wildfire seasons with a high incidence of large and expensive fires, agency budgets for non-fire activities can be threatened when the immediate needs of wildfire management are prioritized. In the United States, wildfire management already accounts for a large and increasing share of the U.S. Forest Service's (USFS) budget, which strains other land management needs. Between 1992 and 2011, the annual budget dedicated to fire management grew from 13 to over 40 percent of total agency appropriations.

This extended abstract describes the development of expenditure models that are capable of providing spatially and temporally explicit information about costs, and provides examples of how such models can complement sophisticated fire simulation models used to support incident management decisions and landscape-scale fire planning. To date, expenditure modelling efforts have yielded insights into the geographic, landscape, socio-political, and management characteristics associated with wildfire suppression expenditures. These insights are based on models that relate characteristics associated with the location and date of ignition of wildfires to expenditure records (e.g., Gebert *et al*. 2007; Gude *et al*. 2013; Donovan *et al*. 2011; Yoder and Gebert 2012). However, decision support tools and wildfire modelling efforts increasingly use detailed spatial and temporal descriptions of geographic, landscape, and weather conditions. Accounting for heterogeneity of such conditions in management expenditure models may improve link between fire modelling outputs and expenditure models for fire management planning and decision support.

Incorporating spatial characteristics in expenditure models has limited precedent in the literature. Priesler *et al*. (2011) create spatially explicit forecasts of expenditures, but the underlying expenditure model is based on ignition-point data. Liang *et al*. (2008) incorporated spatial characteristics of the area within fire perimeters to account for observed spatial autocorrelation of expenditures for limited set of fires in the Northern Rockies region of the United States. Hand *et al*. (2014, ch.4) extend the approach in Liang *et al*. (2008) to include fires in the entire Western United States, but did not evaluate the role of heterogeneity or assess model performance relative to ignition-point models. The data and methods in Hand *et al*. (2014) form the basis of the empirical models in this paper.

To develop spatially and temporally descriptive expenditure models, final fire perimeters were gathered for a sample of large fires (greater than 121 hectares) from the western United States. In total, 406 fires from fiscal years 2006 to 2011 are used in the final estimation sample. The fire perimeters were used in conjunction with several geo-spatial data layers to describe the extent and variation of geographic and landscape characteristics that are thought to be associated with expenditures. The time period between the discovery date of the fire and the date of control or containment was used to examine landscape and geographic characteristics within the fire perimeter that may vary over time.

The spatially and temporally descriptive characteristics are used as independent variables in a regression model to predict total incident expenditures by Federal management agencies.[1] Table 1 describes the variables used in the regression model and the corresponding variables in ignition-point expenditure models that the spatially and temporally descriptive variables replace.

Table 1. Variables used in spatially descriptive regression with corresponding ignition-point variables; obs. = 406

Variable	Description	Source (see table footnote)	Corresponding ignition-point variables
lnexp	Natural log of total federal suppression expenditures in constant 2012 $ (Dep. Var.)	FFIS	--
lnacres	Natural log of area within final fire perimeter	NIFC FTP	--
erc_max	Maximum relative ERC percentile observed during the fire within the final perimeter	GIS calculation of data from Abatzoglou (2011)	ERC at ignition point and time
erc_std	Standard deviation of relative ERC observed during the fire within the final perimeter	GIS calculation of data from Abatzoglou (2011)	ERC at ignition point and time

Preliminary results suggest that spatial heterogeneity of geographic and landscape characteristics affect suppression expenditures. In particular, the spatial pattern of surface fuels, protection designation (e.g., Wilderness Areas), land ownership, and housing values are significant predictors of expenditures. Further, the temporal pattern of fire weather and fuel moisture conditions is an important predictor of expenditures. The spatially descriptive model also improves prediction accuracy and

model fit as compared with analogous models based on ignition-point characteristics. Table 2 compares the size of the standardized residuals (in standard deviation, or s.d., units) in the spatial/temporal model to those in the comparable ignition-point model.

Table 2. Comparison of standardized prediction errors between spatial/temporal model and ignition-point model

Size of standardized residual	Spatial model frequency	Ignition-point model frequency
<= 1 s.d.	104	94
1 - 2 s.d.	101	77
2 - 3 s.d.	87	69
>4 s.d	114	166
All obs.	406	406

An immediate use of the spatially and temporally descriptive expenditure model is to improve the accuracy of expenditure predictions when the final burned area is known. For example, after-season reviews of fire-specific expenditures can be compared to predicted expenditures using the final fire perimeter and the spatial/temporal expenditure model. The results indicate that the modest improvements in prediction accuracy can lead to more reliable comparisons in the future.

The model can also be used to improve the functionality of decision support tools that include predictions of total incident expenditures. In the Wildland Fire Decision Support System (WFDSS), the ignition-point expenditure model is currently used to provide information about expected expenditures for an incident under given conditions (Noonan-Wright *et al*. 2011). The spatially and temporally explicit model may yield more nuanced information about expenditures because it can, in theory, be paired with fire models in WFDSS that result in predicted fire perimeters. For example, the expenditure model can be paired with fire spread models to generate spatially explicit expected expenditure maps. Such an application would leverage variations in fire behaviour generated by the fire spread model (which determines the size and areal extent of the fire), as well as spatial and temporal variations in characteristics that are related to expenditures. As risk management becomes a greater focus of wildfire management, risk-based expenditure information may assist managers in making strategic decisions during a fire incident.

Incorporating spatially descriptive data can provide richer information about how expenditures are affected by alternative land management scenarios. Planning and prioritizing the treatment of hazardous fuels to affect future fire behaviour may incorporate impacts on expected suppression expenditures (Fitch *et al*. 2013; Thompson *et al*. 2013). The spatial/temporal expenditure model could provide greater detail about how changes in fire behaviour relate to expenditures. For example, hazardous fuel treatments may not necessarily affect the expected number of ignitions or number of large fires in a given season, but could affect the spatial pattern of where fires are likely to burn. Ignition-point models of expenditures currently in use (e.g., in Thompson *et al*. 2013) only account for changes in fire size. But fuel treatments are an inherently spatial endeavour, and the location and pattern of treatments may have impacts on wildfire management that extend beyond changes in final fire size. Understanding the magnitude of any potential suppression cost trade-offs can assist managers in determining whether such investments are worth the cost.

In summary, spatially and temporally descriptive models of wildfire management expenditures show promise for improving predictions of expenditures and providing nuanced information for decision support and land management planning. Accounting for heterogeneity of characteristics in space and over time improves the fit and predictive power of wildfire expenditure models, and are readily adaptable to spatially explicit fire modelling tools. The models investigated in this paper are limited

by the fact that they use relatively coarse geospatial data, and do not explicitly model how the progression of fire relates to expenditures. Future research using time-series panel data and finer scale geographic data may help alleviate these limitations.

Evaluating wildfire simulators using historical fire data

George J Milne, Joel K Kelso, Drew Mellor and Mary E Murphy

University of Western Australia. Perth, Australia. george.milne@uwa.edu.au

Abstract
High-performance wildfire simulators allow the future location of a wildfire to be rapidly predicted. The accuracy of such simulators needs to be evaluated; this can be achieved by comparing simulated and observed spread for documented historical fires. A key issue relates to the accuracy of data obtained from historical fires, such as the time-varying fire location, fire-ground weather and accuracy of fuel type, load and structure data. A methodology used to evaluate the accuracy of wildfire simulators using historical fire data is presented and applied to the AUSTRALIS wildfire simulator using the four distinct phases of a large-scale wildfire occurring in Western Australian sand-plain heathlands and a fire reconstruction report on this fire produced by a wildfire expert. Challenges encountered in performing this validation exercise are highlighted.

***Keywords**: wildfire simulation, GIS, fire behaviour models, simulator testing*

Introduction

A methodology used to evaluate the accuracy of wildfire simulators using historical fire data is presented. Application of the methodology was examined using the four phases of a large-scale wildfire occurring in Western Australian sand-plain heathlands and a fire reconstruction report on this fire produced by a wildfire expert. The spatio-temporal dynamics estimated from the reconstruction report was compared with simulated fire behaviour, as produced by the AUSTRALIS wildfire simulator. The availability of rapid automated fire prediction permits the many variables which influence fire spread to be quickly examined by changing simulator input parameters, such as forecast wind speed and direction, to determine how such changes may impact on the spread characteristics of the fire. While simulators such as the AUSTRALIS wildfire simulator allow the future location of a wildfire to be rapidly predicted, and geographical information systems (GIS) maps with forecast fire-lines overlayed on them to be quickly made available to fire managers, the accuracy of such simulators needs to be examined by application to high-quality datasets from prior fires. A key issue relates to the accuracy of data obtained from historical fires, such as time-varying fire location, fire-ground weather and accuracy of fuel type, load and structure data, which are necessary if meaningful comparisons are to be made.

2. Methods

Simulating the spread of wildfire across a real landscape may, like simulation of other complex natural phenomena, be impacted by multiple sources of inaccuracy. First, the input data used for simulation will be subject to inaccuracy. For example, spatial boundaries in vegetation maps have limited precision and may have changed since the map was generated; initial fire perimeters are generally approximate; the closest meteorological observations may have been taken tens of kilometres from the fire-site. Second, predictive models relevant to fire behaviour, such as fire behaviour models for predicting rate of spread, slope correction, two-dimensional fire shape models, and fuel accumulation models, are all idealised models that approximate real phenomena. Third, the simulation methodology itself can introduce inaccuracy. For example, the discrete event simulation approach of AUSTRALIS (Johnston *et al.* 2008) relies on spatial discretisation, where the landscape is partitioned into cells that are assumed to have homogeneous attributes, such as vegetation, slope and aspect. When the spatial

resolution of the cell grid is coarse relative to the features being modelled, then the assumption of homogeneity is likely to be inaccurate for many cells. Given the need for accurate wildfire spread prediction these issues need to be overcome, and this provides the rationale for the reported study.

The general validation technique used in this paper is as follows:

- Obtain topographic, meteorological and fuel data for a historical fire event. Also obtain reconstructed fire spread perimeters and initial ignition/fire front locations
- Simulate the fire using the obtained data and generate a progression of fire spread perimeters
- Compare the level of agreement between the simulated and reconstructed fire progression perimeters
- Assess the impact of uncertainty in the input data, fire behaviour models, and simulation algorithm on simulation accuracy by extensive sensitivity analyses.

In this paper, a case study of the above methodology is presented in which the AUSTRALIS wildfire simulator (Johnston *et al.* 2008) is applied to a large-scale historical fire that occurred in the vicinity of the Boorabbin National Park, Western Australia (WA) in December 2007 and January 2008.

This fire burned a total area of approximately 18,000 hectares over the 4 phases that were simulated. The topography consisted of gently undulating sand-plains and broad, shallow valleys. Two types of vegetation were present: Eucalypt woodland characterised by a very sparse understorey layer and a lack of fuel continuity, and semi-arid sand-plain heath (see Figure 1). Two government reports into the Boorabbin fire were produced as part of a coronial inquest following deaths which occurred on the fourth phase of the fire. These reports provided (i) a comprehensive assessment of the fuel and meteorological conditions occurring during the course of the fire (Bureau of Meteorology 2008; de Mar 2008), and (ii) a reconstruction of the fire perimeters over several phases of the fire at time steps ranging from 15 minutes to 3.5 hours (de Mar 2008). The existence of this detailed fire reconstruction data facilitated use of the following method.

Comparison between the simulator-generated, time-varying progression of the fire-line and an independently produced fire behaviour reconstruction produced as part of a coronial inquiry into deaths resulting from one of the four constituent fire phases was made. The accuracy of the simulated fire against the fire reconstruction contained in the report was determined using a number of measures, such as agreement of the headfire rate-of-spread (RoS) and the fit of the time-varying fire perimeters. The reconstruction report made use of high-resolution (less than 20m) satellite imagery to establish the final fire perimeter; however very limited data (i.e. firefighter recollection and limited aerial and ground photography) was available for the estimation of intermediate perimeters. Four distinct component fire phases were simulated, with the maximum Fire Danger Index ranging from 28 (high) to 104 (very extreme) across the four fire phases.

Figure - 1 Predominant vegetation present at the fireground. Left: sandplain heath-scrub. A short scrub assemblage typical of that occurring in the higher parts of the landscape. Note the low, patchy nature of the vegetation. The taller, isolated shrubs in the background are mature Callitris, and indicate that this area has not been burnt for 25 years. Right: unburnt Tamma scrub. An expanse of Tamma scrub similar to the vegetation that burnt during the run of the fire to the highway where the fatalities occurred. Note the short, relatively dense vegetation structure. Tamma scrub is one of the denser heath-scrub assemblages (high level of fuel continuity) likely to support faster moving fires than occur in patchier heath scrub vegetation types. Photographs and annotations taken from (de Mar 2008).

Simulated fire progression perimeters were generated using the AUSTRALIS simulator, using fuel type and coverage data from the reports, a national vegetation mapping data set (Australian Government Department of the Environment 2014), meteorological data from the nearest Bureau of Meteorology Automatic Weather Station (AWS) at Southern Cross, and a fire behaviour (rate-of-spread) model developed for arid heathland (Cruz *et al.* 2010). Simulator accuracy was assessed via a statistical comparison of the spatial extent of the simulated perimeters against the estimated perimeters taken from the reconstruction report, at corresponding time-steps.

AUSTRALIS employs a discrete event simulation technique (Zeigler *et al.* 2000) that is based on partitioning the landscape into a collection of two dimensional cells and calculating the propagation delay between an 'ignited' cell and each of its 'unburnt' neighbours. Each cell contains state information ('unburnt' and 'ignited') and a number of attributes relevant for calculating propagation delay, including location, elevation, and fuel characteristics such as vegetation type and fuel load. In contrast to other cell-based approaches to wildfire simulation, the cell locations are distributed randomly, rather than regularly, across the landscape. This is done to avoid a form of fire shape distortion that results from using a regular partition, such as with a rectangular or square grid. For all simulations in this study, the average distance between cell centroids was 50 m. Other fire spread simulation systems that use a discrete cellular representation of the landscape include FSPro, part of the U.S. Forest Service WFDSS system (Finney 2002; Finney *et al.* 2011), PYROCART (Perry *et al.* 1999), and FireStation (Lopes *et al.* 2002).

The validation technique presented in this paper may be used to validate any fire spread simulation system that predicts fire-front time of arrival across the landscape. Systems that do not use an underlying cellular landscape structure, such as FARSITE (Finney and Ryan 1995), Prometheus (Tymstra *et al.* 2010), and SIROFire/Phoenix (Coleman and Sullivan 1996; Tolhurst *et al.* 2008), may be accommodated by first running fire spread simulations and then rasterising both the estimated and simulated fire arrival time maps to generate cells for the purpose of accuracy assessment (see below). We note that in order to conduct extensive sensitivity analyses of the type presented in this paper, the ability to run many (hundreds) of fire spread simulations rapidly is beneficial, and it may not be practical to apply this kind of sensitivity analysis to computationally intensive, physics-based simulation systems such as FIRETEC (Linn *et al.* 2002).

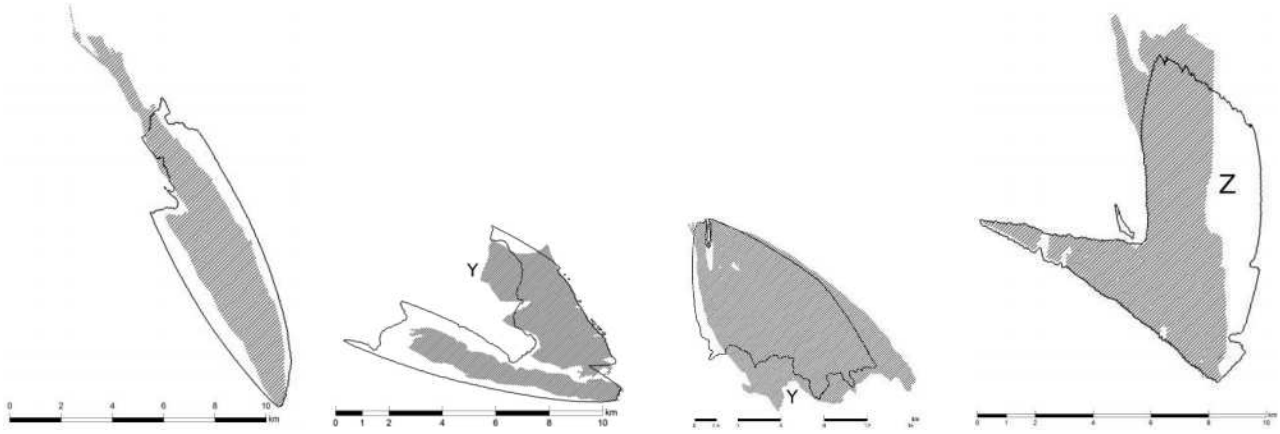
The accuracy of the AUSTRALIS simulator at predicting the fire spread progression of the Boorabbin fire was measured as follows. At the conclusion of a simulation, AUSTRALIS output the fire arrival time for each cell that ignited. The accuracy of the simulated fire spread was assessed by comparison to a

detailed reconstruction of the estimated fire progression which had mapped intermediate fire perimeters throughout the course of the fire at time step intervals of at most 3.5 hours over the four phases of interest. Accuracy was determined using Cohen's kappa coefficient (*K*), a statistical measure of agreement between two geo-spatial datasets, which has been used previously for assessing the accuracy of fire spread simulation (Arca *et al.* 2007). Cohen's kappa is given by:

$$K = \frac{N\sum_{i=1}^{k} x_{ii} - \sum_{i=1}^{k}(x_{i+} - x_{+i})}{N^2 - \sum_{i=1}^{k}(x_{i+} - x_{+i})}$$

where x is the error matrix, i.e. xij is the number of simulation cells where the simulated and reconstructed fires arrive in time period i and j respectively; , $xi+$ and $x+i$ are the marginal totals of row i and column i respectively, and N is the total number of samples. Kappa typically varies over [0,1], where $K = 0$ indicates that agreement is due to chance alone, and $K = 1$ indicates perfect agreement.

Results



Phase 1: 2359 kappa = 0.62 | Phase 2 : 1900 kappa = 0.49 | Phase 3a: 1900 kappa = 0.33 | Phase 3b : 2359 kappa = 0.42

Figure 2. Final fire perimeters estimated by the reconstruction report (shaded) and simulated by AUSTRALIS (black line) at the end of each phase. The agreement statistic kappa is given for each phase, which takes into account agreement between intermediate estimated and simulated fire perimeters (not shown). Spread under-predictions in Phase 2 and 3a marked Y are due to vegetation mapping inaccuracies; spread over-prediction in Phase 3b (marked Z) is due to weather data inaccuracy.

Using the available data AUSTRALIS were able to approximately reproduce the observed fire behaviour in each of the four phases, as shown in Figure 2.

Following the initial simulations of the four phases, an extensive series of sensitivity analysis experiments were conducted in order to determine the factors which limited the accuracy of the simulation system. The simulation input parameters that were varied and the range of values used are given in Table 1. In the case of the weather time series, adjustments were made by adding or subtracting a fixed amount from the value of the variable at each time step. For vegetation cover, all landscape cells containing heath vegetation were set to an alternative percent cover score (PCS) value. For fire behaviour models, each sensitivity analysis simulation used an alternative fire behaviour model to calculate rate of spread occurring in heath vegetation.

Table 1. Simulation parameters varied in sensitivity analysis simulations and the series of parameter values examined for each. Abbreviations are as follows. AWS – automatic weather station; U10 – 10 m wind speed recorded at the Southern Cross AWS; WD – wind direction (degrees clockwise from North); WS – wind speed (kilometres per hour); T – temperature (degrees Celsius); RH – relative humidity (percentage); PCS – percentage cover score; HE – semi-arid heath model (Cruz et al. 2010); MH1 – mallee heath (McCaw 1997); MH2, MH3 – semi-arid mallee heath (Cruz et al. 2010); SH – shrubland (Catchpole et al. 1998); HG - (Burrows et al. 2009).

Simulation parameters and models	Baseline value/model	Sensitivity analysis range
Cell grid		
Cell size (m)	50	50, 100, 250, 500, 750 5 randomly generated grids at each size.
Meteorological variables		
Wind speed measured at 10 m (km/h)	Southern Cross AWS (U10)	U10 ± 5, U10 ± 10, U10 ± 15, U10 ± 20
Wind direction (°)	As above (WD)	WD ± 5, WD ± 10, WD ± 15
Temperature (°C)	As above (T)	T ± 5, T ± 10, T ± 15
Relative Humidity (%)	As above (RH)	RH ± 5, RH ± 10, RH ± 15
Fuel variables		
PCS of elevated fuel layer (0–4)	1.5	1, 1.5, 2, 2.5, 3, 3.5, 4
Fire behaviour models		
Fire behaviour model for heath vegetation	HE	HE, MH1, MH2, MH3, SH, HG

In the following subsections we summarise the results of these sensitivity analyses. We describe the outcome of the analyses in two parts: the effect of simulation algorithm cell size, and results showing a dichotomy between the first two phases of the fire and the second two phases, which occurred under extreme fire weather conditions.

Impact of the cell grid on simulation accuracy

As described previously, the AUSTRALIS simulator discretises the landscape into a set of randomly placed cells. This technique potentially introduces two sources of inaccuracy into the simulation results. Firstly, as with any simulation algorithm based on a cellular landscape discretisation, if cells are too large, it will not be possible for any set of simulation-generated cells to represent realistic fire shapes without either under- or over-fitting. Secondly, since the cell locations used by AUSTRALIS are randomly generated, simulation outputs can vary from one simulation run to another, even with identical simulation inputs. Both of these potential sources of inaccuracy decrease with decreasing cell size, as illustrated in Figure 3. In Figure 3A it can be seen that with a large cell size, the simulation of an ideal elliptical fire spread shape is considerably distorted, whereas in Figure 3B the elliptical fire shape is closely approximated. Comparing Figure 3B with 3C, it can be seen that simulations using two different randomly chosen grids with the same small cell size give rise to very similar fire shapes.

A **B** **C**

Figure 3. Three AUSTRALIS simulation outputs for an idealised case with uniform fuel and a northerly wind. A (left) cell spacing 750m, B (middle) cell spacing 150m, C (right) cell spacing 150m, but with different randomly generated grid.

In order to quantify these effects of cell size in the context the Boorabbin simulation study, each of the four phases of the fire were simulated using cell grids generated with cell spacing ranging between 50–750 m, with five random cell grids being generated for each cell size. Two important results were apparent. Firstly, accuracy (i.e. agreement between estimated and simulated fire spread) increased as cell size decreased from 750 to 250 m, and remained constant below 250 m, indicating that below this cell size inaccuracy in simulation output was not due to discretisation error but was due to other sources (as discussed below). Secondly, the variance in simulation outputs due to the random nature of the cell grid diminished with cell size. For the 50m cell size used in the rest of the study, the results indicated that random grid variance artefacts do not significantly influence our results (95% confidence intervals for Kappa values were +/- 0.016 or smaller).

Impact of extreme fire weather on simulation accuracy

In this section we describe a clear distinction in the simulation accuracy sensitivity analysis results between the first two phases of the fire, during which the fire danger index (McArthur 1966) ranged from 20 – 28 (High), and the third and fourth phases, during which the fire danger index ranged from 47 to 104 (Extreme). For each of 4 key simulation parameters, Table 2 shows which parameter value resulted in the most accurate simulation i.e. the highest kappa value *k*. If this value was not the baseline parameter value (baseline values are given in Table 1), the variation from the baseline is given along with the improvement in kappa over the baseline.

Table 2. Summarised results of sensitivity analysis simulations, showing the best accuracy value kappa (k) achieved by varying each simulation parameter. Where the best k value is greater than that of the baseline simulation, the baseline k value is given in parenthesis for comparison. The simulation parameter value that gave the best accuracy is also shown: where the notation "baseline" is used, this value was the baseline value shown in Table 1; otherwise, the deviation from the baseline value is given.

	Phase 1		Phase 2		Phase 3A		Phase 3B	
Variable	best *k*	value for best *k*	best *k*	value for best k	best *k*	value for best *k*	best *k*	value for best *k*
wind speed	0.63 (0.62)	– 5kph	0.49	*baseline*	0.44 (0.33)	+ 20km/h	0.58 (0.42)	+ 20km/h
wind direction	0.62	*baseline*	0.49	*baseline*	0.47 (0.33)	– 15°	0.42	*baseline*
PCS	0.62	*baseline*	0.49	*baseline*	0.54 (0.33)	+ 3.5	0.58 (0.42)	+ 1.5
FBM	0.62	*baseline*	0.49	*baseline*	0.49 (0.33)	MH1	0.56 (0.42)	MH1

The sensitivity analysis simulations revealed that for Phases 1 and 2, the most accurate simulation results were given by the baseline parameter settings. In other words, the weather time series from the Southern Cross AWS, the estimate of vegetation cover (PCS) as having a value of 1.5, and the selection of the heathland fire behaviour model yielded the most accurate simulation results. In the case of the wind speed during Phase 1, a very slight improvement in simulation accuracy was given by reducing the Southern Cross AWS wind speed by 5 km/h Note that this is not a claim that the baseline parameter values were "correct" – rather, these results show that simulation inaccuracies are not simply explained by errors in the weather data, vegetation coverage estimate, or selection of an inappropriate fire behaviour model. For example, one apparent source of inaccuracy was due to the resolution of the vegetation map. Inspection of the Landsat imagery of the area showed that some areas of the map marked as Eucalypt woodland were interspersed with heath and carried fire; simulation in these areas under-predicted the extent of fire-spread (see areas marked Y in Figure 2).

The situation for Phases 3A and 3B is quite different. In terms of wind direction, in Phase 3A the simulation with the greatest accuracy occurred for a wind direction series in which all wind readings were rotated 15° counter-clockwise from the (northerly) winds recorded at the Southern Cross AWS. This result is consistent with de Mar's (2008) analysis that transient westerly winds occurred during this phase at the fire-site and impacted the shape of the perimeters. In Phase 3B, the wind direction was clearly inaccurate at the beginning of the period (see Figure 4, up to 2100), resulting in over-prediction of westerly spread in the area marked 'Z' in Figures 2 and 4. Unlike Phase 3A, no simple uniform alteration of wind direction improved accuracy.

Table 2 shows that simulation accuracy is improved if the wind speed during the Phases 3A and 3B were 20km/h *faster* than the value recorded at Southern Cross AWS. Simulation accuracy was *also* improved if it was assumed that the vegetation cover of the heath vegetation burned during Phases 3A and 3B was higher than estimated, *or* if a Mallee Heath (MH1) fire behaviour model was used for heath vegetation. These three sensitivity analysis results are actually manifestations of a single factor: that the baseline simulation systematically under-predicted the *rate of spread* during Phase 3B. This is illustrated in Figure 4, which shows both estimated and simulated fire perimeters at 2030, 2045, 2100 and 2359. In each case the simulated fire front lags the fire front position estimated from the fire reconstruction report. The under-prediction of the rate of spread may thus be due to:

1. The actual wind speed being higher than the value recorded at Southern Cross. Given that the Southern Cross AWS was located 75km from the fire ground, and the clear discrepancies in wind direction noted above, discrepancies in wind speed are plausible. The HE fire behaviour model would then predict a faster rate of spread, more closely matching the estimated fire behaviour. Or,
2. The heath vegetation burned during Phase 3B having a higher vegetation cover than in the previous phases. Although the available vegetation input map data did not distinguish between heath scrub types, according to (de Mar 2008) the fire site contained both 'heath-scrub' and 'Tamma scrub'. Of these two types of heath vegetation Tamma scrub, which was present in some areas burnt during Phase 3B, had characteristically higher levels of cover. With a higher vegetation cover, the HE fire behaviour model predicts a faster rate of spread. Or,
3. The HE fire behaviour model under-predicting the rate of spread in extreme fire weather conditions. This is plausible, given that the heathland experimental fires on which the HE model was based were conducted under less severe weather conditions: the maximum experimental fire danger rating was Very High compared to the Extreme conditions during Phase 3B, and maximum experimental wind speeds were approximately 18 km/h, compared to the average Phase 3B wind speed of 37 km/h. Or,
4. Some combination of the above.

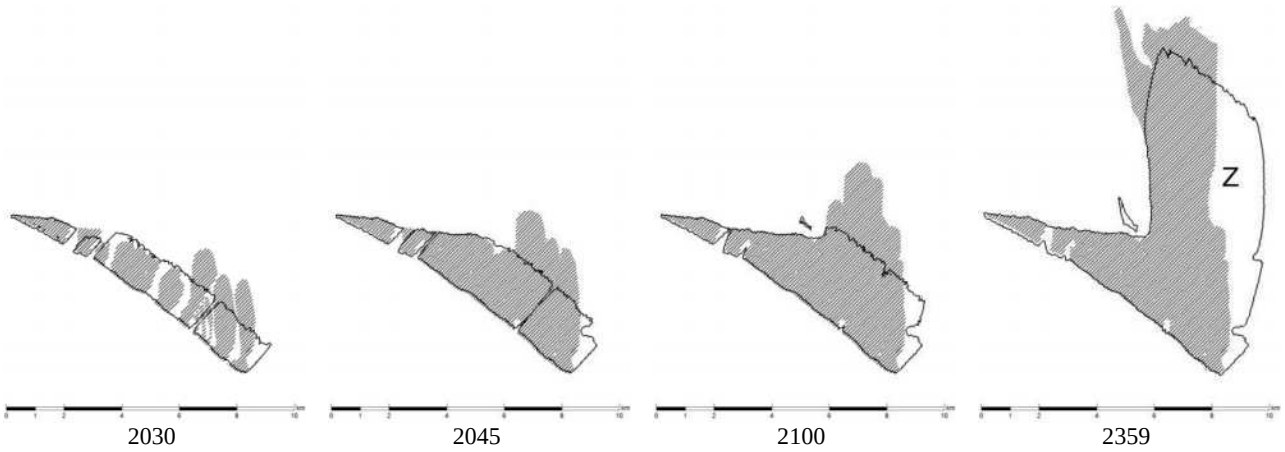


Figure - 4 The progression of the fire during Phase 3B. Simulated (black line) and estimated (shaded) fire perimeters are shown for times 2030, 2045, 2100 and 2359. The annotation "Z" is discussed in the text.

Using the data available for our validation analysis, we were not able to distinguish between the possibilities 1-3 above.

Discussion

Several previous studies have sought to validate fire spread simulation systems by comparing simulated fire spread against historical fire data, for example the studies of Finney (Finney 2000), Fujioka (Fujioka 2002), Arca *et al* (Arca *et al.* 2007), and Fillipi *et al* (Filippi *et al.* 2014). In common with previous validation exercises, this study found that that the ability to perform validation was limited by the reliability of available data, with fireground weather presenting the largest obstacle. While this study identified that the AUSTRALIS simulation system under-predicted the of rate of spread in arid heathland vegetation under extreme fire conditions, it was not possible to further diagnose either wind data, fuel mapping data, or fire behaviour models as the cause of the under-prediction.
The very features which this study highlighted as presenting difficulties in conducting a validation of the accuracy of computer simulation of wildfire spread (using high quality data) are exactly those which impact on the use of such simulation technology "in the field". As well as conducting simulation model validation using historical fire data, there is a pressing need to collect accurate fire data during active wildfires, rather than conducting analysis after the event. Such data-gathering efforts include regular fire line mapping at hourly intervals and the recording of fire ground weather conditions. Together, accumulated GIS data on fuel types, fuel load, and the development of fire behaviour rate-of-spread models which are experimentally calibrated for extreme fires, these data will facilitate: (1) higher fidelity simulator validation studies and, (2) more accurate prediction of "live" wildfires, which currently may be compromised by source data quality. Fire agencies and fire personnel organisations are to be encouraged to address these data issues.

Abstract
This paper draws the attention of the community about the capabilities of an emerging generation of bio-inspired vision sensors to be used in fire detection systems. Their principle of operation will be described. Moreover experimental results showing the performance of an event-based vision sensor will be provided. The sensor was intended to monitor flames activity without using optic filters. In this article, we will also extend this preliminary work and explore how its outputs can be processed to detect fire in the environment.

Keywords*: Flame monitoring, event-based vision sensors, fire detection, NIR, image processing.*

Introduction

Infrared cameras can easily detect fire and hot spots. Unfortunately, they are expensive, difficult to handle, and fragile (Briz *et al*. 2003). For this reason, CMOS cameras are still preferred for some applications where it is not strictly necessary operating in the whole infrared band, (Cheon *et al*. 2009, Naoult *et al*. 2007, Bendiscio *et al*. 1998, Fernandez-Berni *et al*. 2012). Silicon can detect Near Infrared Radiation (NIR) within the band [700 1,100] *nm*. This property can be exploited to monitor flame and fire activity.
Flames have a very characteristic oscillatory behavior. They flicker with certain frequency components that depend on their nature. The study of these frequency components is interesting for industrial processes and applications. Traditionally CMOS cameras with NIR filters have been employed (Yan *et al*. 2006). As an alternative to this traditional approach, recently we proposed a bio-inspired event-based system to monitor flame activity without using optic filters (Leñero-Bardallo *et al*. 2013). The idea behind this method was to compare the photocurrents of stacked photodiodes at different depths. The top one was more sensitive to shorter wavelengths and the bottom one was more sensitive to longer wavelengths, having a very good sensitivity within the NIR band. Just comparing the difference between their photocurrents, we were able to determine if the incident radiation was within the NIR band without optic filters. Moreover, we could process with a real-time algorithm the temporal variations of the NIR levels in the visual scene provoked by flames and compute their frequency components values.
This paper studies how the prior work to monitor flame activity could be extended to detect fire in the environment and emit an alarm in case. We will show that the previously implemented algorithm outputs can be processed to detect fire with a low computational load. Up to date, all the forest fire detection systems with cameras use frame-based vision sensors. With this contribution, we also want to draw the attention of the community about this new generation of bio-inspired vision sensors.
This document is organized as follows: In Section 3, we explain briefly the fundamentals of bio-inspired vision sensors and we discuss their feasibility for fire detection; Section 4 explains what kind of radiation can be sensed with CMOS sensors; Section 5 describes our sensor and algorithm to process its outputs and detect radiation within the NIR band; Section 6 provides experimental results when our system is employed to monitor flame activity; Section 7 explores how the NIR separation algorithm

can be modified to emit an alarm if there is fire in the environment; finally, Section 8 draws some conclusions.

Bio-inspired Event-based Vision Sensors

Conventional vision sensors are frame-based systems (also known as smart imagers). A frame is a 2D-dimensional matrix that contains information about the visual scene (typically light intensity or color). Such sensors always provide a continuous output data flow (frames are transmitted with a continuous periodicity) that can be very redundant if the visual scene does not change. If we compare their performance with the human retina, we can state that they perform worse in the majority of uncontrolled situations and environments: their dynamic range is much lower, their sensitivity to light is also lower, and their power consumption is much higher.
For these reasons, some authors considered the idea of developing bio-inspired vision sensors (also called retinas, (Mahowald 1994, Leñero-Bardallo *et al*. 2010, Leñero-Bardallo *et al*. 2011). These sensors try to mimic the interactions of the cells of the human retina. The retina operates in a very different way to conventional vision sensors. Its cells process the visual information before transmitting it to the brain. Thus, redundant information is not sent through the optical nerve. Retinal cells can compute the spatio-temporal contrast that contains almost all the relevant information about the visual scene. This information is transmitted continuously. There is a massive parallel architecture and cells can send anytime spikes to the brain. Therefore biological systems are inherently faster than classic imagers which bandwidth is limited by the frame rate.
The main drawback of artificial event-based sensors is their low pixel fill factor. Their pixels have more transistors than commercial frame-based pixels with three or four transistors. Extra circuitry per pixel is required to process the visual information and to implement and asynchronous pixel communication (Häfliger 2000). However, such sensors are good candidates for applications like fire detection or surveillance, where high image quality is not mandatory, and speed and low power consumption are preferred. They have a great potential to be nodes of wireless sensor networks. In such networks it is mandatory to minimize the amount of data transmitted from the sensors to a central node which processes the information.

Fire Detection in the NIR Band

A CMOS camera without filters detects radiation beyond the visual spectrum, i.e. Ultra Violet ([250, 390] nm), visible ([390, 750] nm), and NIR ([750, 1100] nm). Hot spots, fire or flames can be detected with a CMOS sensor with a NIR filter (Naoult *et al*. 2007), (Li *et al*. 2010) (hot spots need to be above 350Cº). Smoke detection is possible too when employing NIR sources (e.g. NIR LEDs).
In our particular case, we developed a system (Leñero-Bardallo *et al*. 2013) with an event-based sensor to monitor the temporal variations of the visual scene provoked by flames. Flames have frequency components within the interval [0, 250] Hz and their flickering can easily be tracked with an asynchronous sensor.
As a continuation of this preliminary work, we propose to develop new real-time algorithms, (Leñero-Bardallo *et al*. 2013), to detect fire in indoors and outdoors environments. According to our experimental results, flames provoke very fast and periodic variations of NIR levels in the visual scene that can be identified from other NIR sources like sunlight. Such periodic variations of the NIR levels are easy to detect when they appear, just computing the standard deviation of previously recorded NIR levels and normalizing it.

Methodology

We employ an event-based vision sensor to detect the NIR variations of the visual scene (Leñero-Bardallo *et al*. 2013). The sensors pixels are made up of three stacked photodiodes at different depths. Each one is connected to a circuitry that sends pulses out the chip, with a frequency proportional to its local photocurrent (see Figure 1). The top one is more sensitive to shorter wavelengths. The bottom one is more sensitive to longer wavelengths and to the radiation within the NIR band. This property is based on the light penetration depth. Shorter wavelengths photons have more energy and on average, they travel less time before they generate electron-hole pairs. Longer wavelengths have less energy and they travel more time across the silicon before generating electron-hole pairs.

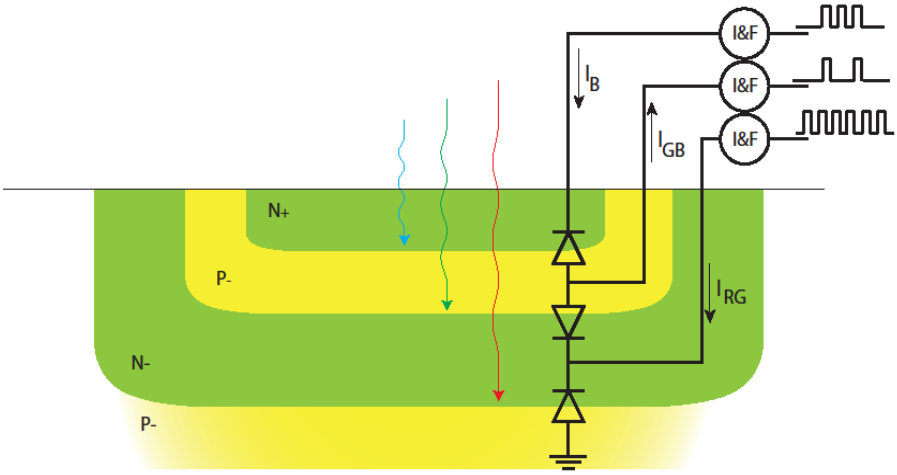

Figure 1. Experimental setup: vision sensor and data logger. Photodiodes cross-section. Each one is connected to circuitry (channel) that generates pulses with a frequency proportional to its inputs photocurrents.

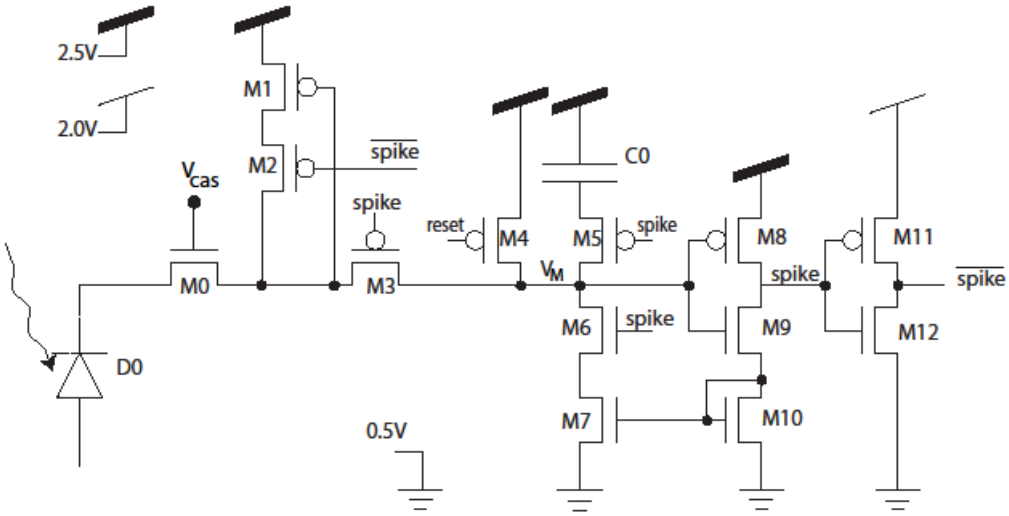

Figure 2. Integrate-and-fire neuron. This circuitry is replicated three times within each pixel. Depending on the input is connected to the photodiode cathode/anode, we use this circuit or a complementary version of it, with p-MOS transistors instead n-MOS transistors and vice versa.

Note that the photocurrents at the inputs of the integrate-and-fire neurons do not correspond with each photodiode current. For this reason it is necessary to process the events outputs to estimate the photocurrent of each photodiode. Unfortunately, we do not know the photodiodes quantum efficiencies, their doping profiles, and the PN junction depths (such information was not disclosed by the foundry). For this reason, it is impossible to know the exact photocurrent values. We denote the photocurrent estimations after processing the integrate-and-fire outputs as $I'_{\{B,GB,RG\}}$. However, to represent the color information of each pixel, we only need to know the relative values of each photocurrent. For this reason, it is possible to represent RGB images after processing the channels outputs. Every time that a pixel integrate-and-fire neuron spikes, its frequency f_* is updated. Periodically, the estimation of the photocurrents is computed according to the following equations:

$$I'_B = \frac{f_B C_B \Delta V_{th\_B}}{e_B} \quad (1)$$

$$I'_G = \frac{f_{GB} C_{GB} \Delta V_{th\_GB} - I'_B e_B}{e_G} \quad (2)$$

$$I'_R = \frac{f_{RG} C_{RG} \Delta V_{th\_GB} - I'_G e_B}{e_G} \quad (3)$$

Where $C_{\{B,GB,RG\}}$ are the photodiodes capacitances, $\Delta V_{th\_\{B,GB,RG\}}$ are the voltage increments at the integrate-and-fire neurons capacitances to elicit one spike, and $e_{\{B,GB.RG\}}$ are parameters that represent the photodiodes quantum efficiencies.

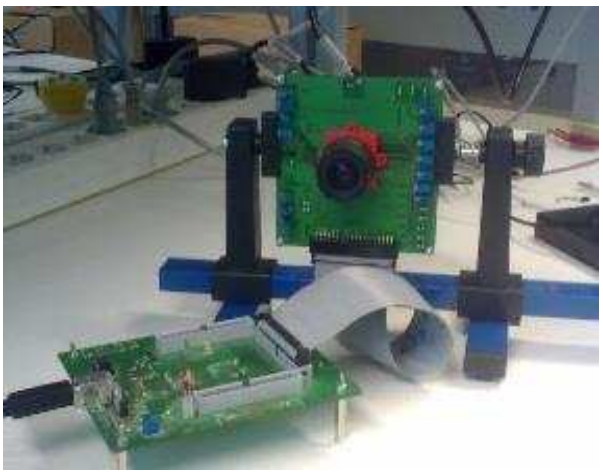

Figure 3–Experimental setup: vision sensor and data logger.

Experimental Results

Figure 3 shows the experimental setup. We designed a custom board for the vision sensor. That board is connected to a data logger that sends the output data to a PC. We programmed a dedicated Java interface (jAER open source) to compute the values of $I'_{\{B,GB,RG\}}$ and show real-time color images. Main system specifications are summarized on Table I.

Table 1 –System Specifications

Array Size	22x22
Technology	STM 90nm
Power Supply	2.5V
Chip Size	1mm x 1mm
Pixel Size	31μm x 31μm
Fill Factor	28%
Power Consumption	0.03mA @ 10Keps
Dynamic Range	>60dB

5.1. Detection of NIR levels

A real-time NIR extraction algorithm was proposed, (Leñero-Bardallo *et al*. 2013). It operates with photocurrents estimations I'_G and I'_R. The NIR levels are proportional to the photocurrents ratio after a certain number of events are received:

$$NIR = \frac{I'_R}{I'_G} I'_R \tag{4}$$

Its performance is depicted in Figure 4. Within the NIR band, the value of I'_R is larger than I'_G. To take into account the light intensity, we multiply $\frac{I'_R}{I'_G}$ by I'_R. Once we have estimated the NIR levels of each pixel, we can use this information to either create intensity images proportional to the NIR levels that each pixel detects or to estimate global NIR levels variations of the visual scene. This can be done computing the FFT of the global NIR levels within a time interval. The pixel updating frequency is in the order of *KHz* and the main NIR frequency components of a flame are below *100Hz*. Hence, the system is fast enough to track flames flickering.

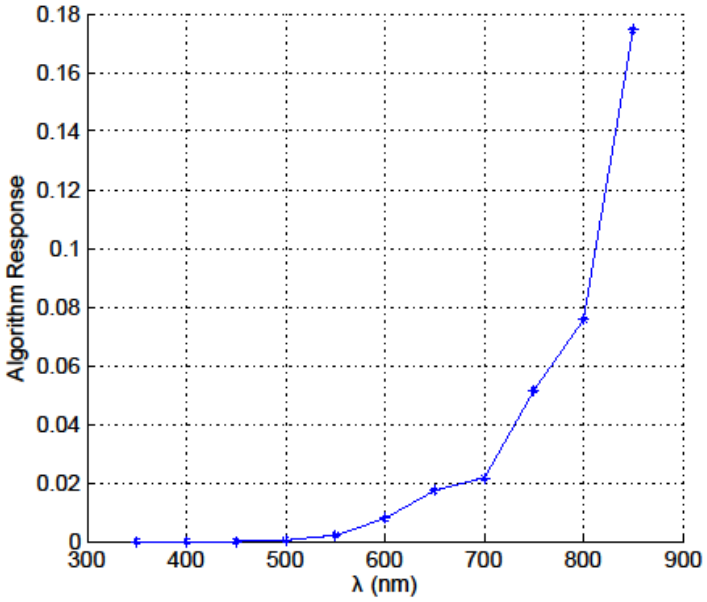

Figure 4. Algorithm response on infrared detection mode. The sensor was stimulated with a monochromator emitting light at different wavelengths.

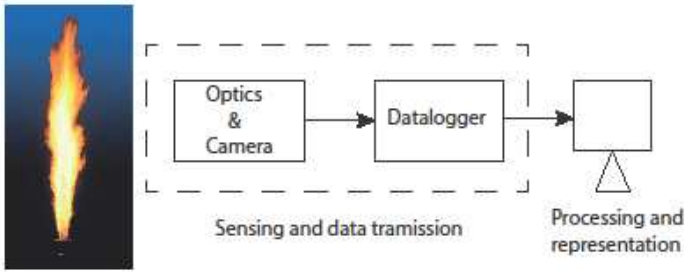

Figure 5. System Diagram for fire detection.

Figure 5 shows a diagram of the experimental setup operating with flames. A gas lighter emitting flames was placed in front of the sensor at a distance of *0.5m*. Figure 6 displays the temporal variations of the NIR levels of the visual scene with and without flames. With flames the NIR levels change with a very characteristic periodicity due to the flames flickering. Without flames, the NIR levels are much more stable. Figure 7 shows the spectra of temporal NIR variations with flames in indoors and outdoors environments. Results are quite similar to the ones reported by other authors with other methods based on optic filters (Yan *et al*. 2006). Sunlight provokes an increase of the average NIR level of the scene and makes more challenging the frequency analysis.

A custom Java interface (jAER open source) was programmed to show real-time NIR images as it is depicted in Figure 8. The interface can display images and implements the NIR algorithm previously explained. Figure 9 shows a snapshot of the NIR levels emitted by a flame. The different regions of the flame can be distinguished. The root and the central region of the flame have less energy than the periphery where the flame emits more energy in the NIR band.

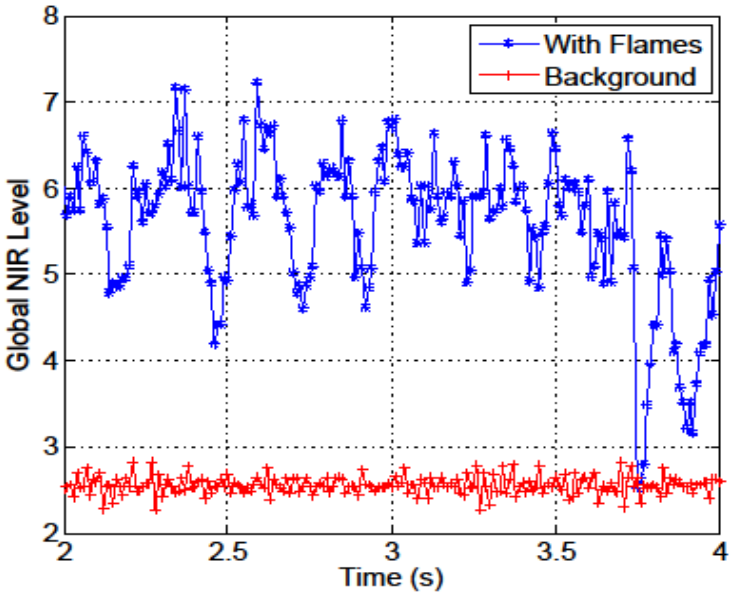

Figure 6. Real-time temporal variations of the NIR levels of the visual scene in different environments with and without flames.

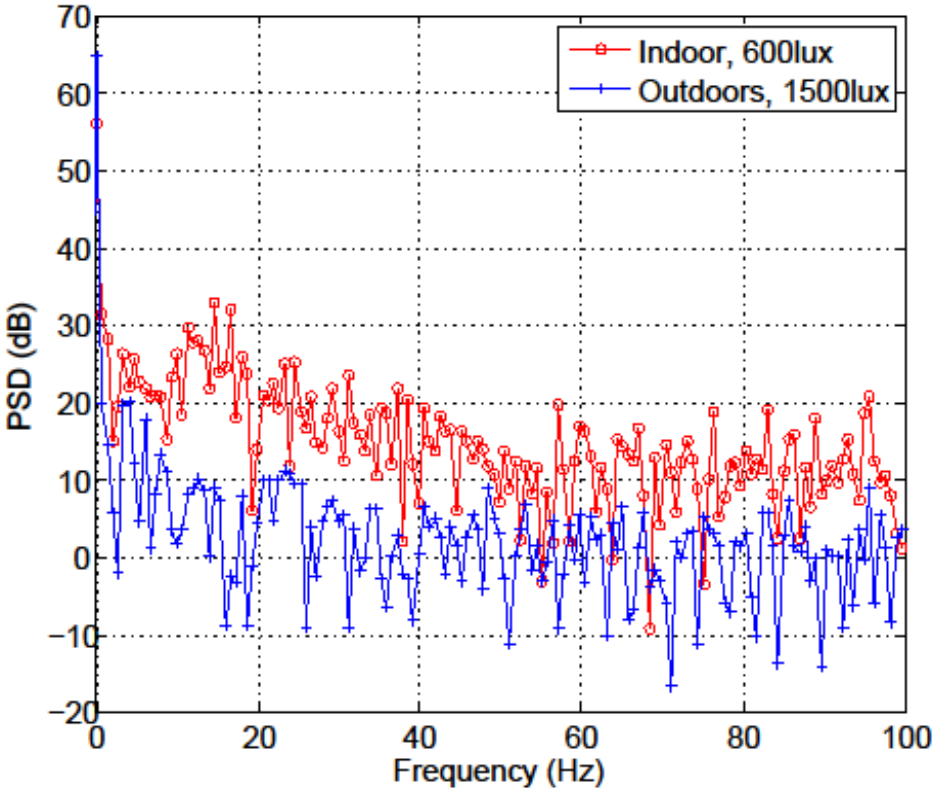

Figure 7. Frequency components emitted by a flame in indoors and outdoors environments. Outdoors the average NIR level is higher due to sunlight.

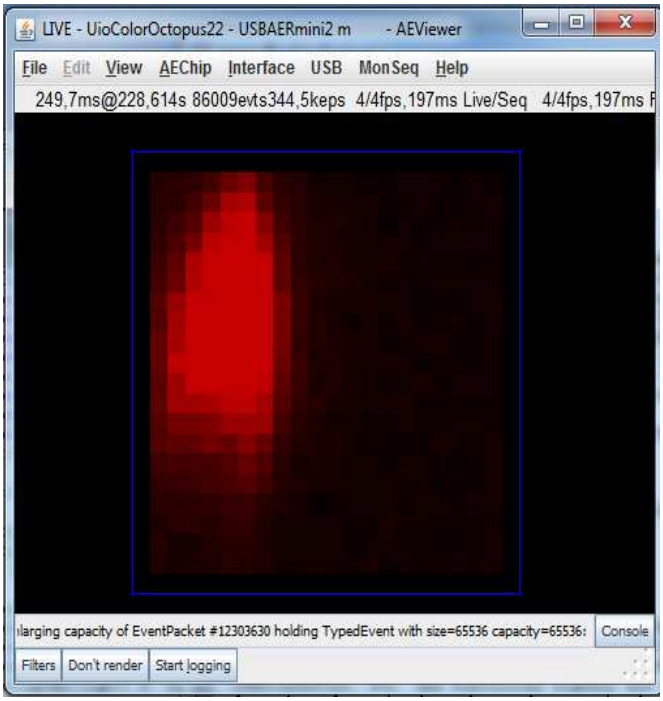

Figure 8. Computer interface showing real-time NIR levels emitted by one flame.

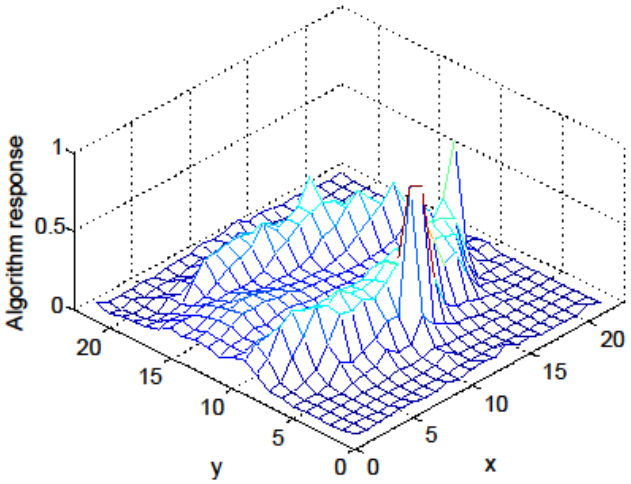

Figure 9. Snapshot showing NIR levels when the sensor was exposed to a flame. It is possible to distinguish the different regions of the flame according to (Yan et al. 2006).

New approach to detect fire

So far an algorithm has been successfully employed to monitor NIR variations of the visual scene and to compute the flame frequency components: see 0 and 0. Once we have computed the global NIR levels in the scene, we can compute periodically the standard deviation of the previously recorded NIR levels and normalize it.

$$A[n] = \frac{\sigma_{NIR} \cdot N}{\sum_{k=0}^{N-1} NIR[n-k]} \tag{5}$$

The parameter $A[n]$ represents the variations of the NIR levels within the visual scene. It does not depend on illumination. If its value exceeds a certain limit, we can assume that there are flames in the scene. Depending on how many previously recorded samples are considered to compute the average NIR levels (see 0), the value of $A[n]$ with and without flames will be different. Thus there is a trade-off between algorithm execution speed, the algorithm robustness to false alarms, and the number of events that have to be received to detect fire. 0 illustrates the values of the normalized standard deviation computing the average NIR levels of the scene with different number of global NIR levels previously computed. Without flames, $A[n]$ values are always lower than 5%. With flames, such value is higher two or three times higher. To prevent generate fire alarms, a value of $A[n] \geq 10\%$ seems to be practical according to our measurements.

The algorithm only requires to store N previously estimated NIR levels and to update the value of $A[n]$ periodically. To reduce the computational cost detecting fire $A[n]$ could be updated every second, for instance.

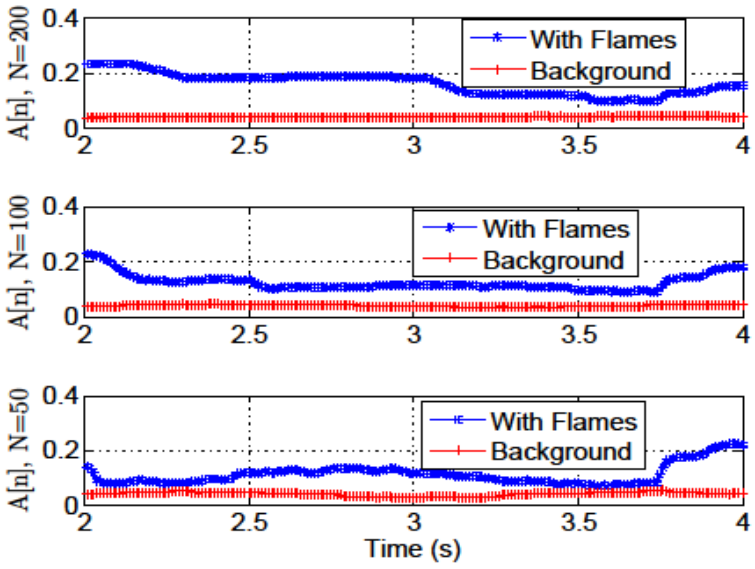

Figure 10. Normalized standard deviation computation. With flames, the value is always higher than without flames. The normalized value does not depend on illumination conditions.

7. Conclusions

In this paper we have presented event-based sensors as an alternative to classic frame-based vision sensors for fire detection and surveillance systems. One particular example of a system with a bio-inspired camera that can be used to monitor flame activity is shown. The sensor outputs can be processed real-time to obtain NIR levels from the visual scene. Furthermore, we have extended this prior work define a real-time algorithm that detects fire in the environment analysing the transient variations of the NIR levels of the scene. Our goal is to create a portable system that emits an alarm if fire is detected in the visual scene. Experimental results with flames are provided. 0 summarizes the main system features.

Abstract
Decisions made by firefighters during suppression operations are highly dependent on personal judgement, experience, and senses. However, recent scientific and technological advances offer a vast number of possibilities towards advanced emergency preparedness during firefighting operations, if integrated in a single on-line platform. In this context, this paper addresses the following question: can models be successfully merged with personal sensors aiming to build an advanced Decision Support System (DSS) focused on the preservation of firefighter's safety, while pursuing an enhanced response to wildfires?
The goal of this research is to develop an emergency response support system for firefighting ground-based operations during forest fire events. The target of the under-development computational tool is to provide knowledge-based aid to firefighters at critical decision-making situations, helping with the safe and successful management of fire. This DSS will support the following features:
- capture of 'live' sensor data from a set of wearable monitoring equipment that will be based on a previously developed certified medical wearable technology named "VitalJacket®";
- capture of meteorological observations from a mast placed in one of the vehicles;
- enable projections of fire progression, smoke levels and critical exposure in a predefined time-step (up to 30 minutes);
- interpretation of results in an easy and intuitive form to be used by fire managers or firefighters involved in operations.
To achieve this goal hardware technology (e.g. wearable, mobile, communications) was combined with processing/simulation software algorithms that run under a user interactive interface. A data assimilation technique will allow near real-time observations from wearable monitoring equipment to be integrated into the exposure forecast modelling system, increasing the accuracy of the estimates.
A first prototype of the DSS, running in off-line mode, will be tested in the terrain during the fire season of 2014. An improved online version of the prototype will be tested in the following autumn in a series of prescribed burns.
In conclusion, this work proposes the development and testing (under real conditions) of a DSS intended to provide optimized firefighting efficiency, enhanced hazard awareness, and knowledge-based response to forest fire events. Advances in the computational modelling of fire and smoke behaviour, in conjunction with personal monitoring data, provide near real-time simulation of local fire conditions and short-term smoke exposure forecasts, with the needed advance in time to permit the safe and efficient positioning of crews in the terrain.

***Keywords**: fire safety; smoke exposure; emergency response support system.*

Introduction

At the operational level, firefighters face extremely severe conditions including steep terrain, falling debris, obstructions to movement, heavy equipment, high temperatures, reduced visibility and toxic atmosphere. Smoke is, in this context, a magnifier of the destructive potential of fire. In fact, a significant number of the casualties occurring in forest fires is caused by smoke inhalation and consequent faint or disorientation due to heavily impaired visibility conditions [e.g., Miranda *et al*., 2005, 2012a]. Firefighters, in particular, are affected by short to long-term health disorders, as shown by several studies [Reinhardt and Ottmar, 2004; Reisen and Brown, 2009; De Vos *et al*., 2009; Reisen *et al*., 2011; Miranda *et al*., 2005, 2010, 2012a]. Miranda *et al*. [2010, 2012a] have shown that forest firefighting can expose firefighters to very high concentrations of carbon monoxide (CO), and also to high concentrations of nitrogen dioxide (NO_2), volatile organic compounds and particulate matter, with potential harmful effects on health, even in wildfires with small burnt areas. A particular concern is the peak and short-term exposure to CO because of the strong increase of the exhaled CO and carboxyhemoglobin (COHb) observed in firefighters after the exposure to smoke, meaning that the oxygen delivery to the body's organs and tissues is strongly diminished after smoke exposure.
Despite the advances on the numerical simulation of fire progression and smoke dispersion, operational models for assisting with decision are still limited in accuracy, resolution, and performance. Meteorological and air quality forecasts can provide some additional help but they are limited to coarse spatial and temporal resolutions.
However, recent developments on new sensor technologies, connectivity solutions and numerical models open unprecedented opportunities for anticipating or mitigating the risks associated to the inhalation of toxic gases. In this context, this paper addresses the following question: can models be successfully merged with personal sensors aiming to build an advanced Decision Support System (DSS) focused on the preservation of firefighter's safety, while pursuing an enhanced response to wildfires?

DSS development and testing

The goal of this research is to develop an emergency response support system for firefighting ground-based operations during forest fire events. The target of the under-development computational tool is to provide knowledge-based aid to firefighters at critical decision-making situations, helping with the safe and successful management of fire. This DSS will support the following features:
- capture of 'live' sensor data from a set of wearable monitoring equipment [Teles *et al*., 2011] that will be based on a previously developed certified medical wearable technology named "VitalJacket®" [Cunha *et al*., 2010; Cunha, 2012] [http://www.biodevices.pt];
- capture of meteorological observations from a mast placed in one of the vehicles;
- enable projections of fire progression, smoke levels and critical exposure in a predefined time-step (up to 30 minutes);
- interpretation of results in an easy and intuitive form to be used by fire managers or firefighters involved in operations.
To achieve this goal hardware technology (e.g. wearable, mobile, communications) was combined with processing/simulation software algorithms and user interactive interfaces. In that sense, and as a result of the requirement analysis, a conceptual architecture of the system was designed, as schematically represented in Figure 1, which relates the different modules and actors intervening in the process.

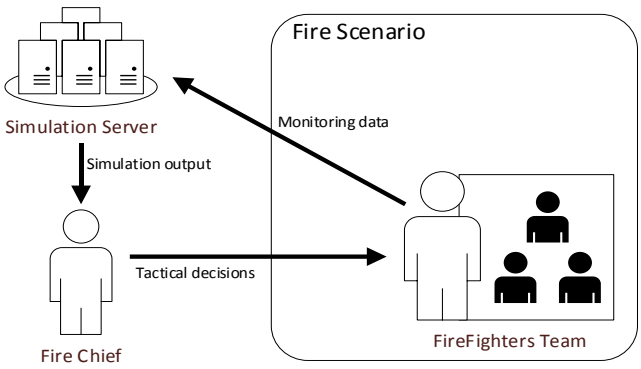

Figure 1. Schematic representation of system deployment.

General framework

As can be depicted in Figure 1 the dataflow relies on a modelling system capable of providing the needed information on fire and smoke behaviour. A simplified scheme of this integrated modelling tool is shown in Figure 2.

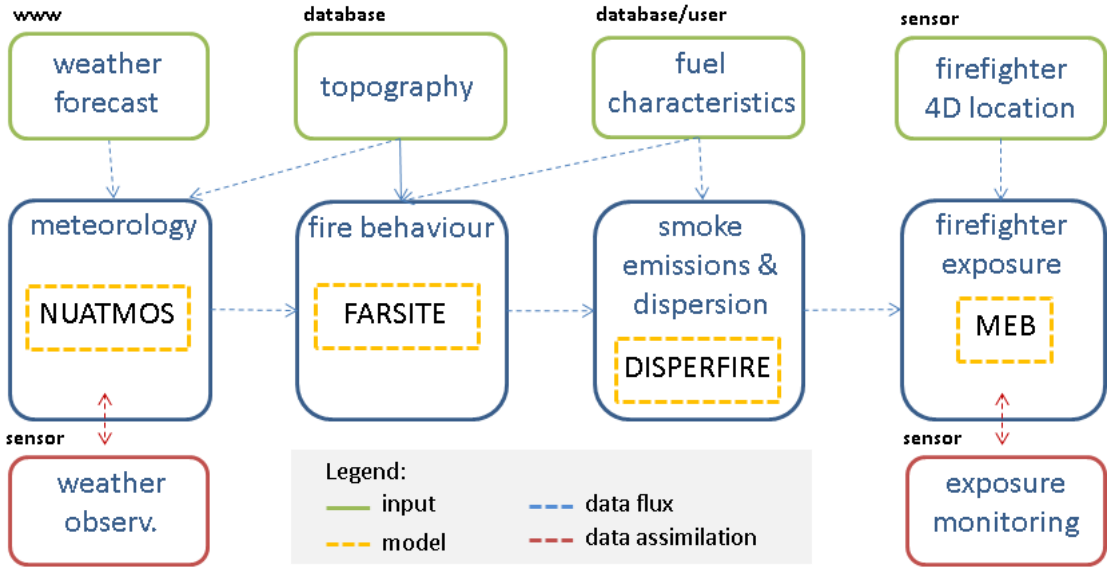

Figure 2. Schematic representation of the DSS core structure.

Graphical user interface

In order to provide a friendly way to interact with the end users, a JAVA Server Faces web interface called “VRTeam” was developed. This web developing platform was chosen because of its flexibility, for instance, the user can access the interface through any computing device (e.g., laptop, tablet, smartphone) with a standard browser and internet connection.

In terms of implementation, the interface works as a client application of two web services:

- "VRData", a JAVA Rest web service (jax-rs standard) that receives, processes and provides the monitoring data acquired in the terrain;
- "VRSimulationEngine", a JAVA WSDL web service designed to operationalize the numerical simulation models and return the results.

Concerning the interface graphical aspect, a hybrid approach between visual attraction and operability aspects was followed, as it is presented in Figure 3.

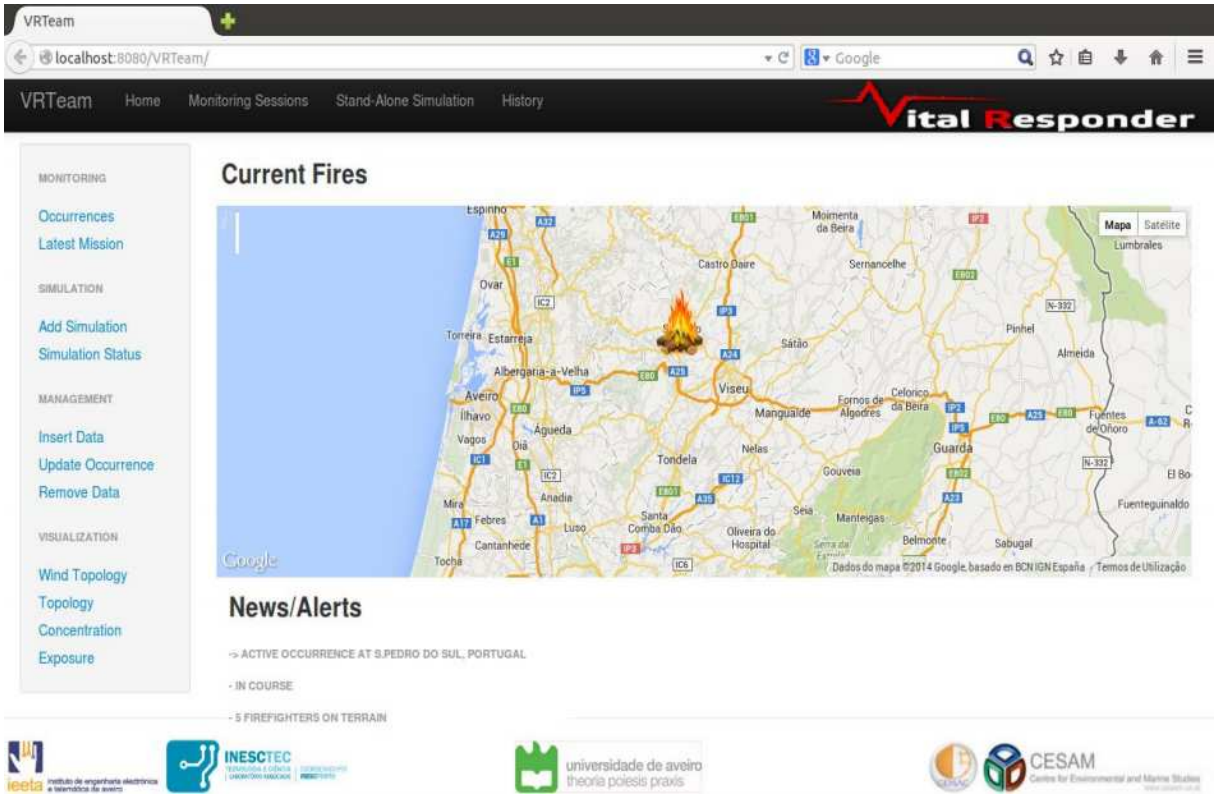

Figure 3. Main menu of the graphical user interface (GUI).

As can be seen in the above figure, the home page consists of a dashboard allowing users to view all active fire occurrences in course. Option buttons (in the left and top of the screen) are available that enable the access to all features provided by the system, namely:
- visualize monitoring data from active fire occurrences;
- simulate fire/smoke behaviour for an active occurrence;
- perform a stand-alone simulation for a random area.

Under development are other capabilities, such as the enriched visualization of occurrences history and monitored/simulated data, visual warnings of hazardous conditions for firefighters and advanced data analysis features for research purposes.

2.3. **Modelling system**

As shown in Figure 2 the numerical modelling architecture is composed of 4 independent models, which compose the main cores of the numerical system. These models are responsible for the simulation of local meteorological fields, fire progression, fuel consumption, smoke production and atmospheric dispersion, and human exposure. The numerical codes implemented have been previously tested [e.g. Valente *et al*., 2007] although not as an integrated system.

The different modules have been linked using a web service developed in JAVA (WSDL standard). This web application implements the workflow depicted in Figure 2 in a way that each numerical model corresponds to one execution stage. Any client application can make execution requests on the web service that are performed by the GUI application. Once an execution request is made, a simulation session for that user is created, and the forecast workflow begins. All related data is kept in cache so every user can have feedback about his simulation job status (see Figure 4).

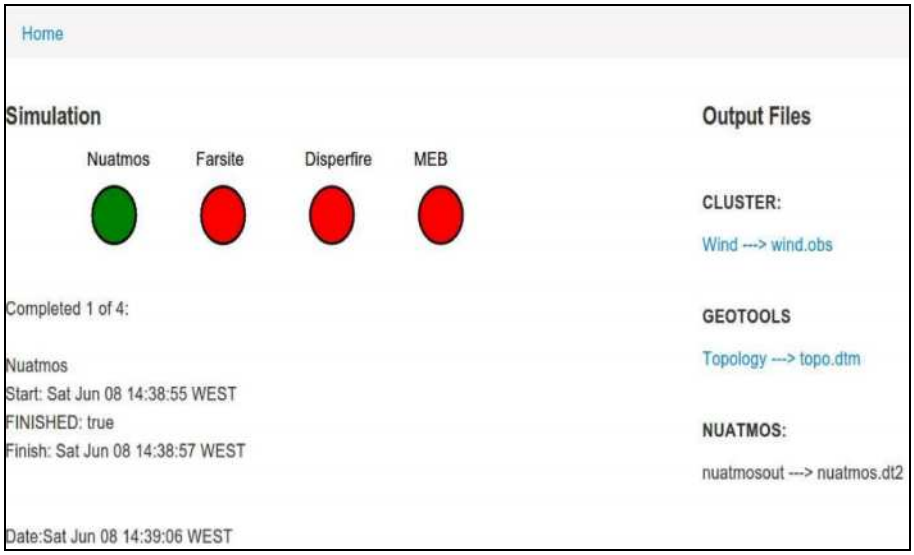

Figure 4. Example of GUI's feedback about the simulation status.

At the end of each execution, the results are stored in the cloud file system (e.g. Dropbox), and the outputs can be viewed using the GUI (section 2.5).
The main features of the numerical modules are hereafter briefly described.

Fuel

An adequate representation of the structural complexity and diversity of fuels, encompassing all the components that have the potential to burn (as trees, shrubs, grasses, woody material, litter, and duff) is needed for an accurate simulation of fire progression and smoke emission. Under development the incorporation into the system of a fuel classification tool based in the Fuel Characteristic Classification System (FCCS) [Ottmar *et al*., 2007] that will allow capturing the structural complexity, geographic diversity and potential flammability of typical Portuguese fuels. This tool is based in the concept of fuelbeds, which provides an easy identification of fuel characteristics in the terrain, and an accurate estimation of fire hazard and smoke emissions. Typical Portuguese fuelbeds were identified and built using the National Forest Inventory, other fuels datasets, published scientific literature, and fuel photo series. The mapping of the defined fuelbeds using vegetation classification and quantitative vegetation data is under development, as also the possibility of the user define the fuel model by selecting, through a touch-screen button, the corresponding image in the interface.

Meteorology

The diagnostic wind model NUATMOS [Ross *et al*., 1988], which has already been tested in this scope with good results [Valente *et al*., 2007; Borrego *et al*., 1999], produces a 3D mass consistent wind field through the interpolation of meteorological values distributed throughout the domain of interest. Instead of relying on meteorological observations, the system is connected to the meteorological forecast modelling system running at the University of Aveiro, thus providing also forecasts for the area.

Fire behaviour

The fire growth simulation model FARSITE [Finney, 2004] incorporates existing models of surface fire, crown fire, point-source fire acceleration, spotting, and fuel moisture. The model produces vector fire perimeters (polygons) at specified time intervals, which makes it adequate for the integration in the DSS.

Smoke behaviour

The estimation of forest fire emissions and the simulation of the atmospheric dispersion of the emitted pollutants are carried out by DISPERFIRE [Miranda *et al*., 1994; Valente *et al*., 2007]. Emission factors specific for southern European conditions, and particularly for the Portuguese forest and shrubland [Miranda, 2004], are implemented. The injection height of the smoke plume is estimated following the Sestak and Riebau [1988] methodology, while the subsequent transport and dispersion mechanisms are tracked using a 3D Lagrangian approach.

Firefighter's exposure to air pollution

It is important to distinguish between concentration and exposure. While the first is a physical characteristic of the environment at a given place and time, the latter quantifies the interaction between the polluted atmosphere and the person [Ott, 1982]. The exposure of each individual in the crew is estimated with MEB model [Miranda *et al*., 2012b], which follows the microenvironment approach from Hertel *et al*. [2001]. Basically, the time evolution of the exposure is simulated by tracking, in each time-step, the georeferenced firefighter's position and the corresponding concentration on that location and time.

2.4. Data assimilation

Under development is a data assimilation technique that will allow near real-time observations from wearable monitoring equipment to be integrated into the exposure forecast modelling system, increasing the accuracy of the estimates.

2.5. Outputs

As described, the system handles two types of data: monitoring data acquired by sensors on terrain and numerical forecasting outputs. Hereafter, the data provided by the system, and corresponding graphical output on VRTeam interface, are briefly described.

Monitored data

The system was designed to support a vast number of monitoring variables due to the scalability properties needed at this level (namely, the possibility of adding more sensors to the grid). At the present version the tool is capable of receiving, processing and displaying the following physiological and environmental variables:

Table 1- Monitored data.

Variable	Units
Terrain elevation	m
Atmospheric pressure	hPA
Air humidity	%
Air temperature	ºC
Luminosity	%
CO concentration	ppm
NO_2 concentration	ppm
Firefighter's location	UTM
Firefighter's heart rate	beats/min
Firefighter's R-R interval	s

The monitoring data is handled by *VRData* module. This module performs the caching of the last data received from the sensors in the terrain during half an hour periods (maximum caching time window). *VRTeam* interface consumes the online cache of *VRData* to present all information to end users, as line charts or custom grid tables (see Figure 5).

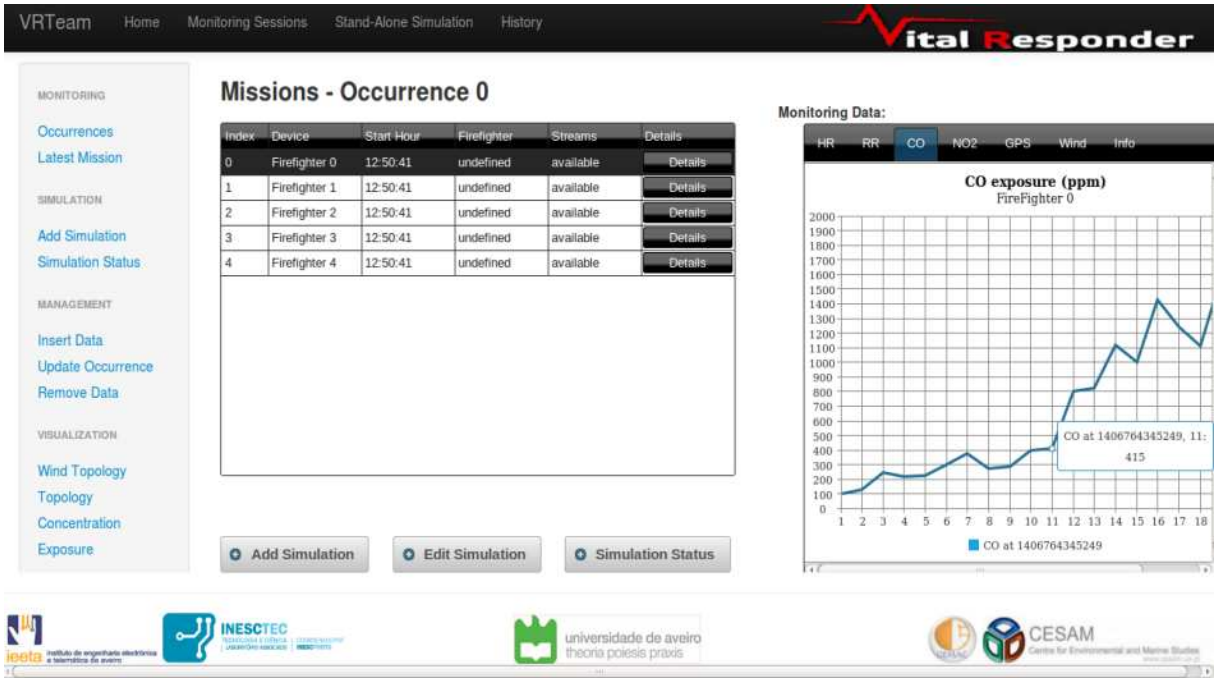

Figure 5. Example of monitored data shown in the GUI.

Simulated data

The results of the simulation's workflow are produced by the *VRSimulationEngine*, which runs the different numerical modules. Figure 6 shows an example of the information available to the *VRTeam* users after a complete simulation session. Enriched visualization of simulation results is shown using multi-dimensional representation of the outputs.

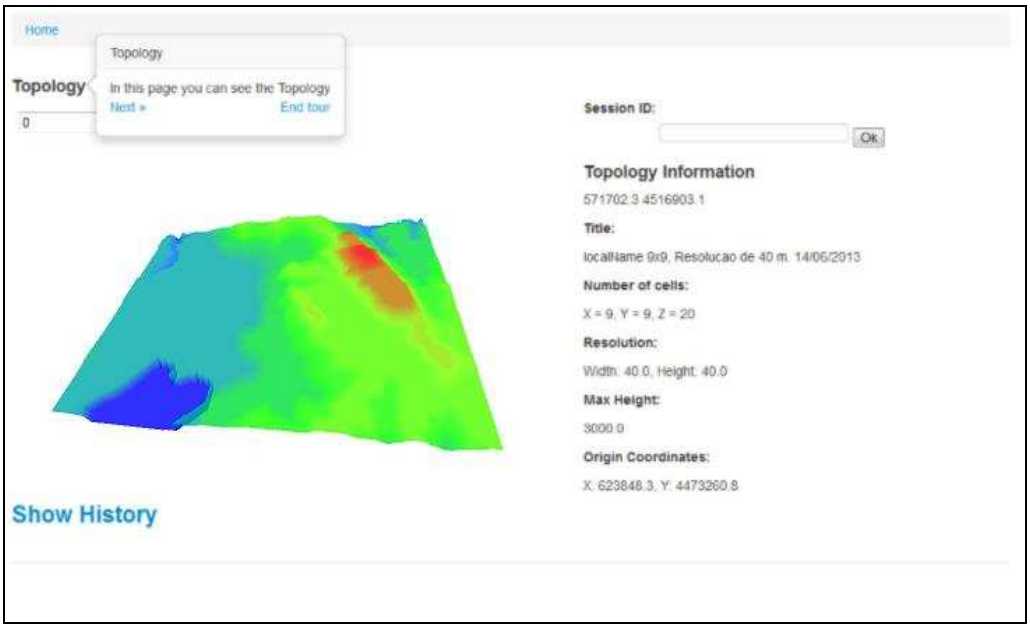

Figure 6. Example of simulation data shown in the GUI.

2.6. Operational testing

A first prototype of the DSS, running in off-line mode, will be tested in the terrain during the fire season of 2014. An improved version of the prototype will be tested in prescribed burning occurring in the autumn of 2014.

Conclusions

Decisions made by firefighters during suppression operations are highly dependent on personal judgement, experience, and senses. However, recent scientific and technological advances offer a vast number of possibilities towards advanced emergency preparedness during firefighting operations, if integrated in a single on-line platform.

This work proposes the development and testing (under real conditions) of a DSS that will provide optimized firefighting efficiency, enhanced hazard awareness, and knowledge-based response during wildland fire. Advances in the computational modelling of fire and smoke behaviour, in conjunction with personal monitoring data, will provide near real-time simulation of local fire conditions and short-term smoke exposure forecasts, with the needed advance in time to permit the safe and efficient positioning of crews in the terrain.

Abstract
Wireless sensor networks have attracted a great deal of research due to the wide range of applications that are enabled by such networks. Sensor networks are used for ecological monitoring, military surveillance and biomedical detection. This paper describes a design of a wireless sensor node to be used for early forest fire detection; it utilizes the WSN principle where each node is a sensing device with various sensors attached, powered by solar recharging and supports wireless data transmission. Each one of these nodes sends its collected data through the network to reach a sink node. The latter has a direct link with a base station (weather station, civil defence operation room, or scientific research center). The base station analyses the received data and takes the decision accordingly to raise a fire alarm or not. The main parameters involved in the decision making are smoke, CO, temperature, humidity and methane gas. This paper details the design as well as the experimental activities which demonstrated that this device is capable of early forest fire detection.

Keywords*: Forest Fire, Detection, Wireless Sensor Network, Energy Efficient.*

Introduction

Forest fires pose a menacing danger to the socio-economical, ecological, and environmental aspects of a community. Moreover, forest fires cause severe “ecological imbalances" through endangering the natural habitats of animals, disrupting the food chain in a vast area that exceeds the burned zone, reducing ground water levels, polluting rivers, and preventing vegetation from growing in burned zone. More specifically increasing fire frequency and severity, threatening forest ecosystems and economic development [Mitri, 2009]. All this gives rise to the urgent need to detect forest fires as fast as possible, so as to limit these effects.
Systems used for forest fire detection can be divided into three groups based on where the sensors are deployed: aerial, terrestrial, or combination. It is worth noting that in many cases similar sensors are used in aerial and terrestrial systems. However, depending on the location of deployment there might be different advantages and disadvantages.

1.1. Aerial Forest Fire Detection

The areal detection is subdivided into two main categories: Satellite Systems and Autonomous Aerial Vehicles. There are two types of satellites that appear in the context of forest fire detection. These are the geostationary satellites and the polar orbiting satellites. The geostationary satellites maintain a higher temporal resolution compared to the orbiting ones. This is the reason why geostationary satellites have an advantage over the polar orbiting satellites in near-real time active forest fire detection. In most cases the satellites are used with a base station that collects the data sent by the satellite(s) and runs the analysis [Manyangadze, 2009, Zhou, 2004, Kelh, 2000, Abuelgasim, 2002]. Satellite imaging is used by several agencies for detecting and tracking fires; such as the Canadian Wildland Fire Information System of the Canadian Fire Service. Three well known satellite systems used for fire detection are the (AVHRR) launched by the National Oceanic and Atmospheric

Administration (NOAA) in 1998, the Moderate Resolution Imaging Spectroradiometer (MODIS) launched by NASA in 1999 on board of the Aqua satellite and the National Aeronautics and the Space Administration's Moderate Resolution Imaging Spectroradiometer (MODIS). The use of satellites for forest fire detection and monitoring remains a dominant option. Yet, this system suffers from a set of disadvantages:

- There is a minimum detectable fire size, usually 0.1 ha. This means that there is some delay to detect the fire, which is at least equal to the time it takes for the fire to go beyond 0.1 ha.
- The accuracy of the system is within 1 km of the actual location of the fire.
- Satellites typically provide images of the monitored area every 1 to 2 days, which is a limitation as fires could go undetected for a long time.
- Clouds greatly affect the Top of Atmosphere temperature as they may lower the temperature measured by the satellite. The interpretation being that clouds usually have cold tops and hence low brightness temperature; thus, fires under these clouds are missed.
- Selection of the processing algorithm varies for different sensors with each having its specific limitations.

Autonomous Aerial Vehicles use a helicopter with infrared and visual cameras [Dios, 2005, Casbeer, 2005]. These helicopters are called “Autonomous Aerial Vehicles" or “Unmanned Aerial Vehicles" (UAVs). A base station is needed as well where the collected data is analyzed. Fire detection is initiated in missions where a UAV fleet embarks on patrolling the forest in question. In order to decrease the probability of false alarms, this system relies on the combined results obtained from the analysis of infrared and visual images. Navigation sensors are installed on the UAV to compute the position and the orientation of the cameras. These calculated positions are then collected in order to locate the actual fire. This system suffers from some disadvantages such as:

- Covering large forests requires the use of a larger number of UAVs or a longer flight time per vehicle, which means more consumption of fuel yielding a higher overall operational cost.
- Monitoring a forest is very difficult when unfavourable or extreme weather conditions are present. In addition, limited visibility when smoke is present.
- Assessing fires will vary significantly depending on the topology of the forest in question.
- Scheduling of the flights poses another concern in this mechanism since issuing UAV flights throughout the day will result in a waste of resources and in an increase in cost.
- Radio communication can be hindered in mountainous areas
- Cost of UAV's starts at around 7000$ and they require specialized personnel to operate and maintain them.

1.2. Terrestrial Forest Fire Detection

Several terrestrial systems have been investigated which include: video surveillance, radio acoustic sounding, fiber optic sensor network, wireless sensor network and a combination of the above.
Video surveillance systems are the most widely used for forest fire detection [Kovcs, 2004, Losso, 2006, Stipanicev, 2006, Bodrozic, 2006, Dios, 1999, Arrue, 2000, Bosch, 2007]. In this system, camera sensors are mounted on communication towers that are placed on a location overlooking a large part of the forest. It is not uncommon for cameras to be mounted on towers of elevation often surpassing 30m, making maintenance and even initial deployment a non-trivial affair. In order to provide a full view of the forest, or a specific portion of it, a rotational mechanism is installed to enable the camera

to rotate. The images obtained by the sensors are processed to detect smoke. This is made possible by the use of algorithms that takes into consideration atmospheric conditions.
Radio Acoustic Sounding System (RASS) refers to the use of wave radiation in order to obtain the atmospheric structure. This system utilizes two main devices which are the radio with fire watch towers and the acoustic source [Sahin, 2009]. The approach is to form thermal maps of forest areas for the detection of potential fires. This relies on the fact that radio acoustic sounding techniques have much higher sensitivity to temperature changes and can remotely provide more accurate air temperature measurements. The process of temperature measurement using acoustic sound waves is made available by a Sonar, or acoustic radar, that operates by transmitting acoustic pulses into the atmosphere and detecting echoes backscattered from atmospheric thermal inhomogeneites. This technique is very effective and reliable and it is believed that, in terms of accuracy, it surpasses any other fire detection technique. Yet, it still has several disadvantages and technical difficulties that are:

- The deployment strategy of this system is critical to the performance. This is due to the fact that echoes in collected data are caused by ground clutter.
- It is reported that the scanning area is to be limited to a certain height that is just above the trees.
- The performance is sensitive to the frequency matching and the power of the signal. The optimal results are only obtained once the frequency and the power of the acoustic signals are determined, taking into consideration several issues such as the forest surface density and the distance between the radar and acoustic sources.

Fiber Optic Sensor Network uses a network of fiber optic sensors based on “Fiber Bragg Grating" (FBG) devices, distributed sensors and gas analyzers, and optoelectronic piloting unit for the grid of fiber optic sensors [Corsi, 2006]. This system is composed of FGB temperature sensors, an FBG acquisition assembly to collect data from FBG sensors, distributed fiber optical sensors to collect distributed temperature variation over the fiber, roads upon which to lay the cable through the forest, and gas sensors and their acquisition unit. The number of sensors and the length of the fiber optic cable depend on the nature of the forest. The FBG temperature sensors measure the temperature values in the presence of fire. The gas sensors collect samples of air, measure the content for CH4, and report the results to their respective acquisition unit. The advantage of this system is that the effect of temperature variation on the wavelength of fiber optics can be exploited to generate ultra-stable temperature sensors. This system has two main drawbacks:

- The fiber optic cables need to be installed throughout the forest on a special type of road or path.
- Crown fires take longer time to be detected, if ever, depending on the height of the trees. This is the case since the cables are laid on ground level.

Recently, a promising technology has emerged based on Wireless Sensor Networks [Hefeeda, 2007]. Sensible Solutions Sweden AB developed robust and environmentally friendly sensors, which can be placed in trees. When high temperatures are detected for a few seconds these sensors transmit a radio signal alerting of the possibility of a fire. The disadvantage of such a system is that it does not provide any environmental measurements which can be used to assess the risk of a fire starting. In addition, they are based on detecting high temperatures, which might take a long time to reach a sensor and which implies sensors only detect fires that do reach them. Temperature, relative humidity and barometric pressure where used in a wireless sensor network to demonstrated experimentally that variations in these parameters could be used to detect fires [Doolin, 2005]. The Forest Fire Surveillance System was designed and deployed in South Korea [Son, 2006]. The nodes used measure temperature, humidity and light. Neither of these approaches used smoke detection to improve the performance of the network. In addition, neither of the references discussed the practical requirements of packaging needed to deploy the sensor network. Several papers had mentioned wireless sensor networks as a tool

for forest fire detection [Yu, 2005, Chaczko, 2005]. However, these papers focused on theoretical issues related to sensor networks in general such as in-network processing and data collection. The work in both papers was theoretical with no actual nodes or network being designed and deployed. Also, they had minimal contribution to the task of early forest fire detection. Combination Forest Fire Detection systems integrate the use of a network of optical cameras linking to a multi-layer GIS database operated by Control Operating Center [Tsiourlis, 2009]. This is referred to as the ``SITHON'' system. The SITHON system consists of a wireless network of optical cameras and an airborne fire detection system based on a fully digital thermal imaging sensor. In turn, the network of optical sensors consists of monitoring towers, transmitters, and wireless transmission links up to an integrated GIS environment. This system shares the drawbacks of all of its components.
In addition to the above mentioned systems, is the none traditional Mobile Biological Sensors [Sahin, 2007]. Animals living in a forest are used to assist in the early detection of the fire. These animals are technically referred to as ``Mobile Biological Sensors'' (MBSs). This system is composed of the MBSs, thermal and radiation GPS equipped sensors, access points for wireless communication, and a central computer system. Data is checked for sudden movement of group of animals, which is believed to be a result of panic among those animals. There are some technical limitations involved in this method:

- Animals and sensors should be chosen in accordance with the characteristic of the forest in question and the forest fire type to be detected. For example, crown fires, surface fires, and ground fires cannot all be detected by installing sensors on reptiles.
- Sensor selection depends on the animal species that is chosen.
- Powering these sensors is another concern as they are expected to operate for a long time.

In this paper we present the design and evaluation of a wireless sensor node for the early detection of forest fires. The rest of the paper is organized as follows. Section 2, describes the proposed design, the operation and the packaging of the device. Section 3 reports the experimental results.

Methods

In order to achieve fire detection within a reasonable time, a number of detection devices (including all its subcomponents) should be deployed in different strategic spots in the forest. This implies that there should be a wireless network linking all these devices together. All the data and signals collected, shared, and transmitted between these devices ought to be sent to a remote base station, located somewhere inside or even outside the forest itself. This base station may be a civil defense office, weather station, office for statistics and analyses, or any concerned authority. Therefore, in order to link this sub-network in the forest to that base station, at least one of the devices in the forest has to serve as a gateway or a “sink" of all the signals and data emanating from the forest devices (sources) to their final destination. Note that these sinks are detection devices as well. The only two differences are that they can communicate with the base station and they have their own schedule of operation. The number of these gateways depends on the topography of the terrain, area of the forest, number of regular devices inside it, and the amount and frequency of data to be sent. The general structure of the network is shown in Figure 1. The figure shows a typical architecture of a deployed network where a number of nodes are mounted on trees or poles. These nodes report to a base station with Internet access to send remote alerts of the occurrence of a forest fire.

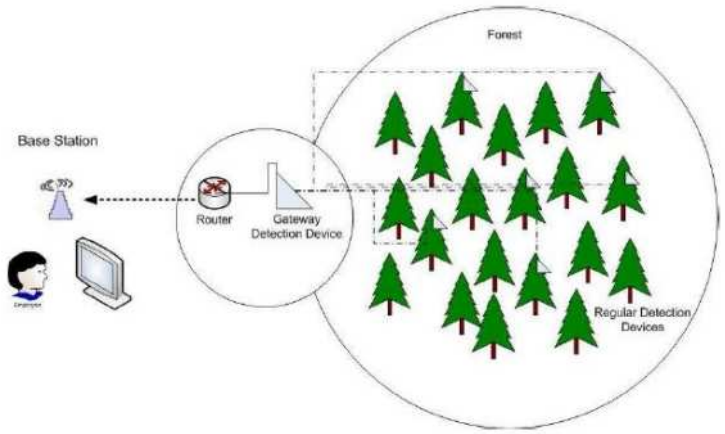

Figure 1. Network Structure

This paper discusses the design and implementation of the nodes used for fire detection. The deployment strategy is beyond the scope of this paper. The device makes use of the components shown in Figure 2.

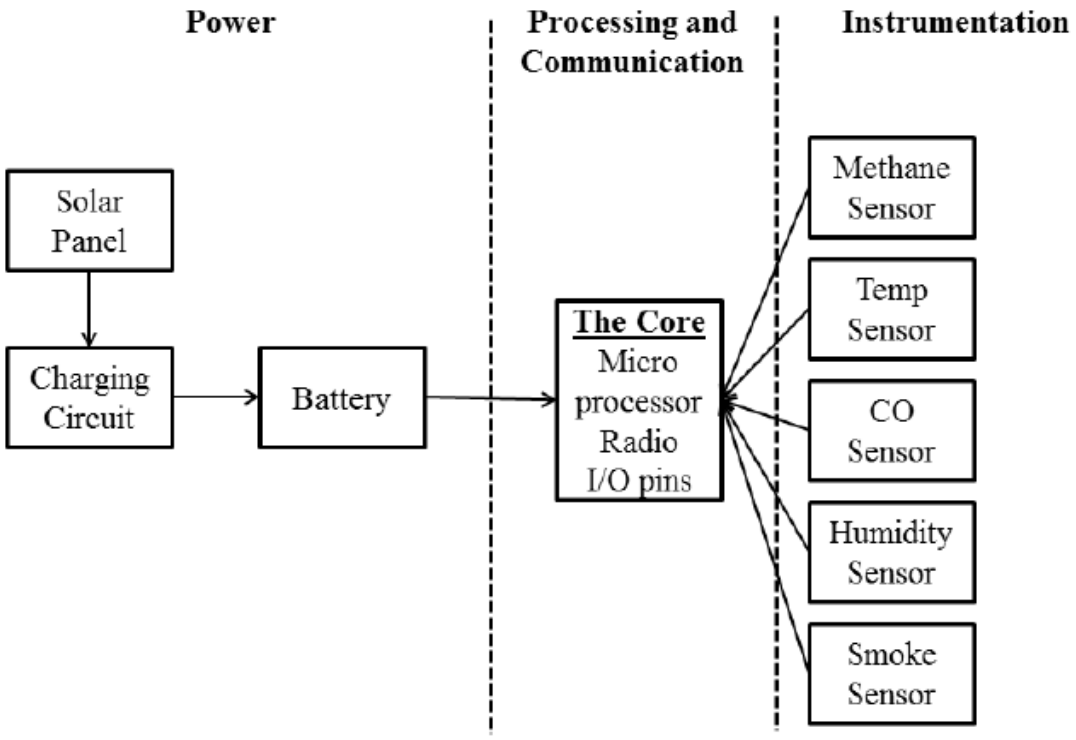

Figure 2. Device's Components

Smoke sensor can provide great help when detecting fires since smoke is the most common and spontaneous product of fire. The smoke sensor chosen is a light Scattering Photoelectric Detector. This smoke sensor produces an output of 1.5 V with a response time which varies between 10 and 20 seconds depending on the concentration of smoke.

Temperature sensor: When a forest fire occurs, huge masses of timber, shrubs, and various plants are burnt, releasing vast amounts of energy in the form of heat. This heat is dissipated in the surrounding atmosphere, causing an increase in temperature. Although this increase in temperature might be a couple of degrees, this can still be a valid indicator especially when combined with other factors. The temperature sensor used is the one built-in the Berkeley Mote (Tmote)
Humidity Sensor: Built-in the Tmote, the humidity has a significant impact on the reliability of the system design since high levels of relative humidity may deceive the smoke sensor, resulting in false alarms. So this sensor can be used to reduce false alarms.
CO Sensor: Carbon Monoxide (CO) is an evident gas released from a forest fire. The S+4CO by Sensor Direct has been used, this sensor is linear, it has a response less than 30 sec, with a resolution of 1 ppm, and a range of 0-500 ppm. However, its sensitivity is considerably low (70 nA/ppm). This implies that a very low output voltage is produced, even for the maximum input value. For instance, if the CO concentration was 500ppm, then the output of the sensor would be 35µA, which is an undetectable value by the Mote. To solve this issue, a special Potentiostatic circuit, recommended by National Semiconductor has been used. This circuit is shown in Figure \ref{circuit} and includes the LMP7721 amplifier which input bias current is only 3fA. The final output voltage of the circuit is the current value multiplied by 10000, which end up being 350mV, an easily detected value by the Mote.
Methane Sensor: Forest fires release huge quantities of combustible gases such as, Methane with average emission rate of 4.96g/kg of dry weight of trees burned. Other combustible gases have lower rates: CH3COOH (3.96), HCOOH (2.61), CH3OH (2.06), C2H4 (0.94), and C2H6 (0.58). Therefore, among the combustible gases, it is most valuable to measure methane levels, in order to help in detecting forest fires. The Methane sensor chosen is the KGS 701 by Korea New Ceramics Co., Ltd. which has an input range of (0-100\% LEL),with a sensitivity 27±5mV / % methane and with a response rate less than 10sec. This sensor also can detect a wide range of combustible gases, mainly propane, iso-butane and pentane.
Battery: a rechargeable Li-ion battery has been chosen. This battery is characterized by a high energy density, a long life cycle (around 300 to 500 cycles), a high drain capability and a fast charge capability. We have chosen a battery with an energy capacity close to 1800mAh and a voltage of 3.7V, since the mote operates on a voltage range of 2.1V to 3.6V.
The Li-ion battery needs a special recharging circuit that guarantees its power functioning and protects it from being damaged. Several requirements are to be considered:

- Set a minimum threshold of input charging voltage.
- Maintain a constant charging voltage independent from the variation of the solar panel's output voltage.
- Stop charging when the battery if full
- Prevent the battery from discharging into the panels when the voltage is low
- Prevent an over-current to enter into the battery, which may damage it.
- To achieve the special charging, the most appropriate IC found was the LTC 1734 by LTC 1734 by Linear Technology, described as “A Lithium-ion Linear Battery Charger". Some of the characteristics of the LTC 1734 are:
- Programmable charge current: 50mA to 180mA
- 1% accurate pre-set voltage: 4.2V
- Charge current monitor output for charge termination
- Automatic sleep mode with input supply removal
- Negligible battery drain current in shutdown
- Under-voltage lockout
- Self protection for over-current/over-temperature

Linear Technology recommends a special circuit to include the LTC 1734 within. Figure 4 shows the LTC 1734 designed to deliver a current of 80mA.
The resistor connecting pin 4 to ground is the control element, which determines the delivered current, based on the following equation:

$$I_{Bat} = \frac{375}{R_{Prog}}$$

Solar Panel: Solar energy is selected due to its higher energy density, simple implementation, reliability, and cost effectiveness. Six solar panels are used to deliver the appropriate energy needed; each rated at 3.7V and 85mAh. This bank of panels is connected as shown in figure 3.

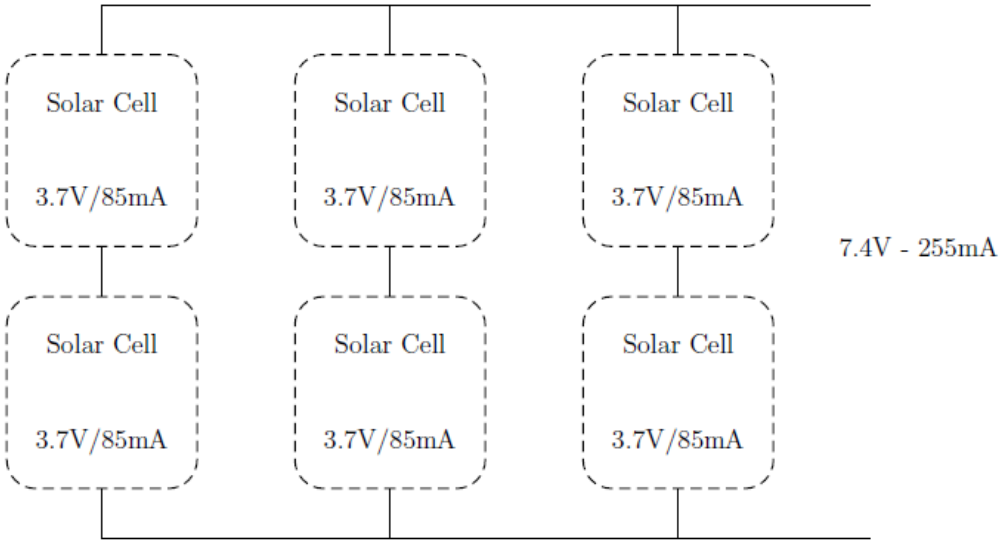

Figure 3. Solar Panel Connections

This configuration produces a nominal rated voltage of 7.4V that is sufficiently higher than the required charging voltage of the battery.
Tmote Sky (Mote-developed by Berkeley University): The core of the node is the processing needed for the sensor outputs, communicating the data to the sink, and checking if there is a fire. The core includes a microcontroller to collect the data coming from the sensors and communicate them. This core is the mote named Tmote Sky that is ultra-low power device and was intended to be used in wireless sensor networks. The mote can be connected to the USB ports of the computer where it can be programmed. Besides, it includes Chipcon CC2420 radio for wireless communication that supports IEEE 802.15.4. It operates at 2.4GHz frequency, and it may communicate with other motes that use the same standard. Hence, the different motes can establish a network automatically upon booting up within their communication vicinity.
The Mote uses MSP430F1611 microcontroller that includes the MSP430 microprocessor produced by Texas Instruments. The 16-bit RISC processor features extremely low active and sleep current which reduces its power consumption. This permits the mote to run for years on a pair of AA batteries. Moreover, it can function on high level operating systems like the TinyOs. This eases the programming of the mote using the NesC language supported by TinyOs.
The module of the mote was designed to fit two AA batteries; however its operating voltage ranges between 2.1V to 3.6V DC. Whenever attached through the USB port, the mote takes its power from the computer. Its power consumption depends on its operation. Consequently, different types of sleep modes can be applied by stopping the components that consume power.

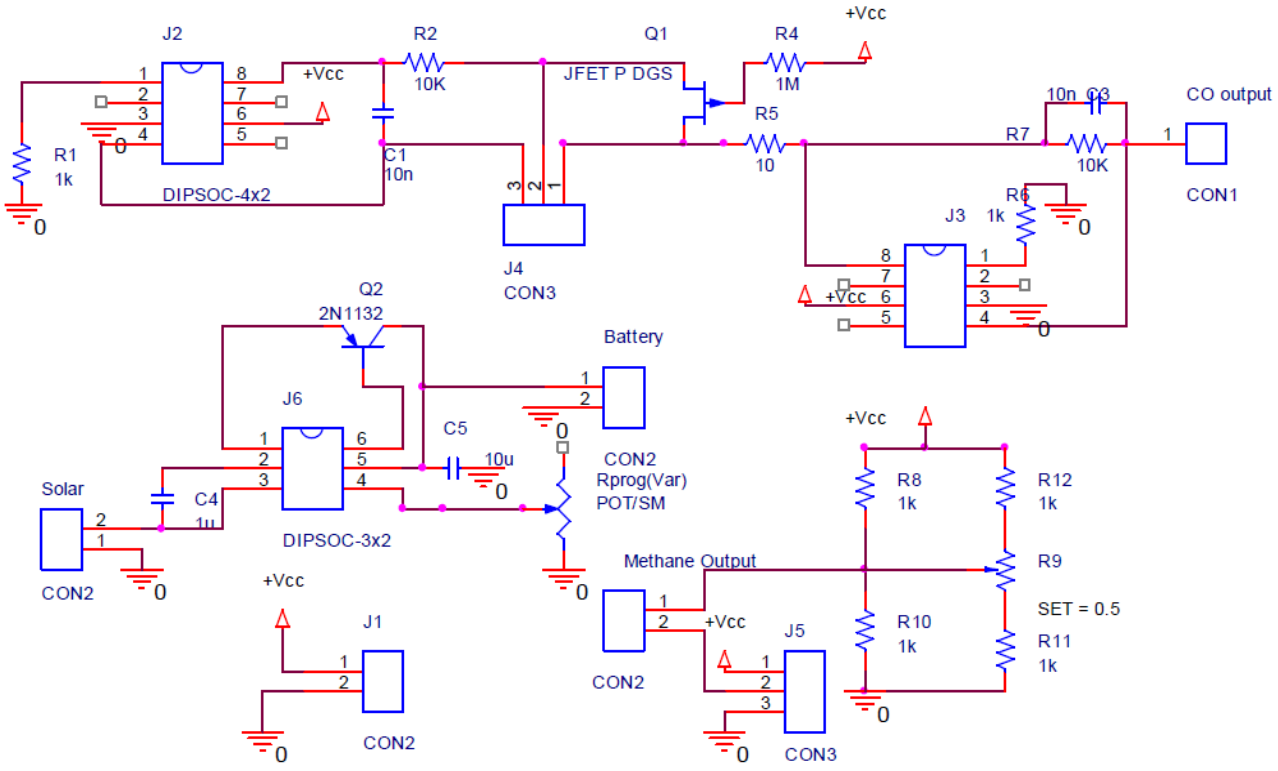

Figure 4. Circuit Design

Design Operation

The main implementation aspect of the mote is its software. The software consists of two main parts: the program on the nodes in the forest and the program on the sink (base station node). Each node shall sense the different parameters (methane, smoke, CO, humidity and temperature) and send them in a single packet to the base station that reads and processes them. The IEEE802.15.4 wireless communication protocol permits automatic setup of the network between the motes that are within communication range. Thus any packet will be routed to its destination by the network itself. The routing supported by the motes was used without modification.

The program proceeds as follows: the sampling timer is initialized by the value set by the base station, whenever it is fired; it turns the output voltage on; this will power the CO and the methane sensor circuits. Then it will initialize a 1min stabilizing timer that will wait for the sensors outputs to stabilize. After the stabilizing timer is fired the program acquires the output of the built-in sensors on the mote, the value of the operating voltage on the mote, and the output voltage of the methane, smoke and CO sensors. Finally all the read values are added to the packet and sent to the base station. The sampling timer can be configured by the base station. The inputs and outputs of the sensor are connected to the expansion pins of the mote where they can take power and send their outputs. The Mote will be in sleep mode when the sampling timer is running. See Figure 5 for the flowchart of the code.

For design reliability, the smoke sensor will remain always on as an existence of smoke will surely mean that there is fire and its output will be used as an interrupt that will awake the mote and send the alarm packets whenever there is smoke. For the methane, its output is the difference between high and low outputs. The two outputs are connected to the mote and their values are subtracted through the software. Both the Smoke and the CO sensors outputs are acquired directly.

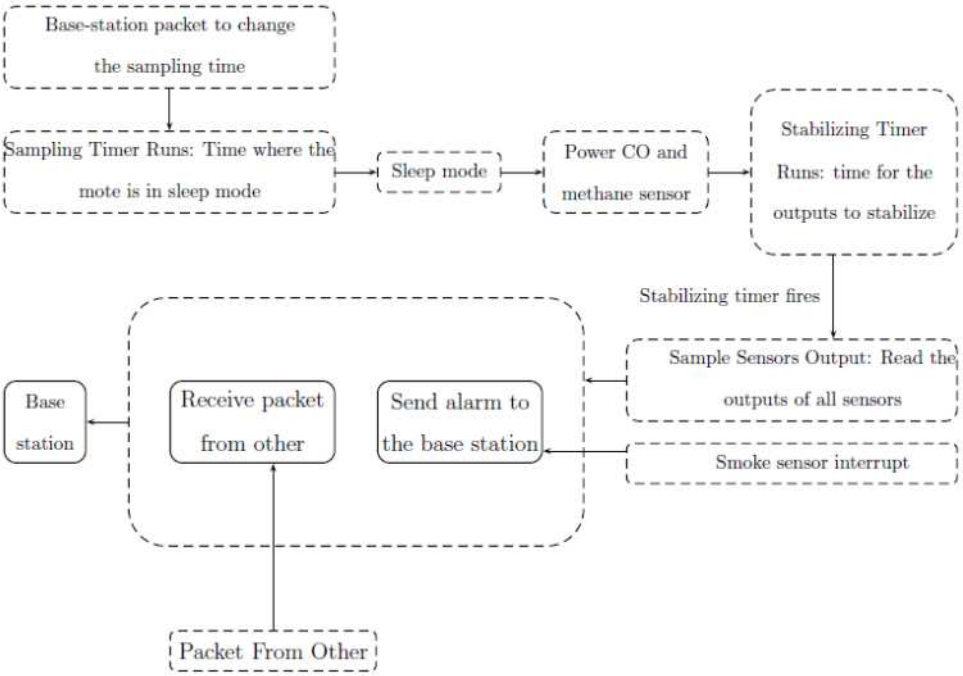

Figure 5. Script Flowchart

Device Packaging

The general shape of the package is right triangular prism where the sensors emerge from the bottom facing downwards. The top cover holds the solar panels and makes an angle of 34^o with the base of the package to increase the solar radiation. The device can be mounted on a pole or tree form the vertical side and its base will be parallel to the horizontal plane. One of the sides can be easily removed in case any component needs to be replaced, modified, or introduced. Figure 6 shows the finalized package.

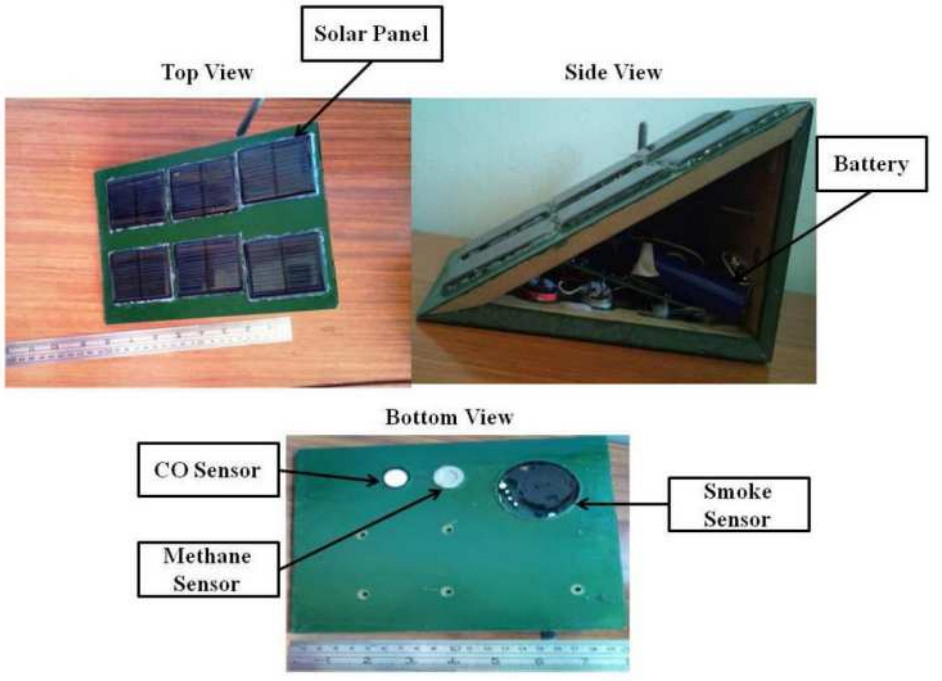

Figure 6. Fire Sensor Module Different Views

Results

Tests were conducted for each sensor and fires were burnt in controlled conditions at different heights. Ash and paper were burnt at the vicinity of the smoke sensor to test its performance. Ten experiments were conducted and the resulting outputs are shown in Table 1.

Table 1. Smoke Sensor Performance T: time, H: height, 1: fire detected, 0: fire missed

T / H	t	t+1	t+2	t+3	t+4	t+5	t+6	t+7	t+8	t+9	Average
0.5 m	0	1	1	1	0	1	1	1	1	1	80%
1 m	1	0	1	1	1	0	0	1	1	1	70%
1.5 m	0	1	0	0	1	1	1	0	1	0	50%

Table2 - CO Sensor Concentration in ppm T: time, H: height

T / H	t	t+1	t+2	t+3	t+4	t+5	t+6	t+7	t+8	t+9	Average
0.5 m	129.2	141.2	114.5	149.5	156.4	147.4	150.4	153.1	145.4	142.1	142.9
1 m	111.7	86.8	115.2	121.4	130.4	117.7	103.0	98.0	105.7	100.5	109.0
1.5 m	84.2	50.8	46.0	86.4	63.4	43.71	74.8	56.8	47.1	49.8	60.3

Table 3- Methane Sensor - % of air composition by volume T: time, H: height

T / H	t	t+1	t+2	t+3	t+4	t+5	t+6	t+7	t+8	t+9	Average
0.5 m	3.463	5.130	5.104	4.230	4.815	3.593	4.111	5.026	4.800	5.107	4.538
1 m	4.085	2.833	3.289	2.863	2.956	3.900	4.063	3.363	4.537	2.841	3.473
1.5 m	2.293	2.185	2.896	2.952	1.826	2.385	2.304	2.678	2.793	2.878	2.519

The results recorded in Table 1 show that the smoke sensor succeeded in detection 80%, 70% and 50% of the time at 0.5m, 1m and 1.5m respectively. The average amplitude of the output voltage generated by the smoke sensor varied from one experiment to another with an average value of 1.5V, which is easily digitized by the mote. It is also important to note that the detection is performed quickly and in close range which is necessary to detect small fires that satellites cannot detect.

Ten experiments of incomplete combustion were done to test the CO sensor with its circuit. A big piece of paper was slightly burnt and then inserted in a bottle. The bottle was closed and got filled with CO. The bottle is then opened and exposed to the sensor. The output CO concentration is shown in Table 2.

The values obtained in Table 2 vary between 46ppm and 156ppm, with an average of 120ppm, which is the typical concentration of CO in such a fire. Moreover the concentration decreases as the distance between the sensor and complete combustion increases. The output voltage ranged between 100 and

130mV, with an average value of 120mV. Taking into consideration the 20mV offset, the output increase is 100mV, which is a significant value, compared to the amount of released CO.
The methane sensor was tested using an unregulated methane source in 10 experiments. We exposed the output of the source to the membrane of the sensor with separation of about 10cm, and released the gas. The average response time was two seconds. The output voltage ranged between 80mV and 160mV, with an average of 110mV. These values signified that the sensor and circuit were working correctly. The percentage decreases as the distance between the sensor and the source increases.
It is worth noting that for all sensors the accuracy of measurement is not critical as the sensitivity. The detection works on processing change in normal operation to detect an increase of a gas. So the absolute value is not as important as the change in the sensor output.

Conclusion

This paper described a sensor node to be used for forest fire detection. The sensing device is characterized by various sensors attached to a mote, solar recharging mechanism, and wireless data transmission capability. The main parameters involved in the decision making are smoke, CO, temperature, humidity and methane gas. The results show high accuracy (80%) of fire detection for close range and slightly lower but acceptable accuracy for higher ranges (60%). As for future work, this device can be used for forest fire prediction in addition to detection. Moreover, the deployment plan and strategy has to be developed to optimize the operation of the overall network.

Abstract
Fire suppression continues to be a costly endeavour in the United States and elsewhere. In order to develop a systematic approach to allocating resources to fight wildland fire, it is necessary to understand the underlying process by which ignitions occur on a continental scale with respect to fire weather. We therefore developed a technique that simulated a gridded fire weather index from historical observations and then simulated ignitions at a local scale. The procedure required two steps. First, a model for fire-days (at least one fire occurring on each 30km pixel) used the localized percentile of the ERC (energy release component) as a predictor. A logistic regression model using ERC percentile at that pixel predicted a binary response (fire-day/no-fire-day). Then, for those pixels where at least one ignition occurs, a VGAM (vector generalized additive model) with a Pareto response also used ERC percentile as the predictor. This yielded a dataset of simulated ERC percentiles and the associated number of ignitions for each pixel and each day. The related metadata for each ignition (cause, time of detection, etc.) are sampled from the historical distributions conditional on location. What results is a simulated equivalent of the Fire Occurrence Database which is ready for use in applications for strategic planning.

Keywords*: Spatial temporal simulation, ignition generation, energy release component, Pareto distribution*

Introduction

In order to develop a system to test various fire suppression resource allocation strategies, it is necessary to have a mechanism to simulate the distribution of ignitions across very large land areas. The main problems facing resource allocation are 1) local scarcity of resources created by ignition episodes (large number in short time frame), and 2) broad-scale scarcity of resources created by spatial synchronicity of fire ignition episodes. Firefighting resources dispatched and coordinated at a national scale, meaning that fire occurrence patterns must reflect spatial and temporal patterns at that scale.
There are several attributes that are necessary to constitute a good practical simulation method. First, the distribution of the simulated ignitions must follow approximately that of the historical distribution at the local scale. This means that the overall shape of the distribution, the rough total number of ignitions, as well as extreme behavior must be similar to a great extent. Second, the overall number and seasonal distribution over the entire country must be similar. Third, the method must make use of the historical relationship between the number of ignitions and fire weather. Regarding the first two points, there is no statistical method that systematically provides all of these desired attributes simultaneously. Thus, we must make use of expertise and intuition in order to evaluate what constitutes an acceptable or unacceptable method.

Methods

The method consists of statistically simulating the spatial and temporal patterns of fire occurrence based on gridded daily fire danger rating index. In (Grenfell 2010), a method was described to simulate fire weather at a continental scale that has the same seasonal variability, spatial, and temporal

autocorrelation. The fire danger rating index Energy Release Component (ERC) from this modeling was used to generate ignitions. The key result from the simulation method developed there was to have simulated fire weather with similar temporal and spatial autocorrelation as the historical data. We rely on the relationship between ignition occurrence and this spatially/temporally correlated weather to provide generate the pattern of coincidence (both spatially and temporally) of ignitions. The technique relies upon a fire occurrence database (FOD) (Short 2013) which contains fire records from 1992-2011 coincident with the years generated by the weather simulation model. To choose the appropriate model, data exploration were conducted.

From the FOD, we see that the distribution of the number of ignitions at a particular pixel generally appears to follow a Pareto distribution. In Figure 1, data for a Fire Planning Unit (FPU Colorado-05) are plotted as a histogram of the observed number of ignitions, a histogram where zero ignition-days were excluded, a histogram of 1000 simulated Poisson values from the estimated mean of the historical data, and 1000 simulated Pareto values with the same shape parameter as that of the historical data.

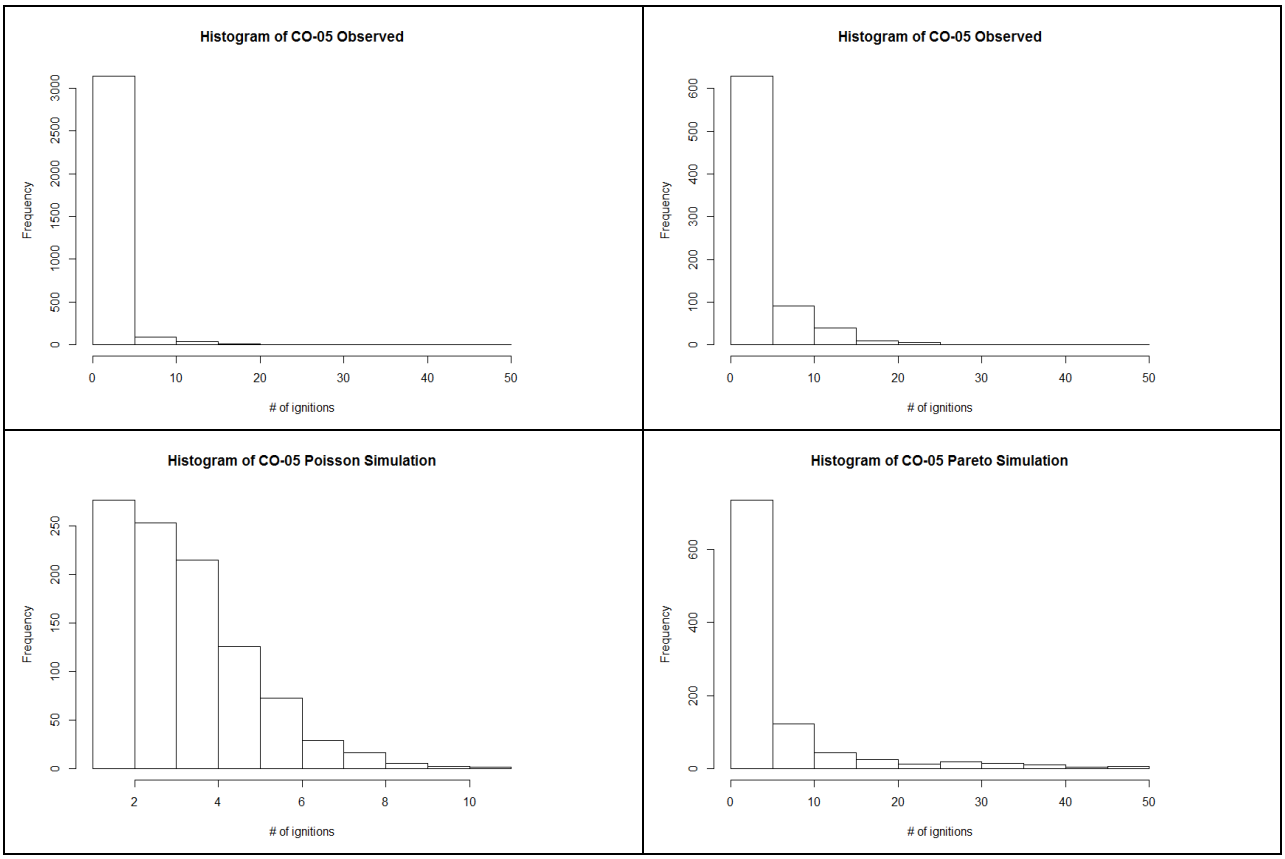

Figure 1- Above left (a), histogram of number of ignitions in FPU CO-05. Above right (b) histogram of number of ignitions on days with at least one ignition. Below left(c) histogram of 1000 simulated days using the average number of ignitions from (b). Below right (d) Histogram of 1000 simulated days using the shape parameter estimated from (b).

Notice that there are more zero-values in the historical histogram than in the simulated dataset. This is a commonly observed phenomenon known as overdispersion. In order to resolve this, we built a two stage model. For the first model, we perform a logistic regression with ERC percentile from the NARR grids being the predictor and the response being whether there are zero ignitions (0) or greater than zero (1). We use percentiles rather than just the ERC values because there are different local relationships with ERC and ignitions (a location where an ERC value of 60 would be in the 90th percentile would be indicative of high fire danger in some places, whereas a location where an ERC value of 60 would be in the 50th percentile in another location would be indicative of far more moderate fire danger).

Once we have developed the logistic models to determine whether ignitions (at least one ignition) have occurred or not, we then use the VGAM package in R in order to perform a Vector Generalized Additive Model regression. This regression method allows for a much broader set of response variables, in this case a response with a Pareto distribution. It is here that the virtues of the Pareto distribution become a hindrance, as left unsupervised the erratic nature of distribution in the right tail can come to dominate the overall phenomenon. To avoid this, we truncate the maximum number of ignitions that can occur at one pixel in one day at fifty percent above the value of the 4th from last order statistic. This allows for the simulation method to produce results greater than what was observed in the historical record (which is the reason for not simply using the historical distribution in a bootstrap-like approach), while not having values so extreme that the overall behavior of the simulated results becomes unrecognizable.

With the two sets of models in hand, we can now begin the process of simulation. It is essentially just the estimation process but in reverse. First, we derive the ERC percentiles from the simulated ERC grids. We then use the percentiles at each location on each day to determine from the logistic model whether or not there will be ignitions. If there are, we use that ERC percentile in the VGAM model to determine how many ignitions will be simulated on that day. In figure 2, we se a selected day from a simulated season (Julian day 180), with a grid of the ERC values (not percentiles). In addition, we can pass on simulated metadata values taken from the FOD, such as cause and time of day. For our purposes, we simply built tables for each location and drew a sample from that.

3. Results

In order to assess the overall quality of the simulation method, we evaluate the simulated tables of ignitions and consider several qualities- the overall number of ignitions, the behavior of the extreme values of the distribution, and patterns of seasonality. To get a sense of the scale and variability in the historical and simulated data, we examine a table of the mean, median, standard deviation, median absolute deviation, and maximum for both the 19 historical years and the 41 simulated years.

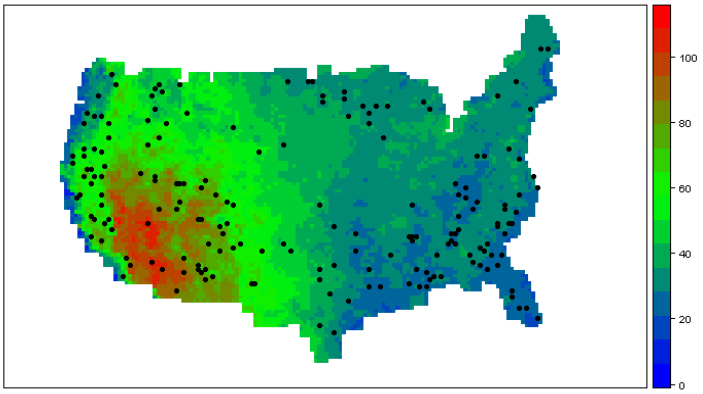

Figure 2. An example of a day's worth of simulated ERC values across the continental United States and the associated simulated ignitions for that day.

	Historical (19 yrs)	*Simulated (41 yrs)*
Mean	65,309	71,780
Median	61,225	71,556
SD	14,369	17,554
MAD	15,280	21,822
Maximum	103,120	109,930

Both the mean and median are within one standard deviation or MAD (respectively) for both the historical and simulated sets of ignitions, providing good evidence that the simulation method is doing a good job of matching the overall behaviour of the historical data.

Abstract
Knowledge and models of firefighting are of great importance for decisions on presuppression planning, dispatching of firefighting forces and operational planning of fire suppression. Significant research effort has been devoted to built such knowledge so far. However, all such information has to be interpreted carefully because it can be affected by various local factors. One example of missing information in regard to firefighting performance is the rate of hose laying by ground forces trying to reach and follow the head or flanks of a fire. Such knowledge is necessary for modelling fire suppression in countries such as Greece where direct attack on the flames using water provided by fire trucks is the main ground firefighting method. The study presented here is an experimental effort to identify some of the key factors affecting the hose laying rate and to establish some initial values for commonly encountered situations in Greece.
Data were collected by building hose lays in Aleppo pine (*Pinus halepensis*) forests with shrub understory on mount Hymettus near Athens, Greece. The hose lays were built by professional firefighters on forest roads or trails that did not hinder their movement. The parameters that were varied were a) Number of firefighters (FF); there were 2 or 3 firefighters laying hose in addition to the driver, as is usually the case with firetrucks in Greece b) Site slope (%) (SLOPE); it varied between -28 and 27%, and c) Length of hose lay (LENGTH); three lengths were selected: 100, 200, and 300 m. The trials were timed with a chronometer and a hose laying rate (HLR) was calculated. Multiple linear regression analysis of the data resulted in the following equation:

HLR = 1.028 - 0.003 * LENGTH + 0.477 * FF -0.024 * ABS_SLOPE

Where (ABS_SLOPE) is the absolute value of SLOPE and FF is the number of firefighters. The value of the equation, its limitations and its potential uses are discussed in relation to the approaches taken in other studies on fireline production rates.

Keywords*: forest firefighting, hose laying rate, Greece*

Introduction

In forest fire management, decisions on presuppression planning, dispatching of firefighting forces and operational planning of fire suppression require knowledge of the productivity, the effectiveness and the limitations of the aerial and ground resources (Xanthopoulos 2002). Numerous studies have examined and tried to model the firefighting process (Fried and Fried 1996, Fried *et al*. 2006), building on other studies that examined, for example, fireline production rates with bulldozers and hand crews (Broyles 2011), length of fire front extinguished by water and retardant drops from various types of aerial resources, etc. All such information has to be interpreted carefully because it can be affected by various local factors (Fried and Gilless 1989, Hirsch and Martell 1996). The same is true for the development and use of firefighting models.
One example of limited reliable information in regard to firefighting performance has to do with use of water under pressure and the related production rates. The studies focusing on this subject, either based on in-field measurements or on expert opinion, are relatively few and the results are very variable (Parker *et al*. 2007). This variability is the result of the multitude of influencing factors such terrain, wind speed, flame height and fuel type. It might be possible to reduce this variability if the effect of

various factors is first measured separately and then the effects are combined. For example, in regard to water based ground firefighting, it might be possible to examine the rate of hose laying by ground forces trying to reach and follow the head or flanks of a fire, before considering the difficulty of extinguishment posed by the variation in flame length.
The study presented here is an experimental effort to identify some of the key factors affecting the hose laying rate (HLR) and to establish some initial values for commonly encountered situations in Greece. This subject has received relatively limited attention globally and there is no specific knowledge for Greek conditions. Such knowledge is necessary for modelling fire suppression in countries such as Greece where direct attack on the flames using water provided by fire trucks is the main ground firefighting method.

Methods

Data were collected by building hose lays in Aleppo pine (*Pinus halepensis*) forests with shrub understory on mount Hymettus near Athens, Greece. The hose lays were built by professional firefighters on forest roads or trails without vegetation that would hinder their movement. The hose used for all tests was of the type most commonly used for forest firefighting by the Fire Service in Greece: 2.5 cm (1 inch) in diameter adhering to the standard PR EN 1924-1, in lengths of 25 meters with Storz type couplings. The parameters that were varied were:

- Number of firefighters (FF). There were 2 or 3 firefighters laying hose in addition to the driver, as is usually the case with firetruck crews in Greece.
- Slope (SLOPE). It varied between -28 and +27%.
- Length of hose lay (LENGTH). Three lengths were selected: 100, 200 and 300 m.

The experiments took place between June and November 2012. Weather conditions, namely air temperature, relative humidity, wind speed, sunshine or cloudy conditions, were recorded for each trial. The aim was to check for probable influence of these factors in the performance of the firefighters. The trials were timed with a chronometer and a hose laying rate (HLR) was calculated by dividing the length by the time (m/s). A total of 24 trials were performed (Figure 1).

Figure 1. A photo of one of the hose laying trials

Analysis and results

The data were analyzed using the SPSS statistical software. The descriptive statistics of the data set are shown in Table 1. HLR varied between 0.7 and 2.44 m/s (2.052 to 8.784 km/h). The highest HLR was achieved by 3 firefighters creating a 100 m long hose lay downslope, on a 14% slope.

Table 1. Descriptive statistics of the 24 record data set.

Parameter	N	Minimum	Maximum	Mean	Std. Deviation
Temperature (ºC)	24	15.0	32.0	22.79	5.2670
Relative humidity (%)	24	24.0	75.0	59.79	18.2350
Wind speed (km/h)	24	1.9	27.8	10.500	5.7424
Number of firefighters (FF)	24	2.0	3.0	2.50	0.5110
SLOPE (%)	24	-28.0	27.0	1.125	17.7462
LENGTH (m)	24	100.0	300.0	175.00	84.6990
HLR (m/s)	24	0.57	2.44	1.3041	0.52909

Multiple linear regression analysis using the stepwise procedure excluded the weather parameters from the list of selected independent variables. As steep slope may impede efforts both upslope and downslope a derived variable ABS_SLOPE, equal to the absolute value of SLOPE, was calculated and tried. The model developed is:

$$HLR = 1.028 - 0.003 * LENGTH + 0.477 * FF - 0.024 * ABS\_SLOPE \quad (1)$$

The multiple regression equation has a p-value<0.001 and an adjusted R^2= 0.641. The constant of the equation has a p-value = 0.013. All the coefficients of the variables are statistically significant at the 0.005 level.

The effect of slope was investigated further by plotting SLOPE against HLR for the laying of 100 m of hose by two firefighters (six measurements) and by three firefighters (six more measurements). The data points and the polynomial lines capturing the trends are shown in figure 2. As seen, HLR increases for downslope hose laying on gentle slope, up to approximately 10%, but then drops as a steeper slope makes downslope firefighter movement more difficult.

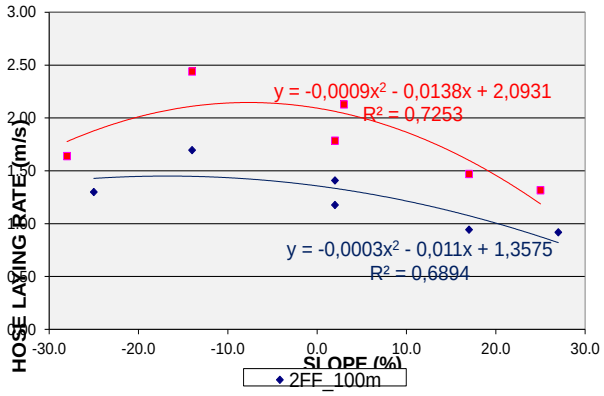

Figure 2. The effect of SLOPE on HLR for hose laying tests of 100 m LENGTH by two or three firefighters.

Discussion and conclusions

The equation developed identified three of the important variables affecting HLR and can be useful in ground fire fighting modelling in Greece, namely number of firefighters, length of hose lay and slope. The lack of influence of weather conditions can be explained by the lack of extreme conditions at the time of the tests and the short duration of each trial which does not allow fatigue to build-up. These conditions may be important if firefighting continues for hours.

The equation can be used for quick calculations either in the form of a table or of a graph (figure 3). It is recognized that it has limitations due to the small sample size, the limited range of values of the variables and the omission of certain other influencing factors such as building hose lay in thick vegetation that impedes movement of the firefighters. The most important weakness is that it does not account for the increase in HLR when hose is laid downslope on slopes less than about 15%. A larger data set would be needed in order to establish with confidence the exact slope threshold beyond which negative slope reduces HLR. If using the equation for estimating HLR for laying hose on negative slopes (downslope) in the range 5-15%, for example in a computer based model for fire suppression, it is suggested to use the HLR estimated for 0% slope increased by 10% in order to reduce error.

The HLR values calculated by equation (1) should be considered as optimum. Such performance can be expected realistically by non-fatigued initial attack firefighter crews arriving to a fire. Future work on the subject is expected to provide additional data and to even allow examination of a non-linear influence of the independent variables on HLR outside the range of values tested so far.

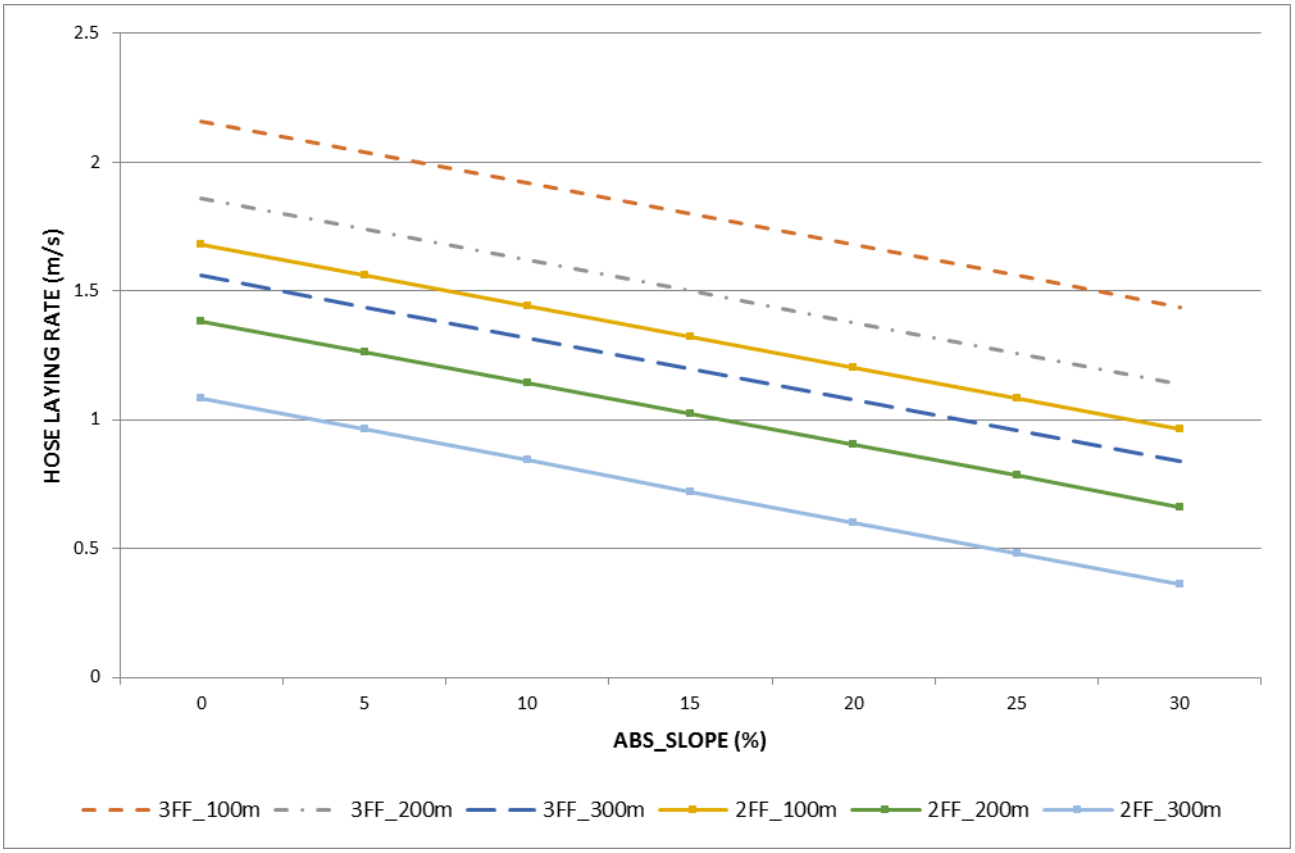

Figure 3. HLR vs ABS_SLOPE according to equation (1), for teams of 2 and 3 firefighters and hose lay lengths of 100, 200 and 300 m.

As a final note, it should be mentioned that the HLR values reported here are not comparable with the values reported in studies such as those of Fried and Gilless (1989) or reviewed by Parker *et al*. (2007) because they do not include fire extinguishment of any short as is the case in those studies. Thus, they can be used, for example, when trying to estimate the time required for reaching a fire front or flanking with hose. Then, the fireline production rates with engine hose lay depending on the type of vegetation (as for example reported in Table 1 of Fried and Gilless (1989)) can be used.

Instant foam technology to improve aerial firefighting effectiveness

Agoston Restas

National University of Public Service, Budapest, Hungary, Restas.Agoston@uni-nke.hu

Abstract
Introduction: This paper describes a new technology, making the process of aerial firefighting more effective. Instant foam technology based on adopted patent, called Foam Fatal, used by petrol industry. Methodology: Before starting the project prepared a study which is focused the economic efficiency of aerial firefighting. This study says that the effectiveness of aerial firefighting using just pure water is very limited but there are possibilities for extending this effectiveness. Instant foam technology can use any traditional foam solution in a special tank installed on board and this liquid emitted in the required place by pressure. Whit this process the quality of the created foam become very homogeneous and some feature also can be modified during the process. Results and discussion: No doubt, in the market there are already some special water tanks, even with pressured systems, however the results comparing the extended efficiency of the instant foam technology to the others is notable. Moreover, instant foam technology is even cost effective, making the process of aerial firefighting real effective.

Keywords*: instant foam, homogenous foam structure, effective fire suppression, aerial firefighting*

Introduction

One effect of global climate change is the increased risk of forest and vegetation fire and the higher intensity of these fires, thus the resulting damage is more severe. The application of aircraft and helicopters in large-scale forest fires is a globally widespread practice. They can transport great amount of extinguishers, mainly water to places which road vehicles cannot reach. However, even this amount is often not enough. The author aims to present a potential new method of increasing the effectiveness of extinguishers.
The new technology is based on a Hungarian patent[1], whose goal is to effectively extinguish extensive fires of containers used in petroleum industry with instant foam. The adaptation of this technology in forest fire fighting has raised interest. Thus, the author wishes to introduce and develop this technology as an innovation in the market of forest and aerial fire fighting with the consent of the owner of the patent. The article describes the author's related research, result and the adaptation of the technology.

Possibilities and barriers of water extinguishing

Theoretical backgrounds of water extinguishing

The most common extinguishing material used in fighting against forest fire is water. Unfortunately its maximum volume is objectively limited on surface (Csontos *et al*., 2007). Twigs of an average age (40 – 80 years) pine forest is able to hold about 4 – 5 litres water per square meter. These amounts of water makes the surface wet but using more amounts will drop to ground and be out of the burning zone without any effect. All resources we used for carrying this water can be evaluated as a waste and useless expenditure.

[1] Foam Fatal technology; http://foamfatale.com/

Based on specific heat capacity of 1 litre of 20 C^0 water [1] (4.2 kJ/kgC^0 x 80 C^0 = 336 kJ/kg) and counts with its evaporation heat[2] (2684 kJ/kg) the cooling capacity is 3020 kJ/kg. Based on the 5 l/m^2 maximum weight of water on the surface its cooling capability without waste is 15100 kJ.
The volume of the biomass per square meter at a mature forest obviously can move at a wide scale. Based on the author's experience its volume which can catch fire during burn is about 6 – 10 kg/m^2. Based on Nagy (2007) its heat of combustion (≈18500 kJ/kg) is about 111000 – 185000 kJ.
Water content of the biomass is taken as 70 % (Nagy, 2007) during an extreme weather condition perhaps less. Based on the above the rate of water of a 6 – 10 kg bulk is about 4.2 – 7 kg that has to be evaporated by its own combustion heat. Cooling capacity of the above amount of water is between 12684 – 21140 kJ.
The heat combustion of the part of pine bulk, can be count during burn is (111000-185000 kJ) much higher than the common cooling capacity of water content of the bulk (12684-21140 kJ) and the maximum water amount on its surface (15100 kJ). It means with water the suppression of a developed fire is objectively not possible. The difference between the combustion heat and the cooling capacity is at the lower threshold 4 times, at the upper level 5 times higher for the combustion heat! Based on the above the practice can be demonstrated, above that fire intensity where 5 kg/m^2 water is not enough for suppression, the active, fighting tactics is avoided with pure water even in case of aerial firefighting (Georges, 1975; Hardy, 1985).

Losses of aerial firefighting

Losses during transportation

In case of helicopters there are significant water losses during transportation. Bucket has no cap therefore there is a friction between the water surface and moving air. This effect, like the Bernoulli principle, takes lots of water out from the bucket and it looks like an evaporation cloud above-after the bucket. This loss depends mainly on the speed of transportation and the carrying distance. The other type of losses is caused by mechanical effect, mainly immediately after the upload but also during the whole transportation route. Water swing in the bucket and clashing to the wall lots of water will splash out from the bucket. Based on some observers above losses can be over 30 %, in extreme conditions even 50 % (Jambrik, 2007, Imreh at al., 2009).

Figure 1. Losses of aerial firefighting

[1] Specific heat capacity (c) of water is: 4.2 kJ/kgC^0; Formula is: E_c = c m dT = 1680 kJ
[2] Evaporation heat (p) is: 2684 kJ/kg; Formula is: E_p = p m

Losses during water dropping

After opening the valve water decomposes to drops creating water cloud. Usually it is generated by the strong airflow spontaneously; however there can be generated also some technical means. Raising the speed of the fly the rate of spray will also rise. Unfortunately, the very small water drops can leave the requested area without significant help in the suppression or the rate at the surface is below the effectiveness threshold. Some observations say this loss can be about 5 – 10 % (Delforge, 2001).

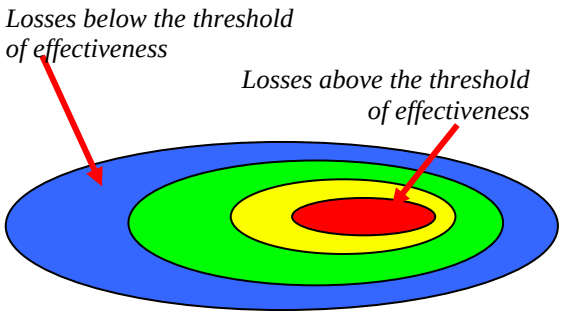

Figure 2. Losses above and below the threshold of effectiveness

Losses above and below the thresholds of effectiveness

For the effective suppression we must ensure there is enough water quantity per square meter. If this water quantity is below a threshold there is no suppression effect of water; it means this volume is lost. All resources we spent for this volume to be carried to the fire front is a useless expenditure. Since the footprint of water dropping is never homogenous, from the middle to the edge less and less, unfortunately this loss can't be avoided. Even if experts keep this minimum threshold volume different[1] it is between 0.2 – 0.8 l/m^2.

In the middle of the footprint of dropping water the water quantity can be higher than it is required. Bulk can hold no more than 5 l/m^2 water on leaves. Above this quantity water drip to the ground and there is no effect for crown fire; it means this volume is loss. All resources we spent on this volume to be carried to the fire front is also a useless expenditure. The rate of losses above and below the thresholds of effectiveness is about 10 – 20 %.

Loss of evaporation

If water dropping is not directly to fire front but some meter before it making a wetting zone a significant evaporation loss can be noticed. It is caused by the huge surface (wetting leaves), small water drops and high temperature. It takes time the fire front moving ahead and reach the wetting zone. Depending on the distance and the speed of fire propagation the time interval – fire front reaches the wetting zone – can be significant and during this time loss of evaporation can be remarkable; it means evaporated volume is loss which can be more than 25 % (Delforge, 2001).

Other losses

There are other losses, like targeting, navigation or coordination losses, however these are almost the same technologies, therefore different analysis is not necessary.

Based on the above, author counts with the average rate of losses 25 % in case of on-board installed tanks and 50 % in case of buckets.

[1] It depends on literatures, those are differences, e.g. 0.5 l/m^2 (Szabo, 1994); 0.8 l/m^2 (Delforge, 2001)

2.3. Possibilities enhancing water capabilities

Regarding the above problems experts search different ways to enhance water capabilities. It means different applications, like using retardant, gel, foam agent, specially developed explosion extinguishers[1] or even developing new kind of extinguisher materials[2].

Technical solutions

Based on the above analysis, it can be seen one part of losses are not avoidable, other part – mainly in case of helicopter – it relates to using bucket. This latest one – because of the Venturi effect – can cause even more than 30 % losses of transport capacity. This loss can eliminate in case of using tank, therefore different types of its appeared like on-board[3] or to belly installed tank[4].

Knock out effect

In many cases practice uses the kinetic energy of dropped water to suppress fire, so called „knock out" effect. In this case aircraft pilot drops water directly to the fire front and besides the cooling effect the kinetic energy of water mass also helps to suppress the fire; it breaks the chain reaction of burning process tearing down the flames. This method gladly used by aerial firefighting. An aircraft with flight speed of 180 km/h and altitude of 20 m generates kinetic[5] and potential[6] energy of 1 kg water about sum 1.45 kJ. The problem is that even if this method many times effective way to suppress – "knock out" – a short section of the fire front but the used kinetic energy of 1 kg water is much less than either the specific heat capacity or the evaporation heat capacity of water. Economically author evaluates this method waste because the extinguishing potential of the carried water is much higher than just the kinetic energy. (Naturally during knock out effect besides kinetic energy the cooling effect has also an important role. Its rate requires more analysis.)

[5] $E_{kinetic} = ½ m v^2$; in the above example 1250 J

[6] $E_{potential} = mgh$; in the above example 200 J

Retardants

There are also other solutions to enhance water capability which are based on different agent additions. One of these is using retardant that makes water drops more homogeneous causing less waste and there are not just cooling but also chemical based effects. Author focused on energy balance and potential suppression capability of extinguishing materials therefore the water equivalent of chemical based effects of retardant is missing however the value of its obviously can be very interesting and also planned to be one of author's next research topic.

Foam

Besides the retardant there is another method to enhance water suppression capability that is using agents to generate foams from its solution. In case of foam beside the cooling effect there can be also extra extinguishing effects. One of them is that agent reduces water's surface tension therefore the pine bulk can be covered by more homogenous foam drained solution. Other kind of the effect is that the structure of foam creates an isolation effect that can protect leaves from heat radiation. Based on this extra extinguishing effect fire propagation can reduce significantly and there is no enough radiation heat to keep chain reaction of flames alive. Based on authors study there is a way to optimize the isolation effect of foam and expand its capability to that dimension where pure water objectively can't be effective.

Figure 4. Aerial firefighting with using foam traditionally

Opposite to generate a foam structure there can be another aim to use foam agent. As mentioned above minimal rate of foam agent mixed to water can reduce the surface tension. In this case the rate of agent can remain below 1 % however this amount is enough to enhance the water effectiveness. Before fire it means water can cover pine bulk homogenous, after fire water can wet the glowed or sooty surface more effectively.

In case of foam using the evaporation loss is also less. Other side depending mainly on the type of foam agent the water draining from foam structure is natural phenomenon. Unfortunately this phenomenon reduces the foam effectiveness however with a good firefighting tactic – optimizing the distance between the fire front and foamed strip – it can minimize, that means a minimum „waiting time" fire front reaches the foamed zone.

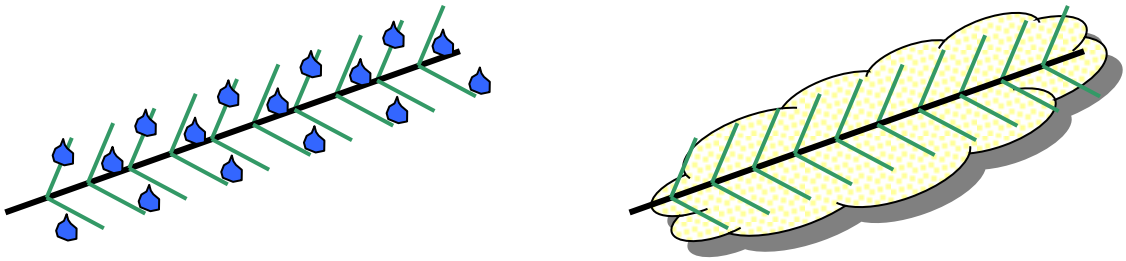

Figure 5. Water drops and foam blanket on pine bulk. Structural graphic

Based on the above, next part uses practical and theoretical investigations focusing on the possibilities of raising foam effectiveness.

Problems extinguishing with foam

In common cases using modern foam are believed to be very effective. Firstly, as addition of agent it is able to reduce the surface tension resulting better wetting effect, the other one is that with different equipment we are able to generate a foam structure. This structure depends on many conditions however in most cases it generates mechanically by the collision of solution and equipment dropping solution to air.
In case of aerial firefighting we can also face to use foam however there are some barriers of effective use. Dropping solution from the tank it strikes a grid or net to mix with air and generate foam but in most cases solution collide with air spontaneously (Figure 4), resulted foam. In case of bucket a special „foam sack" attached to water sack and its net mix air and solution generating inhomogeneous foam structure.
The effectiveness of foam depends on many conditions, like the mixing rate, expanditure rate, speed of solution dropping (flight speed), altitude and also the homogeneity.

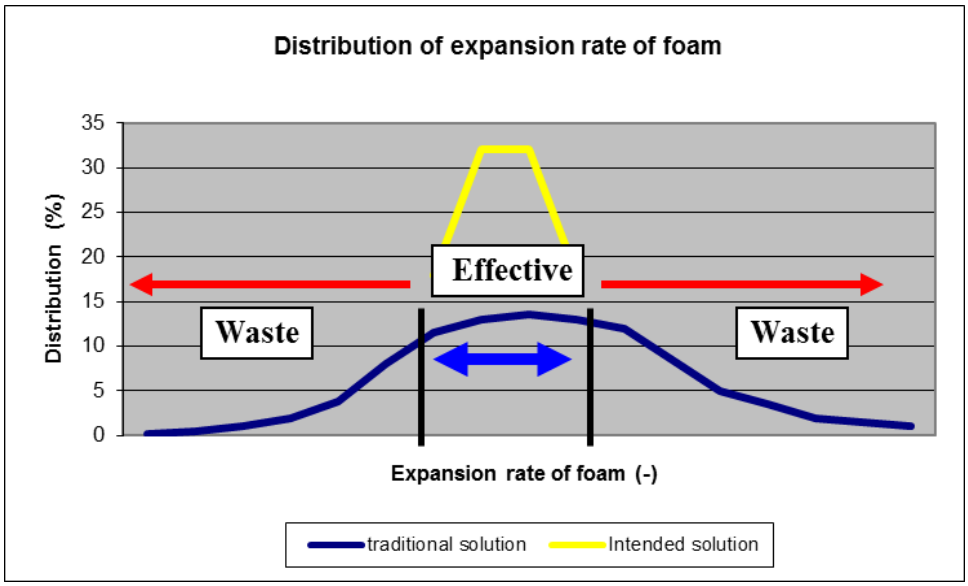

Figure 6. Foam bulb's distribution of traditional and new technologies depending on expansion rate

Foams with different structure and feature have different behaviour. Foams with large expanditure rate can be driven from the required place by the rotor wind of helicopter or by the fire caused convection

and there is no effect to suppress fire. Foams habitant on crown depends on its dense; light dense foam remains on the top of the crown, heavy dense foam – like a Newtonian fluid – flown down to ground. The effective suppression requires that the foam need to be – more or less – homogenous at all cross-section of the crown. Naturally the crown structure is not ideal thus the foam homogenate can't also be ideal. Probably there is no technology to create an ideal foam homogenate at all cross-section of the crown however the technology to improve it will result higher foam effectiveness.

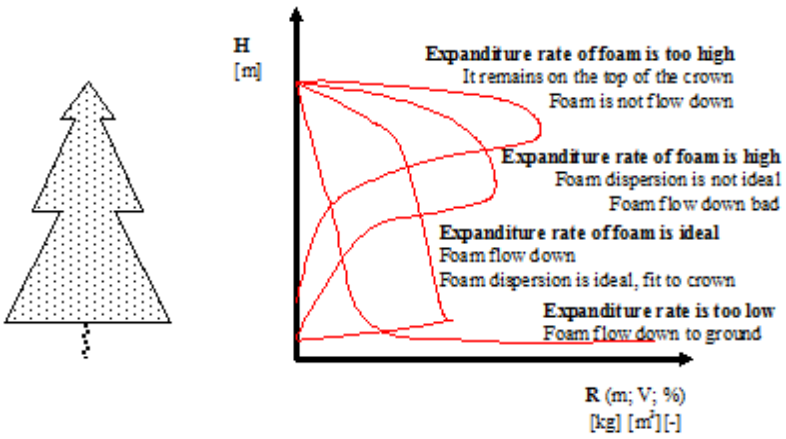

Figure 7. Foams blanket depending on expanditure rate

Basic requirements of foam for effective suppression:

1. Expanditure rate of foam must be such quality it ensures both the cross flown the canopy and its remaining on twig surface to cover it.
2. The foam weight on the unit surface must be such quantity it ensures to stop fire propagation.
3. The foam structure must be such quality it ensures the minimum water drain and long term stability.

Summarizing the problems regarding using foam:

1. The foam we need is of homogenous quality. Its density is suitable to maintain its insulation effect yet it can flow down from the crown and provide protection for the required time.
2. The foams designed specially for fighting forest fire meet the condition of remaining on the surface for the required time based on author's assumptions and the information provided by the manufacturers.
3. The current transport methods and means can only partially meet the condition of homogenous quality. It reduces the extinguishing capability of foams.
4. The favourable features of foams are present even at lower foam expenditure for a certain period.
5. In the case of low foam expenditure, the foam maintains it fluidity, typical of Newtonian fluids.

Instant foam for fighting forest fire – I4F technology – is able to ensure that the quality of foam structure is enough homogeneous therefore the losses caused by the different expanditure rates can be reduced and minimized.

Summarizing – concept of adaptation Foam Fatal technology

Based on the R-20F method foam has an extra extinguishing effect caused by the isolation effect; total suppression effect of foam is – averagely – twice higher than just the quantity of water that foam

contains (Restas, 2012). Other side, based on the R-10A method the foam remains on canopy 3 times more weight than just pure water (Restas, 2014). Above extra effects can give 6 times more effectiveness than just pure water per unit surface. It means new technology is able to protect the unit surface of vegetation against 6 times higher heat radiation of fire.

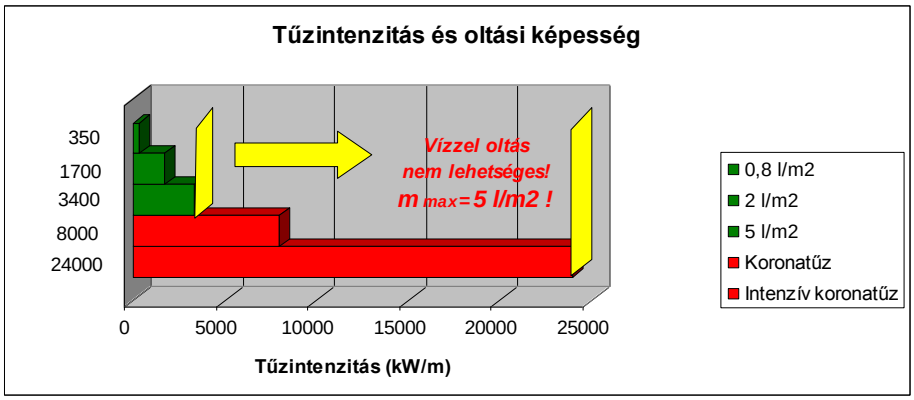

Figure 8. Capability of water and fire intensity. Above 3400 kW/m fire intensity water is not effective (red tubs)

The maximum amount of water remains on canopy surface is about 5 l/m^2; it is enough to suppress fires no more than with about 3400 kW/m intensity; it means both the effectiveness (capability) and also the barriers of pure water. However in case of canopy fire we can face about 8000 kW/m, in extra situation to about 24 000 kW/m fire intensity. Logically follows that using water traditionally is objectively can't be effective in case of canopy fire. Based on the above it also follows that using new technology the extinguishing capability of foam theoretically can extend even to 6 times higher fire intensity – it can be above 20 000 kW/m – similar to water capability. It means using new technology canopy fires can be supressed that was unable by traditional solution. The above clearly shows the benefits of new technology, which can be supplemented with the comparison of losses.

Table 1—Losses depending on technology

Losses	On-board tank	New technology
Loss caused by inhomogeneity	30 %	0%
Loss caused by technology	0%	15%

The basic difference between the two technologies can be found in the quality of the foam, which can be demonstrated by inhomogeneity. With the application of new technology the losses are reduced by half.

Extinguishment with instant foam is not new. It is present in hand portable extinguishers, and in petroleum industry at storage tanks as a Hungarian patent. It should be noted that author does not differentiate between instant foam and compressed air foam system (CAFS) regarding the extinguishing capability.

Tank must to be filled about of 4/5 part with water, then add the required amount of foam-forming agent (0.1 – 6 %). After that, with the help of a special pump we add gas to the solution until the pressure reaches the suitable value. Practically, the instant foam is ready. The extinguishment starts with the wide opening of the valve of the container. Within an instant, the solution is able to leave the container through the pipeline. As a result, the pressure suddenly and drastically drops which causes

the solution to become foam. The continual release of gas results in the slow decrease in pressure within the container, which enables the continual and quick release of the liquid and the instant foam. The special hose at the end of the pipeline the homogenous instant foam can reach long distances similarly to water jet.

Figure 9. Foam Fatal tank made of composite and install on helicopter board

In order to install the system on board making composite tank instead of meatal one is required. It maximizes the useful part of the loading capacity and makes aerial firefighting more cost effective solution. Author plans to finish tests in 2015.

Abstract
The purpose of this paper is to present a multidisciplinary work in order to propose a simple tool that forecasts fuelbreak safety zone sizes at the field scale. The main question associated with safety zones is determining the Acceptable Safety Distance (ASD) between the fire and firefighters required to prevent injury. This distance is usually set thanks to a general rule-of-thumb: it should be at least 4 times the maximum flame length. A common assumption consists in using an empirical relationship between fireline intensity and flame length. To quantify the fireline intensity, a closed physical model is applied. So, this Web Service uses a simulation framework based on Discrete EVent system Specification formalism (DEVS), a theoretical fire spreading model developed at the University of Corsica and a mobile application based on a Google SDK to display the results.

***Keywords**: Decision-Making Tool, Fire Model, Acceptable Safety Distance, ASD, Calculation Tool, DEVS, Mobile Application*

Introduction

In the last few years the increasing influence of global warming on the environment has produced periods of drought which in turn have led to wildfires with devastating consequences. There is a growing need for firefighters to have decision-making tools. However, wildfires are so unpredictable that reducing their impact is still a complex task.
For several years, our *fire team* works on a models set. These different models are used to fire studies at different detail level, from fire laboratory to real forest fire. Recently, we developed some models to calculate the radiation rate and thereby compute the safety distances. In this work, we propose its integration into an online calculator: a Web Service. This web service will be interrogated by a mobile application to provide, as shown in Figure 1, an acceptable safety distance defined from a geographical area (GIS: Geographical Information System). These first results were introduced in Bisgambiglia *et al.*, (2013).
Our tool has been designed with and for fire-fighters, to meet their needs. A mobile application is of great interest because it is portable and allows you to go on the ground.
In the first and second part, we present the physical model and the formalism used to implement it. Fire model is an analytical model based on University of Corsica's forest-fire propagation model. The model is called ASD for *Acceptable Safety Distance*. It is used to place the fire-fighters on the ground and assess the radiation rate to which they are exposed. The role of this system is twofold: (1) it calculates a safe distance for the prevention of forest fires. This distance is used to realize a fuel break by vegetation clearing; (2) it can also calculate a safety distance during the struggle. This distance informs the fire-fighters on the degree of heat in the vicinity of the fire front. This is an analytical model based on radiative heating, and a whole set of parameters, such as vegetation, meteorology, topography, etc. The flame model adopted is based on the radiant surface approach; it is generalized to take into account the effect of the fire front width. So far this model prediction has been compared against measured flame length of several experimental fires conducted at the field scale through a

variety of natural vegetation in Corsican mountain region. The used formalism is called DEVS for *Discrete EVent system Specification;* it can be defined as multi-formalism and seen as a computational tool. DEVS is flexible, fast and open. In the field of Discrete Event Systems, many efforts have been devoted to develop appropriate tools to study, and model in a formal way the dynamics and the mechanisms of interaction of the natural systems. For several years the community is changing the DEVS formalism so that it can become a powerful tool for modelling complex systems. DEVS allows the reusing models through library already developed and also interconnecting of these models to compose heterogeneous models based on different formalisms.
In the third part, we will detail our software architecture. Including how the physical model has been modelled in our framework and what are the input data used. Then, we present how our DEVS models were migrated into a Web Service. Finally, we will detail the mobile application and its GUI (graphical user interface). Fire models have been implemented in a DEVS framework and coupled with a computational model of acceptable safety distance (ASD). The simulator is hosted on a Server to be queried remotely. At the start of the process, the user sends to the server a message with several positions. The server queries the Web Services to determine local parameters (slope, wind, etc.), and for each position compute the ASD. Finally, results are returned to the client for visualization in GIS.
In the fourth part, we describe our results. In collaboration with fire-fighters, we defined five vegetation types. These types have been incorporated in the software. With the GUI, the user can choose a vegetation type. We propose a comparison of results based on different vegetation.

Figure 1. An overview of the application

Physical Models

The fire behaviour at the field scale is difficult to forecast. It is a tricky task because the physical processes of combustion and heat transfer and how they are influenced by meteorological conditions and the arrangement and type of fuel are complex. It belongs to the framework of strongly coupled non linear transport phenomena. The aim of this section is to propose a model of fire behaviour that is

simple in concept and transparent to parameterize too. The main objective of this approach is to facilitate the use of existing vegetation models. A simplified surface fire spread model has been developed since 2007 at the University of Corsica in France. It has been tested on experiments carried out across fuel beds under slope and wind conditions at different field scales (Balbi *et al.*, 2007; 2009; 2010). The two main equations of this physical 3D model are the following:

$$\left.\begin{aligned} \tan\gamma &= \tan\alpha + \frac{U_n}{u_o} \\ R &= R_o + AR\,\frac{1+\sin\gamma-\cos\gamma}{1+\dfrac{R\cos\gamma}{r_o}} \end{aligned}\right\} \quad (1)$$

where R is the fire spread rate across an equivalent homogeneous combustible medium and under slope and wind conditions. It is obtained by using a thermal balance assessment in the combustible zone downstream to the fire front. This relationship is the sum of two terms. The first one, R_o, evaluates the rate of spread under no wind and no slope (it represents the contribution of the radiation from the fuel burning particles area). The second one determines the radiant heat flux, which comes from the flame body. γ represents the flame tilt angle. This angle is calculated using the local slope (α), the normal wind speed to the fire front (U_n) and the upward gas velocity (u_o). For an in-depth look at the determination of the rate of spread on the basis of this physical model, readers are encouraged to consult scales (Balbi *et al.*, 2007; 2009; 2010).

A flame height submodel (Marcelli *et al.*, 2011) is added to the simplified physical rate of spread model described by equation (1). As $h_f = l_f \cos\gamma$, where l_f and h_f denote the flame length and the flame height respectively, the flame length is expressed as

$$l_f = \frac{2\chi_0 r_{00}\Delta H \rho_v \nu}{BT^4\cos\gamma} \quad (2)$$

where χ_0 is a radiant factor (usually close to 0.3), r_{00} is a universal rate of spread (ROS) factor (equal to 2.5×10^{-5}), ΔH is the heat of combustion of the pyrolysis gases, ρ_v is the fuel density, ν is the fuel absorption coefficient, B is the Stefan-Boltzmann constant and T_f is the mean flame temperature.

The main question associated with safety zones is determining the safety distance between the fire and firefighters required to prevent injury. This distance is usually set thanks to a general rule-of-thumb: it should be at least 4 times the maximum flame length (Butler and Cohen, 1998).

Fuelbreaks divide expanses of natural fuels into smaller units. Native vegetation on these strategically located wide strips of lands is modified so that fire burning into them can be more readily and safely controlled. Fuelbreak generally has a low-growing ground in order to protect the soil against erosion. But, fuelbreaks with safety zones providing safety for firefighting personnel and equipment under critical conditions should be wider than other parts of a fuel break. In selecting the widths of fuelbreaks safety zone, the forest manager must estimate the distance from the flame front necessary to prevent serious burns from radiated heat and direct ignition from radiation too. Green and Schimke (1971) estimated that the distances from the flame front necessary to prevent ignition from radiation are half of the distances considered necessary to prevent disabling burns. Hence, ignition from radiation across a wide fuelbreak should not be a problem. Assuming that the safety distance is in the center of the break, the total width of a fuelbreak safety zone must be equal to 2 times this distance.

DEVS formalism

Simulation is used to study fire evolution model. For example, the DEVS formalism has been used to model physical equations describing fire evolution; we can quote (Harzallah *et al.*, 2008; Muzy *et al.* 2002; Bisgambiglia *et al.*, 2006; Nader *et al.*, 2011). This work focuses on the spreading aspect; our application aims to provide a safety distance.

Since the 1970s, formal tasks have been performed to develop the theoretical foundations of modelling and simulating of discrete event systems. Discrete Event System Specification is an extension of the Moore machine formalisms which is used for modelling and analyzing general systems. Our interest focuses on the *Discrete EVent system Specification* formalism (Ziegler *et al.*, 2000). DEVS provides a way of expressing discrete event models and a basis for an open distributed simulation environment. DEVS is universal for discrete event dynamic systems and is capable of representing a wide class of other dynamic systems. Universality for discrete event systems is defined as the ability to represent the behaviour of any discrete event model where represent and behaviour are appropriately defined. Concerning other dynamic system classes, DEVS can too simulate discrete time systems such as cellular automata and approximate, as closely as desired, differential equation systems. It also supports hierarchical modular construction and composition methodology. This bottom-up methodology keeps incremental complexity bounded and permits stage-wise verification since each coupled model build can be independently tested (Ziegler, 2005).

Major efforts have been made to adapt this formalism to various domains and situations as to study forest fire spreading (Harzallah *et al.*, 2008; Innocenti *et al.*, 2009; Muzy *et al.*, 2005; Ntaimo *et al.*, 2004; 2008; Nader *et al.*, 2011). DEVS permits the modelling of causal and deterministic systems with two types of components. A DEVS model is either an Atomic (AM) or a Coupled (CM) model. An AM is a structure: $<X, Y, S, \delta ext, \delta int, \lambda, ta>$ with

- X the set of external events,
- Y the set of output events,
- S the set of sequential states,
- $\delta ext: Q \times X \longrightarrow S$ the external state transition function,
- where
- $Q = \{(s,e) \mid s \text{ in } S, 0 \leq e \leq ta(s)$ and
- e is the elapsed time since the last state transition;
- $\delta int\ S \longrightarrow S$ the internal state transition function;
- $\lambda: S \longrightarrow Y$ the output function and
- $ta: S \longrightarrow R+0 \longrightarrow \infty$ the time advance function.

The AM describes the behaviour of the system. A atomic model is based on continuous time, inputs, outputs, states and functions (output, transition and lifetime of states). More complex models are constructed by connecting several atomic models in a hierarchical way. The interactions are created via the models' input and output ports, which favours modularity. A CM describes the composition of several DEVS sub-models, i.e AM or CM, it is described by the following formula: CM: $< X_M; Y_M; C_M;$ EIC; EOC; IC; L >.

Where,

- X_M: is the set of input ports;
- Y_M: is the set of output ports;
- C_M: is the list of models that composed the coupled model CM;
- EIC: is the set of the input couplings, which links the coupled model to its components;
- EOC: is the set of the output couplings, which links the components to the coupled model;
- IC: is the set of the internal couplings, which links the components to one another; and,
- L: is a list of priorities among components.

Many works have been proposed with the aim of mapping DEVS models in Web Services (Harzallah *et al.*, 2008; Al-Zoubi and Wainer, 2009; Kim and Kang, 2005; Mittal *et al.*, 2007; Wainer *et al.*, 2008). Generally the aim of this works is twofold: (1) provide a service based on a DEVS model, and (2) extend the interoperability of DEVS formalism. We do not propose evolution at these levels, but simply the use of these concepts applied to another application field: the ASD calculation. Our approach is general because we want to use DEVS as a calculation tool. We also propose a comparison

with a calculation program scientist and to equivalent results our environment is much more efficient. In addition, we can use DEVS to transform our calculation tool in online tool, and propose complete software architecture; efficient and adapted to the problem we were asked. That is to say: developing a tool for fuelbreak dimensioning.

Application and software architecture

In Bisgambiglia *et al.*, (2013) the software architecture of our application was introduced. To summarize, our tool is fairly standard, it looks like in this work (Harzallah *et al*., 2008), and is based on DEVS-Ruby framework (Franceschini *et al.*, 2014). We constructed a computational service as Web Service. Our Web Service is based on the DEVS formalism. It allows sending a safety distance, used to planning aid (fuelbreak) and prevention against forest fires. For our calculations, we need a certain number of data, and these data are either acquired locally, such as geolocation, or retrieved through other Web Services, such as ground slope. A main Web Service hosting a DEVS simulator to calculate the ASD. It can connect to another Web Services. The client sends data and displays the results. The Figure 2 describes this architecture. A main Web Service hosting a DEVS-Ruby simulator to calculate the ASD. It can connect to another Web Services. The client sends data and displays the results.

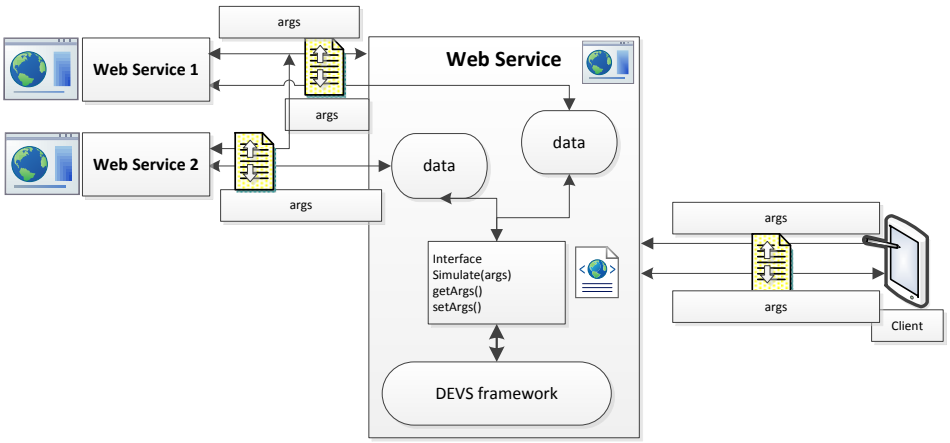

Figure 2. An overview of the overall approach.

The first step was to map the physical models to a DEVS models, then identify the major input parameters and finally transform the DEVS models to a DEVS Web Service. The computer architecture and the underlying technologies are described in Bisgambiglia *et al.* (2013).
Modelling the vegetation, denoted hereafter by fuel, is essential for the purpose of predicting the behaviour of a fire, either for fire danger rating system or fire spread model as well as to assess the impact of fire. Characterization of fuel particles is therefore required as an input to semi-empirical and physical fire behaviour models. The physical, chemical and thermal properties of fuel particles are assessed at the level of the individual particle or element
The different fuels characterization which are used in the mobile application in order to compare the values of the acceptable safety distances are presented in table 1.

Table 1. Examples of fuel description in the Mediterranean

Fuel type	Corsican tall shrub	Corsican shrub	Sardinian shrub (type 1)	Sardinian shrub (type 2)	grassland
Fuel Height (m)	4	2	0.48	1.8	0.3
Fuel load (kg m-2)	0.89	0.39	0.39	1.2	0.166
Fuel Moisture Content	0.08	0.08	0.08	0.08	0.08
Surface area-to volume ratio	5544	10200	2000	2400	11400
Heat of Combustion (kJ kg-1)	19640	18620	18620	18620	18620
Fuel density (kg m-3)	720	750	478	734	288
Specific Heat (J kg-1 K-1	1912	1900	1740	1820	1440

Results

5.1. Confrontation of the proposed physical model with field scale experiments

This section deals with the comparison of thirteen experimental literature field shrubland fires with model results.

Experiments were located in mountain areas in the southern Cape Province of South Africa. Fires were conducted at two sites. The first site is situated in the Kogelberg State Forest (110 m above the sea level). Detailed experiments description can be found in Van Wilgen *et al.* (1985).

Table 2. Observed and predicted flame lengths during the Kogelberg State Forest experiments.

	Flame length (m)						*NMSE (%)*	*FB (-)*
Wind speed ($m \cdot s^{-1}$)	3.56	1.5	2.67	2.67	3.11	3.11

Nelson and Adkins (1986)	4.48	9.74	8.23	4.75	1.67	5.82	7.64	6.76	10.81	0.18
Van Wilgen (1986)	5.23	11.76	9.86	5.57	1.88	6.87	9.13	8.03	24.03	0.34
Vega *et al.* (1998)	8.20	17.84	15.06	8.70	3.07	10.66	13.99	12.38	87.4	0.74

With regard to flame length models, four models are quite adequate to predict flame length in the Kogelberg (Table 2) and the Cederberg experiments (Table 3). These data are accurately fitted with the empirical relationships proposed by Fernandes', Nelson's, Nelson and Adkins's laws and by the physical model too.

Empirical laws are useful to quantify flame length but should not be used to compare fires in fuel types, which are structurally very different (Morvan *et al.*, 2002). Besides, really hazardous fires, such as those burning under conditions of strong wind at the field scale, cannot be properly quantified because of the contribution of heat convection to the heat transport ahead of the flame front. Moreover, empirical laws are not predicted. It is a strong argument for a physical approach. So, a physical simplified approach is applied to obtain an analytical expression of the flame length.

5.2. Comparison of the results given by the mobile application on various vegetation types

This section deals with the computation of Acceptable Safety Distances in which a fire spreads across five different fuels in the Mediterranean area (the intrinsic characteristics of each fuel are detailed in table 1). Two wind speed values are randomly chosen (3 and 5 $m.s^{-1}$). Table 4 presents the ASD obtained with the rule-of-thumb stated by Butler and Cohen (1998) and the physical model presented in section two.

Table 4. Comparison of the ASD values (m) obtained with a rule-of-thumb, applied to five different fuels in the Mediterranean.

Wind (m.s-1)	Corsican tall shrub	Corsican shrub	Sardinian shrub (type 1)	Sardinian shrub (type 2)	grassland
3	10.14	11.16	11.05	10.48	8.86
5	14.87	16.06	20.46	15.32	14.37

If the values of ASD are similar for a 3 $m.s^{-1}$ wind speed whatever the fuel bed, they are quite different when the wind speed increases. As the physical model (especially the flame length sub-model) gives a good precision (see the errors given in tables 2 and 3), it is necessary to have either accurate characteristics of the vegetal stratum or a good modelling for an equivalent fuel.

5.3. Graphical user interface

ASD results provided by our Web Service are useful for firefighters on field when evaluating distances for fuelbreak, the client side must then provide a clear GUI to visualize the terrain and our results, an unobtrusive way to feed input data and a way to retry computations in case of a network failure. In order to fit such requirements, the client has been implemented as a mobile application on both iOS and Android platforms and designed to run primarily on tablets. The results presented are from iOS client. The application is in French. The user interface will be essentially composed of:
(1) a sliding panel on the left side providing a section containing a list of previous cached computations and the ability to create a new one. Another section is there for configuration purposes. This menu is shown in Figure 3.a, it also allows you to select a fuel types (Corsican tall shrub, Corsican shrub, Sardinian shrub (type 1), Sardinian shrub (type 2), grassland), or configure a local wind;
(2) a map fitting the whole screen and representing the current selected computation. The map contains the user location if available; the path for which we want the results and when these are available, the ASD zone is drawn as a polygon. The user can touch the zone to display detailed information about results (Figure 3.b);

(a) left menu (b) drawing the path (c) result

Figure 3. Display example.

(3) the map has three distinct modes: the normal mode, the user-tracking mode and the drawing mode. Each of these are detailed respectively below : (3.1) the normal mode displays all available data for the current selected computation and allows user interaction to show detailed information; (3.2) since our Web Service input is essentially a set of coordinates, these GPS enabled devices allow us to provide

a handy user-tracking mode. Thereby, as the user location is updated we can spawn requests to our Web Service and draw a polygon that will represent the ASD; (3.3) finally, the drawing mode allows the user to place a set of locations directly on the terrain and adjust each of them. The final result is shown in Figure 3. We can see the contours of the safety zone.

Conclusions

This paper presents a multidisciplinary work and argues a software tool to compute Acceptable Safety Distance (ASD). This distance was usually set thanks to a general rule-of-thumb: it should be at least 4 times the maximum flame length. This distance is very important because it is used to design fuel breaks. In our approach, to quantify the fireline intensity, a closed physical model is used. The model is hosted as a web service, and used a simulation framework based on Discrete EVent system Specification formalism (DEVS). In this new work, we present various results based on the vegetation characterization.

One goal of this study is to provide an accurate quantification of a safety zone at the field scale. To quantify this area different flame models (one simplified physical model and twelve empirical correlations) are tested using several experiments. Model predictions are compared against measured flame length of spreading fires through shrub vegetation. This work shows that the simplified physical approach presents a main advantage: its capability to be used for all types of fires under a wide range of conditions if fuel models, describing structural types of vegetation, are available. So, this model can be seen as an alternative operational length flame model, which can be applied to calculate more accurately safety distances.

Now, as expected fire-fighters, we will now turn our application on desktop.

Abstract
The efficiency on forest fire control is directly related to the quickness on detection and localization, which significantly can minimize the potential of damages. The current technology used in the manufacture of weather radars has opened new opportunities for research, making it possible to detect small signals, not necessarily used in the daily rain observations. The objective of this research is to use the capacity of weather radar, configured to execute tasks of high sensitivity, to monitor and detect "non meteorological targets", i.e., the smoke produced by sugar cane burnings and, by similarity, forest fires. An experimental model was developed and applied to the S-band weather radar operated by the Meteorological Research Institute – IPMet/UNESP, located in the central region of the State of São Paulo, Brazil. In the first experiment, all the monitored sugar cane burnings were efficiently detected by the radar with a delay of 2 to 9 minutes, with an average of 4.67 minutes, a significant reduction in the response time of 15 minutes, considered optimal for conventional detection systems. In the second experiment, the weather radar monitored forest area when the fire danger rating index was medium or high and the same events observed by the observation towers were detected by the weather radar. The methodology used in this study can add significant value to the information in the forest fire suppression decision-making. The results showed the efficiency of weather radar to detect smoke. Therefore, weather radars systems could be used, in the absence of rain echoes, for monitoring agriculture burnings and detecting forest fires.

***Keywords**: Fire detection, Weather radar, Forest fire*

Introduction

The efficiency on forest fire control is directly related to the rapidness on the occurrences detection and localization, what significantly minimizes the potential of damages. There are several difficulties and limitations in the most widely method used for monitoring and detection of forest fires, the observation towers. The high cost of installation and operation is one of the handicaps of the system. When the number of towers is not sufficient, some fires are detected when the intensity is already high and the suppression more difficult.

Trying to improve monitoring and detection of forest fires, this research used the remote sensing technology to detect events related to fire. The biomass combustion process produces large amounts of smoke, an excellent target which can be detected by deploying various electromagnetic wavelengths. The particles and water vapor that constitute the smoke is an excellent electromagnetic spreader.

Due to the absence of rain, during the dry season, the degree of fire hazard increases. Therefore an experimental model of fire detection was developed, and initially tested on the frequent and programmed sugar cane harvesting burnings in the central region of São Paulo State, which is monitored by a weather radar equipment "S-band Doppler", operated by the Meteorological Research Institute, UNESP, located in Bauru. County. In the same region covered by the radar system, there are

large plantations of pine and eucalyptus owned by Duratex, that in the second phase of the experiment were monitored during high fire danger indices

Methods

Weather Radar

The Radar (***Ra**dio **D**etection **A**nd **R**anging)* is considered an active element, considering that it illuminates the target with a microwave beam and identifies this target through the detection of the energy portion reflected back. The choice of the operation wavelength (λ) is primarily defined according to the type and size distribution of the targets to be investigated or detected. (Doviak 1992; Lhermitte 2002).

Detection Capability

Operacional and research weather radars have already been deployed in the past to observe "non-meteorological targets" such as: wind speed profiles, gust fronts, particles in suspension, flocks of birds, clusters of insects as well as smoke plumes (Banta and Olivier 1992; Calheiros and Gomes 1999; Erkelens and Venema 2000; Gary *et al*. 1998; Held *et al*. 2011). This became even more feasible with the continuous technological advances of data acquisition and signal processing, sensitivity and improved detection capability as well as mitigating the associated measurements errors.

2.3. Fire Detection

The detection of a fire occurs indirectly, since it is detects not the fire flame or the heat, but the smoke produced by the biomass burning. Initially, a high sensitivity parameter task is programmed (low PRF, pulse length of 2 microseconds). Unlike its conventional Unlike its conventional operation mode, while the radar monitors rain from up to the soil surface, in the forest fire detection the monitoring occurs from the soil surface to up in the sky.

When forest fuel or biomass burns, the released smoke rises and crosses the microwave beam of the radar, backscattering incident energy, resulting in the event detection (figure 1). An important detail is the effect of the curvature of the earth in determining the height of the center beam, because the height relative to the ground increases with distance from the radar site. The purpose of this study was the detection of smoke originated from biomass burning as close to the ground as possible.

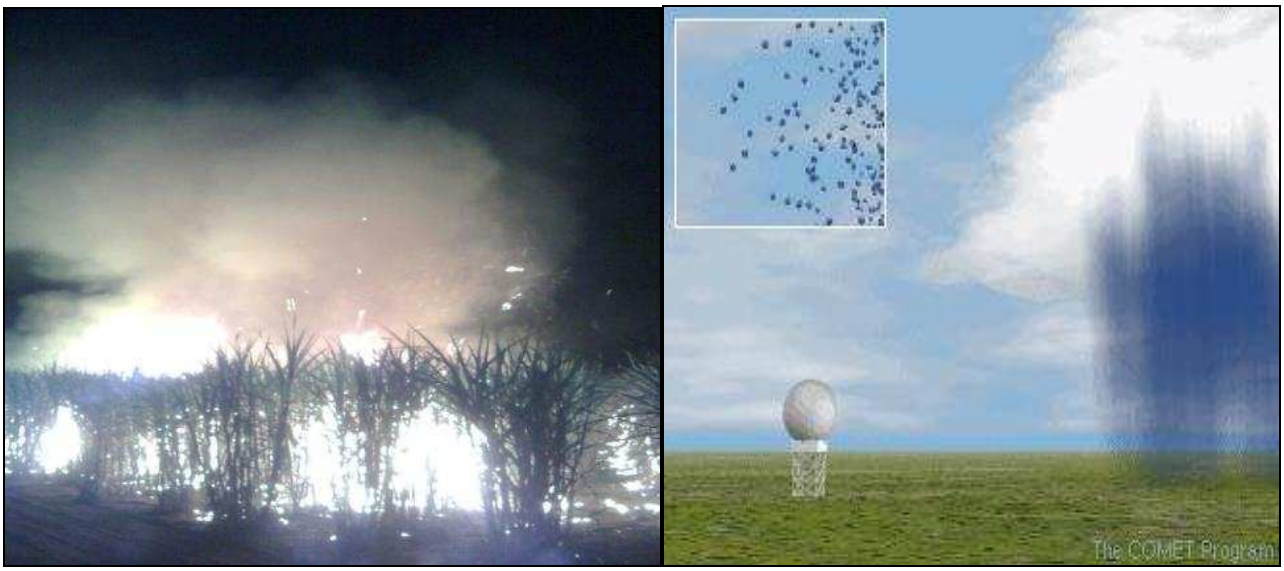

Figure 1. Vegetation fires release smoke and intercept the radar beam.

As the fire starts in the soil surface and the quicker it is detected easier is its control. Idealy the radar beam should be as low as possible on height above the monitoring area, but not too low as reflect ground echoes and contaminate the image with noises**.**
The study area should not be too close to the radar in order to avoid the effects of side lobes of antenna radiation that impair detection efficiency. With the distance of around 50 km from the radar, and antenna elevation between 0.3 and 2 degrees, the beam intercept smoke up to 2000 meters above ground level.

Results

Data from the burned plots, including time of ignition and detection, duration of fire, and response time between ignition and detection are showed in Table 1.

Table 1. Summary of monitored and detected events

Sample	Area (ha)	Schedule of Burnings (GMT)			Radar Detection	Response Time (min)
		Start (hh:mm)	End hh:mm)	Duration (min)	Start (hh:mm)	
1	6,42	22:28	22:48	20	22:30	2
2	15,11	22:17	22:31	14	22:20	4
3	10,29	22:56	23:20	24	23:00	4
4	4,86	22:20	22:36	16	22:29	9
5	8,73	22:07	22:19	12	22:13	6
6	8,35	22:07	22:24	17	22:11	4
7	8,68	21:48	22:13	25	21:52	4
8	5,56	21:02	21:18	16	21:07	5
9	**8,23**	**22:02**	**22:32**	**30**	**22:07**	**5**
10	5,81	22:25	23:02	37	22:30	5
11	10,85	21:18	21:32	14	21:22	4
12	3,99	21:26	21:42	16	21:31	5

Running task with high sensitivity and temporal sampling of 7.5 minutes, the S-band Doppler weather radar monitored the 12 burning events in the sugar cane plots. All the burnings were accompanied *in situ*, and with the time synchronized to the radar time system; the exact ignition time and the events duration were recorded.
The radar data have been treated with the TITAN software, developed at NCAR (National Center for Atmospheric Research), for applications in nowcasting the displacement of storms based on the methodology of centroids (Dixon and Wiener 1993). The images used are Cartesian products called CAPPIs (Constant Altitude Plan Position Indicator) with the viewing plane at constant average height of 1.5 km amsl (above mean sea level). Figure 2 shows the area of study and distance of radar site.
The response time ranged from 2 to 9 minutes with an average of 4.67 minutes (table 1), reducing in 68.9% the response time considered ideal in the conventional detection systems (Soares and Batista 2007).
Figure 3 shows the sample n° 9 (table 1), before ignition of burning and without radar echoes (22:00 GMT), while figure 4 (22:07 GMT) depicts it 5 5 minutes after ignition (22:02 GMT) and with the first radar echoes. The figures 5 and 6, show the area of sample n° 9 with the radar echoes during burning (22:15 and 22:22 GMT).

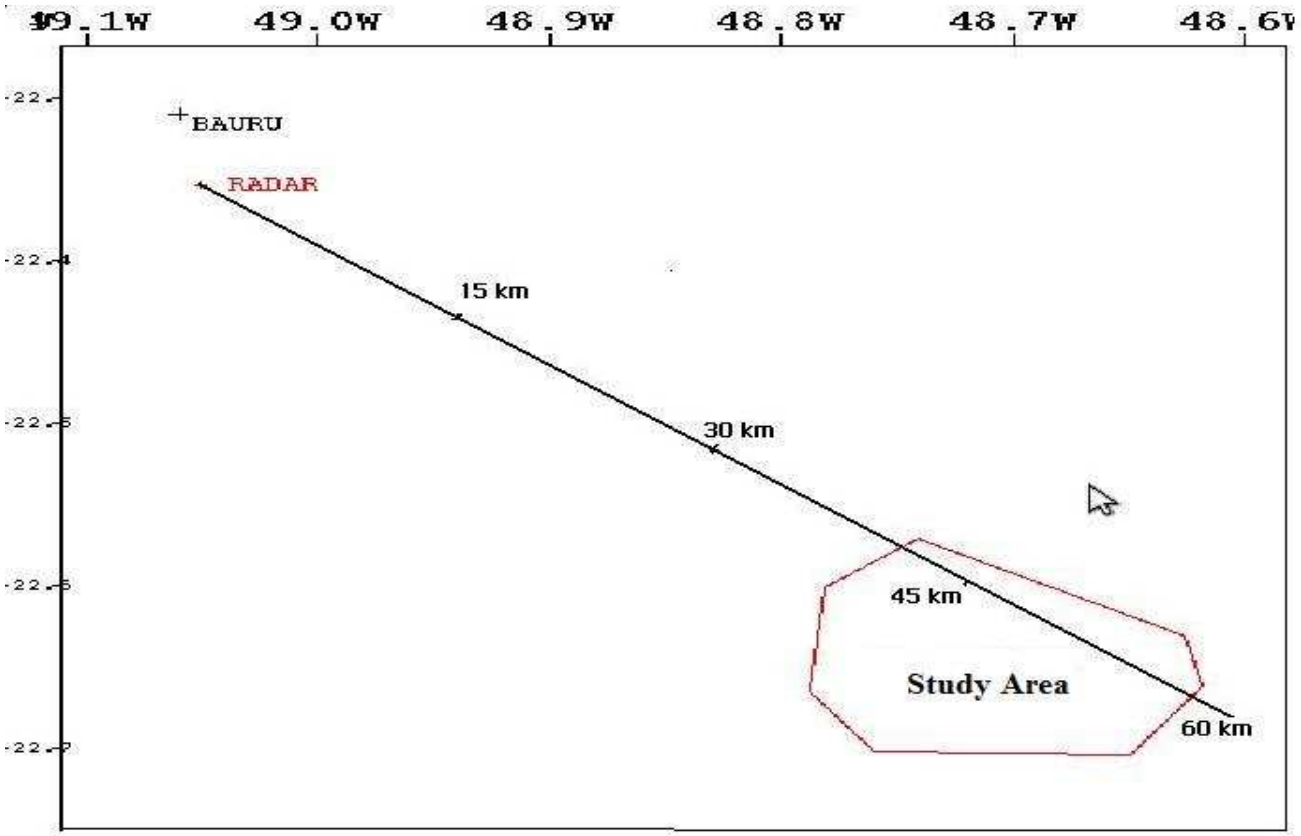

Figure 2. Study area (red polygon) and distance of radar site

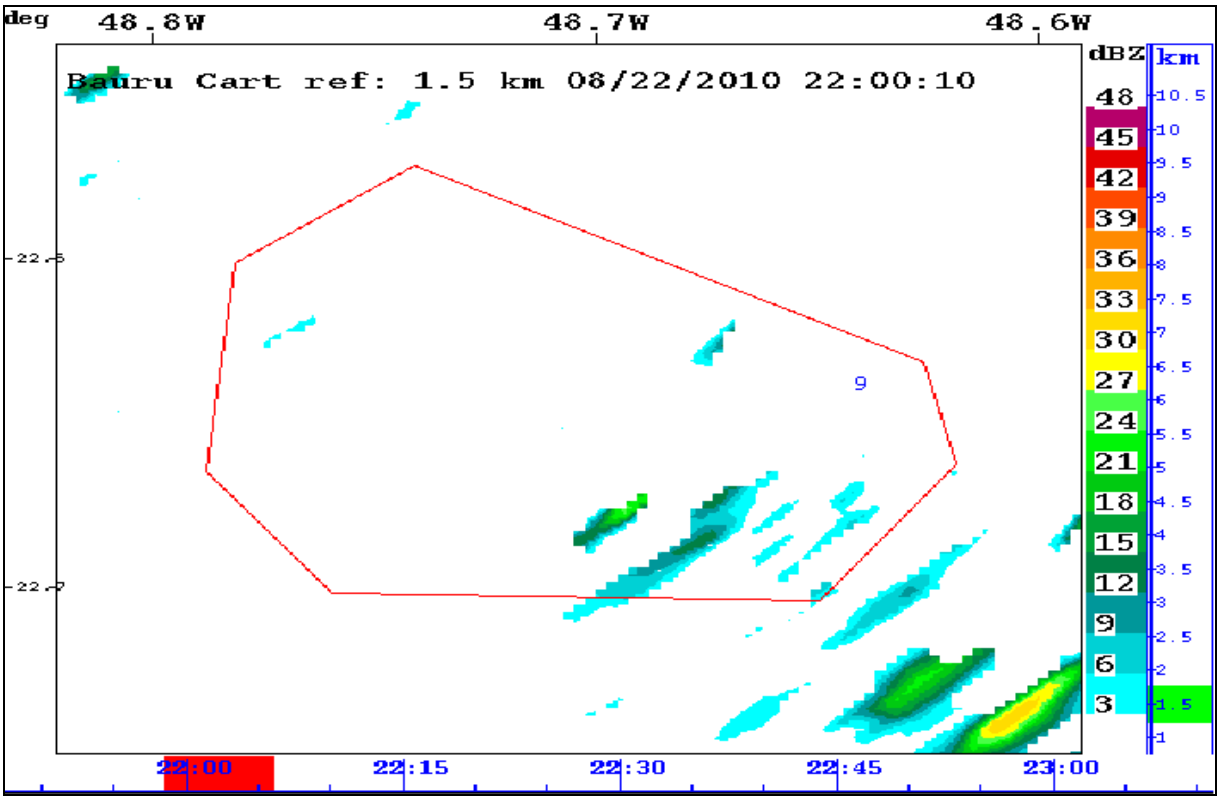

Figure 3. Image of the location of sample n° 9 (indicated by the number 9)

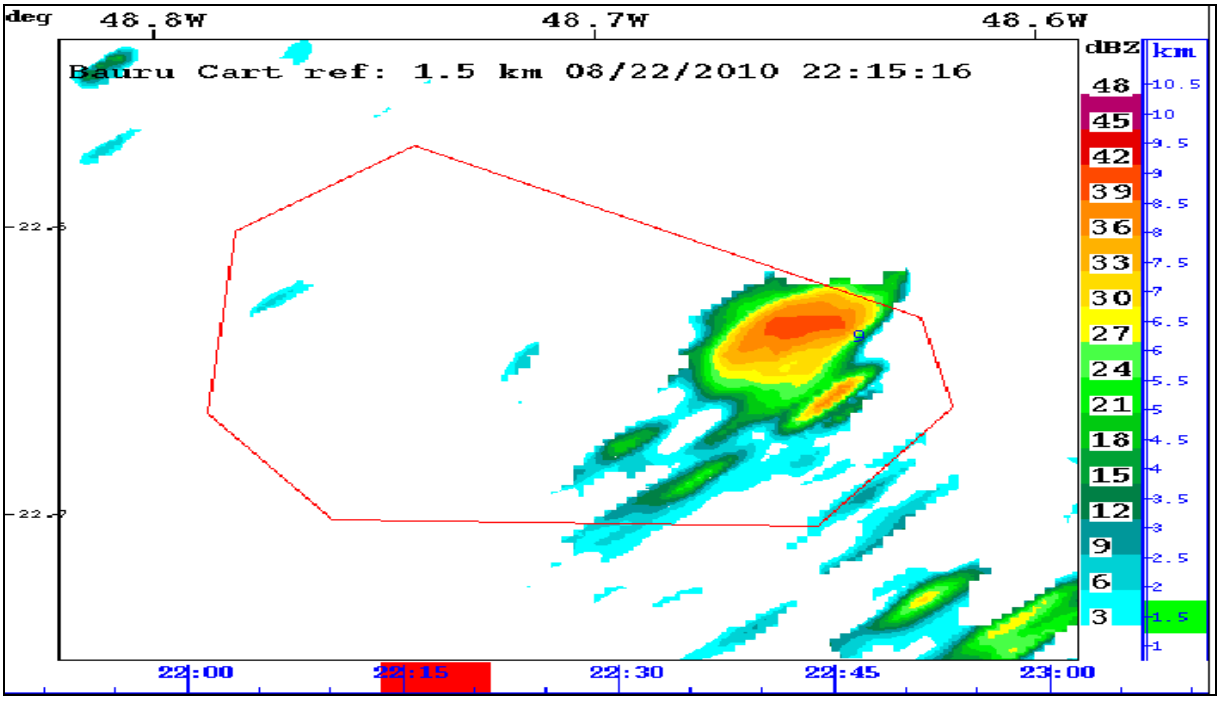

Figure 5. Location of sample n° 9 with radar echoes during the fire (22:15)

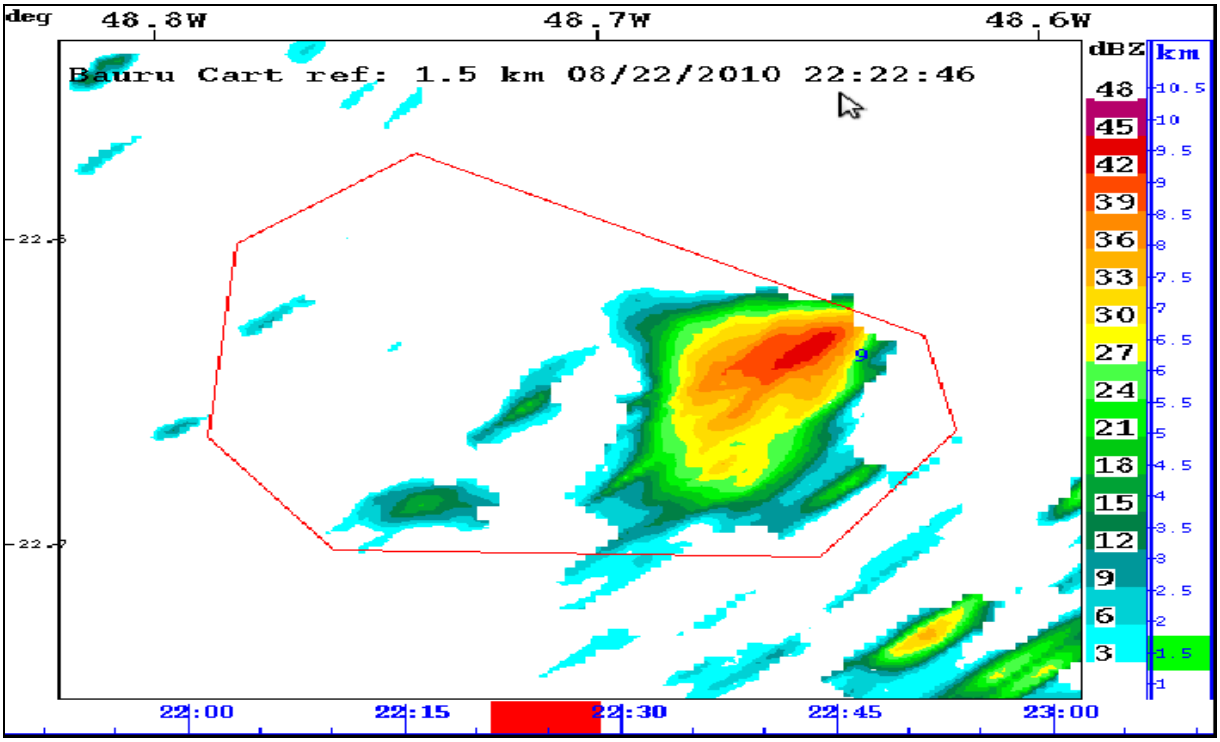

Figure 6. Location of sample n° 9 with radar echoes during the fire (22:22)

The figures 7 and 8 shows the sample n° 9 at 22:37 and 22:45 GMT, 5 and 13 minutes, respectively, after the end of burning and already without radar echoes within the monitoring area.

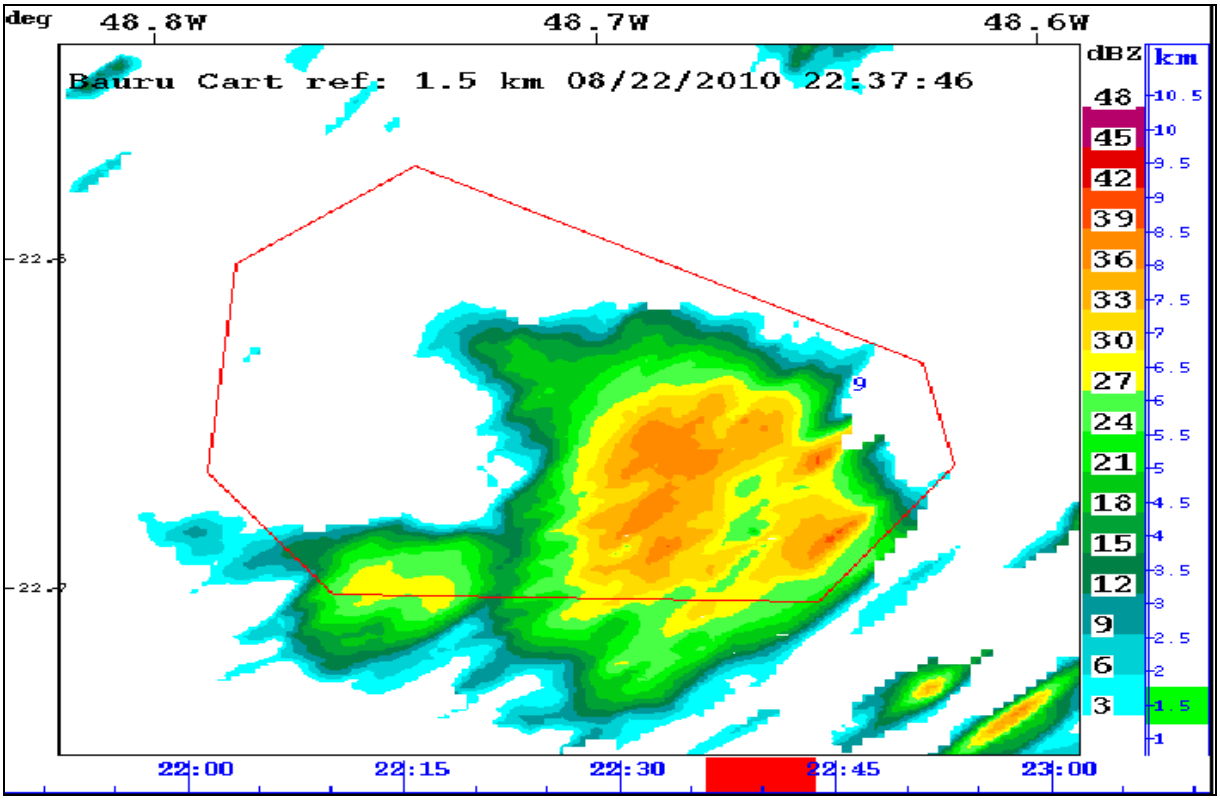

Figure 7. Sample n°9 after burning and without radar echoes (22:37)

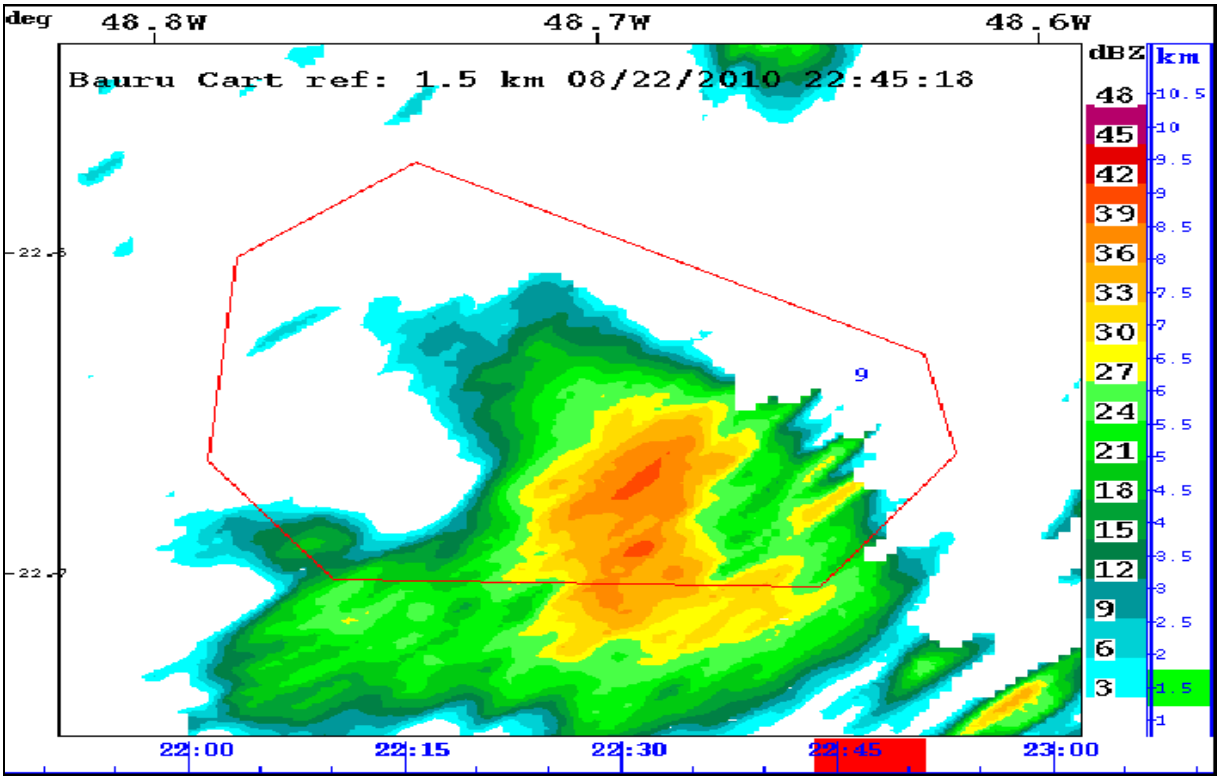

Figure 8. Sample n°9 after burning and without radar echoes (22:45)

Durant August 2013, which was a period of high index of fire danger in the region, the radar was operated again with high sensitivity and the temporal resolution shortened to 5 minutes, monitoring the reforestation areas owned by Duratex Company. The only two small fire spots detected by the company's observation towers were also detected by the radar system. Synchronizing the time from the radar and the observation tower, the radar detected the fires 6 an 8 minutes in advance, respectively.

Conclusions

The Bauru S-band Doppler weather radar had successfully detected of burning of 12 plots of sugar cane. The two events identified by the observation towers in the reforestation area during the second experiment were also monitored and detected by the radar.

Based on the results, weather radar can be considerate an important auxiliary tool for detecting unauthorized burning and forest fires, adding significant value to the information for decision-making in monitoring, detecting and suppressing wildfires.

The X-band radar, for example, with its own technical characteristics combined with increased temporal resolution, would be more suitable for smaller targets and smoke, could be an even better alternative to fire detection, and shorter response time.

Abstract
Forest fires are one of the most devastating natural disasters occurring in Portugal mainland over the summer season, with a strong impact on the economy, environment and climate. In last four decades the increase of wildfires problems in Portugal linked to Industrialization, urbanization, rural exodus (in recent past), and emigration (nowadays), with tendency to be worst in the future, lead to a mutation in Portuguese society. Severity of wildfires its worst year to year, besides the effort of the State, increasing human, operational, technical and economic resources to solve the problem. The fire combat continue very difficult and the number of occurrences of fires getting out of control, becoming larger and larger with a heady impact the increase of destruction.
Present work aim to contribute to a development of a support decision tool to be used in combat operations, monitoring fire spots and fire evolution using LSA SAF (*Land Surface Analysis Satellite Application Facilities*) products. The FRP (*Fire Radiative Power*) a product of LSA SAF are available and free distributed, in NRT (*Near Real Time*) and off-line, every 15 minutes for all pixels with a delay of about 20 minutes. These data can, subsequently, be used to obtain the carbon (or the equivalent CO_2), estimated for each pixel and integrated for a given area and period of time or, simply, to map and monitor forest fires.
This work is showing the possibility of monitoring forest fires, using FRP product with about 4 km of spatial resolution, taking advantage of the very interesting temporal resolution (15 minutes). As test, two major wildfires of 2013 had been used: Alfândega da Fé (Picões), from 8 to 11 July, and another one, in the region of Caramulo, from 21 to 30 August. Burnt area was, respectively, 14000 ha and 9416 ha, according data provide *by ICNF*.

Keywords: carbon release; monitoring forest fires; meteorological satellites; LSA; SAF; EUMETSAT

Introduction

The spectral characteristics, temporal resolution and coverage of meteorological satellites, allow, in addition to weather monitoring, surveillance and forecast, the use of data in other areas of activity, such as climate monitoring, agriculture and forestry support, namely, on forest fires monitoring.
The operation of the European System of Geostationary Satellites (METEOSAT SECOND GENERATION – MSG) is under the responsibility of EUMETSAT (https://www.eumetsat.int/). EUMETSAT ground segment includes, not just a central unity, *Central Application Facility* (CAF), but also, several different centres for satellite applications, *Satellite Application Facilities* (SAF).
The Portuguese Sea and Atmosphere Institute (IPMA) is responsible for the *Land Surface Analysis Satellite Application Facilities* (LSA SAF), ensuring the development of algorithms for obtaining various biophysical parameters on the ground, such as descendant radiative fluxes on small and long wavelength (DSSF and DSLF), the surface temperature of the earth (LST), various vegetation parameters (LAI, FVC, fAPAR) and also the radiative power of forest fires (FRP) (Trigo *et al*, 2011). From these basic parameters it is possible to compute the radiative balance which plays a crucial role in the control of soil moisture and evapotranspiration processes, in turn, depending on the type, level and condition of vegetation and photosynthetic activity. Table 1, shows four LSA SAF products linked with forest fires together with a summary of some of the features of the products.

Table 1. LSA SAF products linked with forest fires

	Processing frequency	Product Name	Status	Observation
FD&M	15 Minute	*Fire Detection and Monitoring*	Operational	Identification of pixels with fires in Europe and Africa
RFM	Daily	*Risk of Fire Map*	Operational	Index associated with the forest fire risk in Europe
FRPPixel	15 Minute	*Fire Radiative Power*	Operational	Fire Power in each pixel - MSG resolution
FRP-GRID	Hourly	*Fire Radiative Power – Gridded*	Operational	Fire Power in a 5º resolution grid

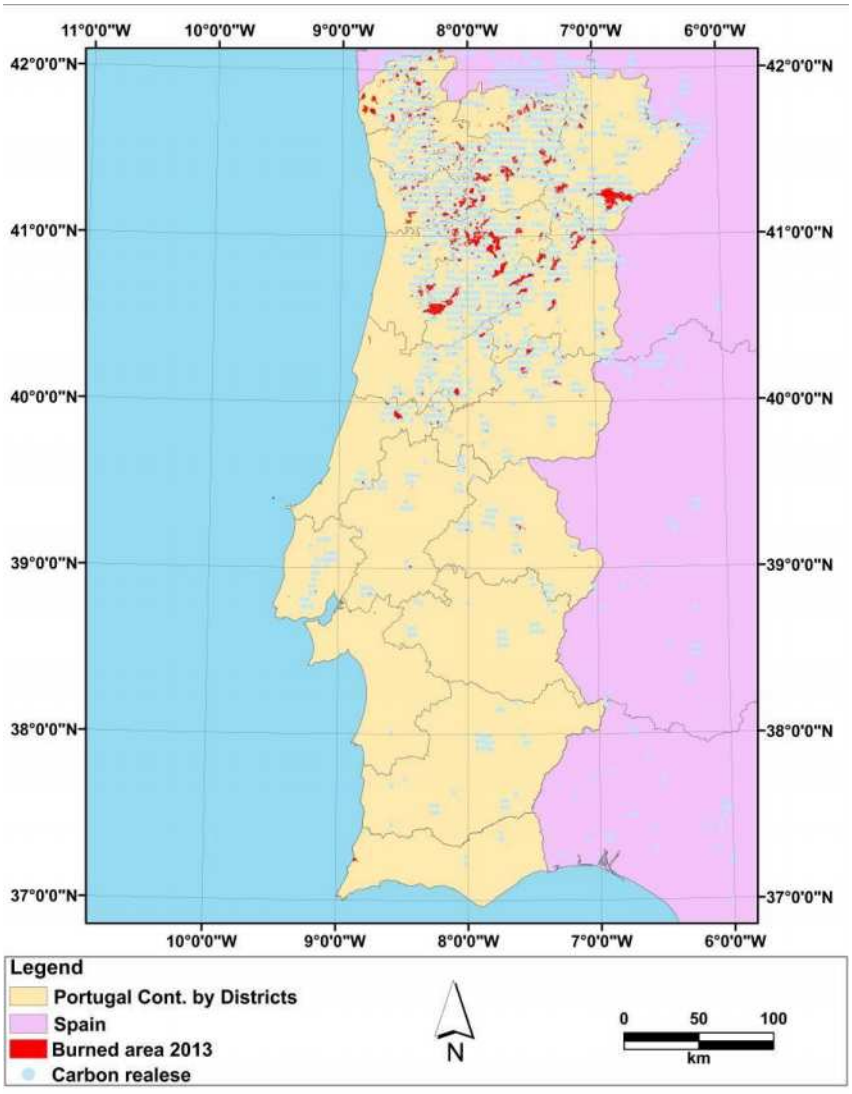

***Figure 1** - Forest fires map to 2013, based on FRP-Pixel LSA SAF product*

SEVIRI (*Spinning Enhanced Visible and Infrared Imager*), is the radiometer on board of MSG satellite systems, with 12 spectral channels each with 3 km spatial resolution (1 km for the high-resolution visible channel) at nadir (Latitude and Longitude are ear 0º, 0º) corresponding, in our latitudes, to a spatial resolution of about 4 km. Temporal revisiting time is of 15 minutes.

Navigation of pixels is possible (associating a Latitude and Longitude to the centre of each *pixels*) and can be used to navigate fire occurrences mapping Carbon or CO_2 over Portugal. Figure 1 shows a fire map for Portugal (January to October 2013): burnt area and CO_2 estimated thorough FRPPixel.

The map was done extracting Portugal mainland from the Europe window of the LSA SAF FRP product distribution. All these products are available for other windows, namely, Europe, Africa (two windows Northern and Southern regions) and South America where this methodology can also be used.

This paper is showing the possibility of monitoring forest fires using FRP product over a region, such as districts, municipalities or other areas of interest, taking advantage of the temporal resolution (15 minutes) of the system. Monitoring specific areas during consecutive days to get information about the evolution of large fires can also be done.

This capability will be illustrated using two large fires: Alfândega da Fé, Picões, (from 8 to 13 July) with 14000 ha of burned area and, in the region of Caramulo (from 21 to 30 August), with 9416 ha according data provide by ICNF (*Instituto de Conservação da Natureza e Florestas*). These 2 large fires where studied in detail by the CEIF (*Centro de Estudos de Incêndios Florestais*) team (Viegas *et al*, 2013).

Data and Methodology

Using the *Fire Radiative Power* (FRP), it is possible to estimate the amount of carbon emitted into the atmosphere, due to forest fires. These parameters can be used in various fields of applications, such as mapping fire carbon emissions over the country, allowing strategic decisions to minimize the effects as, for example, reducing health impact.
The FRP estimate the power of wildfires. It is calculated in megawatts (MW) representing the radiant energy, released per unit time, during the forest fire (Wooster *et al*., 2005). The time integration of the FRP during the wildfire lets allows to estimate the total energy released FRE (*Fire Radiative Energy*). The energy released is directly related to combustion and to the rate of fuel consumed process, through a thermal efficiency rate, where carbon is oxidized releasing CO_2. One fraction is emitted as electromagnetic radiation, which can be detected using remote observation (in the case the SEVIRI sensor, installed in the MSG system). The rate of consumption of biomass (TCB), measured in kg/s, is given by the following expression:

$$TCB\ (kg / s) = 0.368\ (\pm 0.015) \bullet FRP\ (MW)$$

Consumption of biomass (CB) estimated in kg, can be calculated from the following expression:

$$CB\ (kg) = 0.368\ (\pm 0.015) \bullet FRE\ (MJ)$$

From the biomass, it is possible to estimate the amount of carbon (C) released into the atmosphere, using a linear statistical approach to estimate the value (in g) for each kg of fuel burned.

$$C\ (g) = 0.47 \bullet CB\ (kg)$$

The statistical value usually used is 0.47. The equivalent amount of CO_2 released into the atmosphere, is approximately four times higher the amount of carbon.
Either, the equivalent amount of CO_2 or the Carbon released into the atmosphere due to forest fires, presents a good fit with the burnt area provided by the Institute of Nature Conservation and Forestry (ICNF) (Bugalho, L. and Pessanha, L., 2011).
IPMA forest fire reports are including, since 2011, a comparison of the full amount (per day) of carbon/CO_2eq released into the atmosphere, and burnt areas (ha), provided by ICNF. Figure 2 represents the CO_2 equivalent released into atmosphere and the burnt area, in 2013 (May to October), for full Portugal mainland.

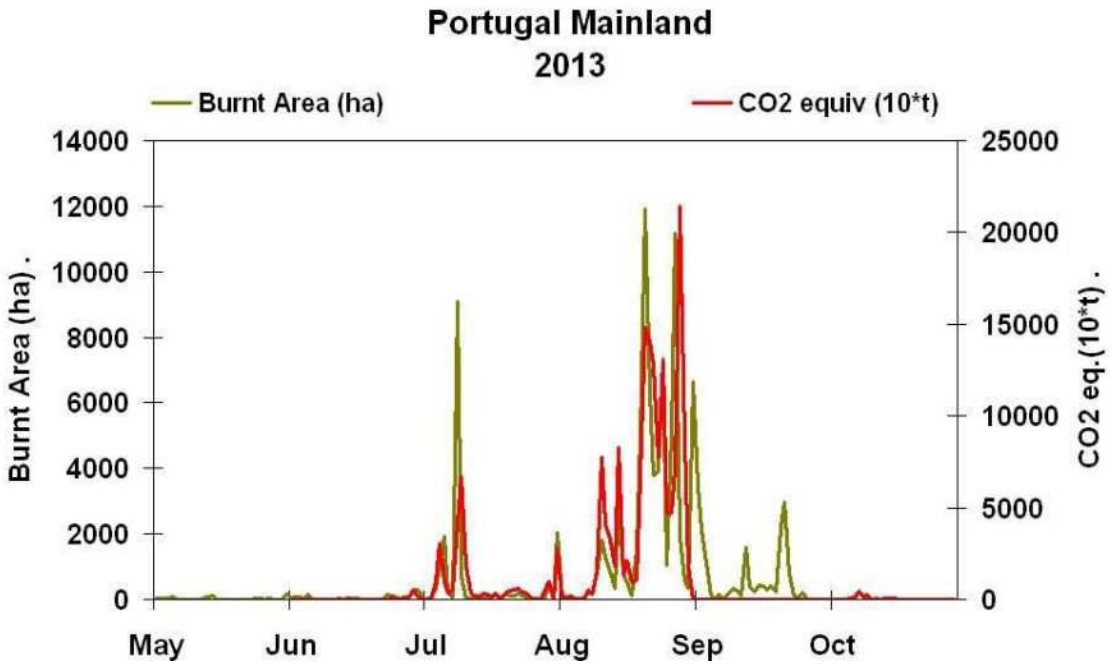

Figure 2. Daily evolution of the equivalent amount of CO2 released into the atmosphere by forest fires across the country (red, 10*tons), based on FRP and burnt area provided by ICNF updated on November 12/2013 (green, ha)

LSA SAF FRP is produced and distributed, in NRT (Near Real Time) and off-line, every 15 minutes for all pixels. These data can, subsequently, be used to obtain the Carbon (or equivalent CO_2), estimated for each pixel and integrated for a given area and period of time. Can also to be used to map and monitor forest fires.

This work is showing the possibility of monitoring forest fires, using Carbon computed based on FRP with 4 km of spatial resolution, taking advantage of the temporal resolution (15 minutes) of the system. As test, two major wildfires of 2013 had been used: Alfândega da Fé (Picões), from 8 to 11 July, and another one, in the region of Caramulo, from 21 to 30 August. Burnt area was, respectively, 14000 ha and 9416 ha, according data provide by ICNF.

On July 8th of 2013, at 14:44 h the biggest wildfire register in Portugal in 2013, ignited in the inhabited village of Cilhade, parish of Felgar, municipality of Torre de Moncorvo, district of Bragança, northeast region of Portugal. Few minutes (less than 10 min) after the initial alarm, all the human and material resources available in the region were fighting this wildfire. The combat to fire was difficult by the extreme slope, characterised in this region. On the July 8^{th,} after a few hours of fighting, the fire was dominated and the progression stopped near to Picões in the municipality of Alfândega da Fé (Figure 3), with a burned area relatively small of 180 ha. Despite all the efforts and vigilance strategies of the firelighters of Alfândega da Fé, on July 9th at 14:00 h the fire rekindle and outbreak the perimeter and started a new event with capacity to evolve to a large fire. This wildfire became known as Picões fire, due the location of the rekindle.

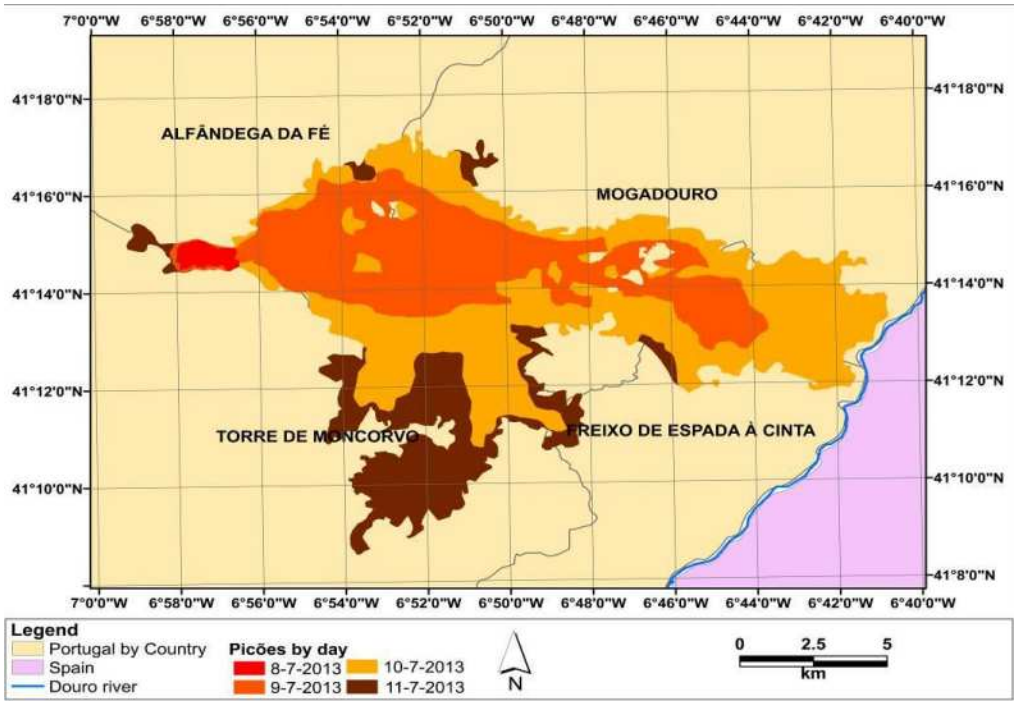

Figure 3. Daily evolution of the burnt area for Alfandega da Fé forest fires

To a better understand of the fire behavior, it is necessary to characterize the region, land use and vegetation, as well as, climate and meteorological aspects.

The geographic characterization of the region from the physical aspect, is continuous mountains with steep slopes and several waterlines running belonging to the basin of the Sabor river.

Land use was mainly occupied for subsistence agriculture, connected to an aged population, olive oil and almond production. *Pinus pinaster* and *Eucalyptus globulus* stands for production of pulp paper.

Meteorologically, the year of 2013 started with large amounts of rainfall. The values of accumulated amounts of precipitation between October 1 of 2012 and June 30 of 2013 were, in general, higher than the normal (average), and ranged from 100% to 150%. The meteorological condition in Portugal mainland, for the initial 10 days of July 2013, according to Novo *et al*, was characterized by an anticyclone system located near to Golf of Biscay, after the 3 of July and again between July 6 and July 10, leading to a very dry and warm air mass, transported from the centre of Spain, resulting in heat wave around the country which last to July 13.

On the July 9th the air temperature record (IPMA meteorological station of Torre de Moncorvo), on the Northeast region of Portugal at 14:00 h (rekindle of the Picões wildfire) attained values over 38ºC, the relative humidity was lower than 13% and the maximum wind velocity was close to 45 km/h. Due the extreme weather conditions the moisture content of fine forest fuels are close to 7%. These conditions were favorable to the development of large fires (slopes, high temperatures, low moisture content of fine forest fuels, strong wind aligned with the drainage basin of the Sabor river).

The wildfire of Caramulo occurred from August 21 to August 30, Figure 4. Most than 20 occurrences were register in these period of time, grouped in three major wildfires, Alcofa (1522 ha of burned area), Silvares (1346 ha of burned area) and Guardão (6548 ha of burned area). These wildfires are the most deadly recording in 2013, reaping the life of four fire-fighters and injuries in several crew members in two human accidents register. Each fire are aggravated by the difficult of the terrain (slope), stands, fuels that provoked embers and burning particles starting often new fire focus and, also, the human limitation to fighting in such conditions.

On August 20th at 23:54 h the Centre of Operations of Tondela firehouse, received an alarm of a wildfire near to the small village of Alcofra. The main cause of this fire was, according to the Portuguese authority, arson.

Reconstruction of these fires was made by the CEIF team, using testimonies of the main interlocutors such as fire-fighters, hotshots, crew members, authority's, civil protection members and local habitants.

The geographic characterization of the region from the physical aspect is continuous mountains with steep slopes. Land use was mainly occupied for subsistence agriculture, connected to an aged population, shrubs, *Pinus pinaster, Eucalyptus globulus* stands, and a Forestry Park under the jurisdiction of the National Forestry Service (ICNF).

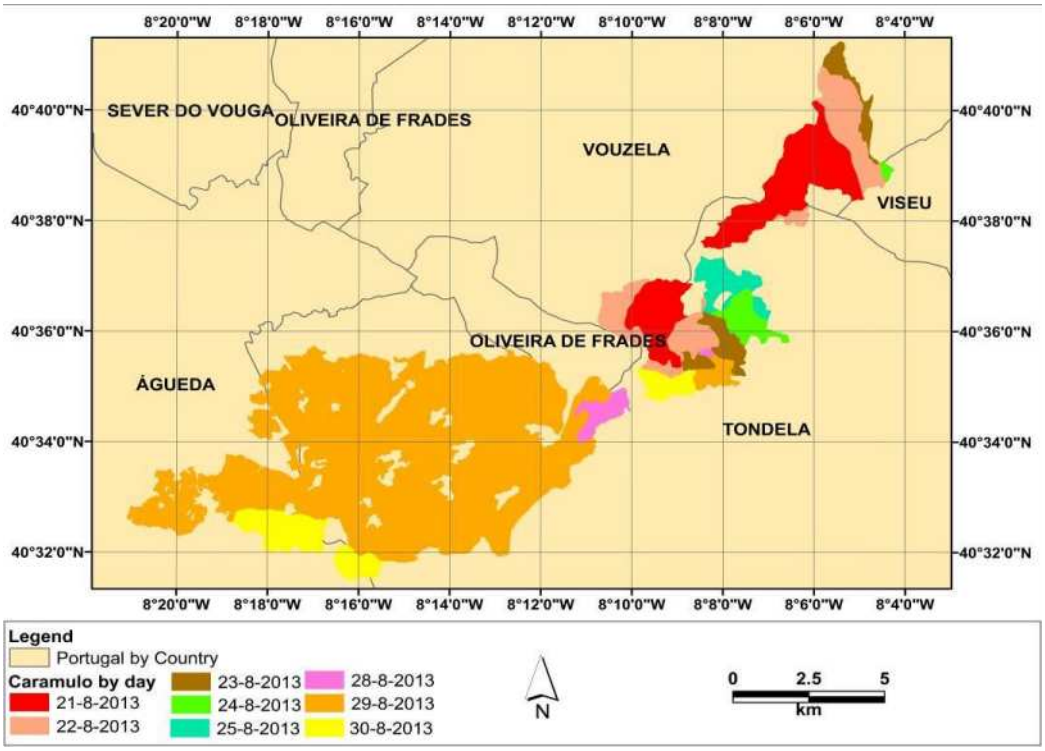

Figure 4. Daily evolution of the burnt area for Caramulo forest fires

The meteorological records shows, from August 21 to August 30, in the station of Viseu, 30ºC of temperature, relative humidity near to 20% and 27 km wind velocity without defined direction, in the first hours of the Alcofa wildfire. The next two days presented same conditions without changes on meteorological conditions. After the August 24, the temperature registered in Viseu oscillated in the range of 10 to 20ºC during the night to around the 30ºC during the day. The wind velocity increased to 50km/h with maximum speed of 60km/h.

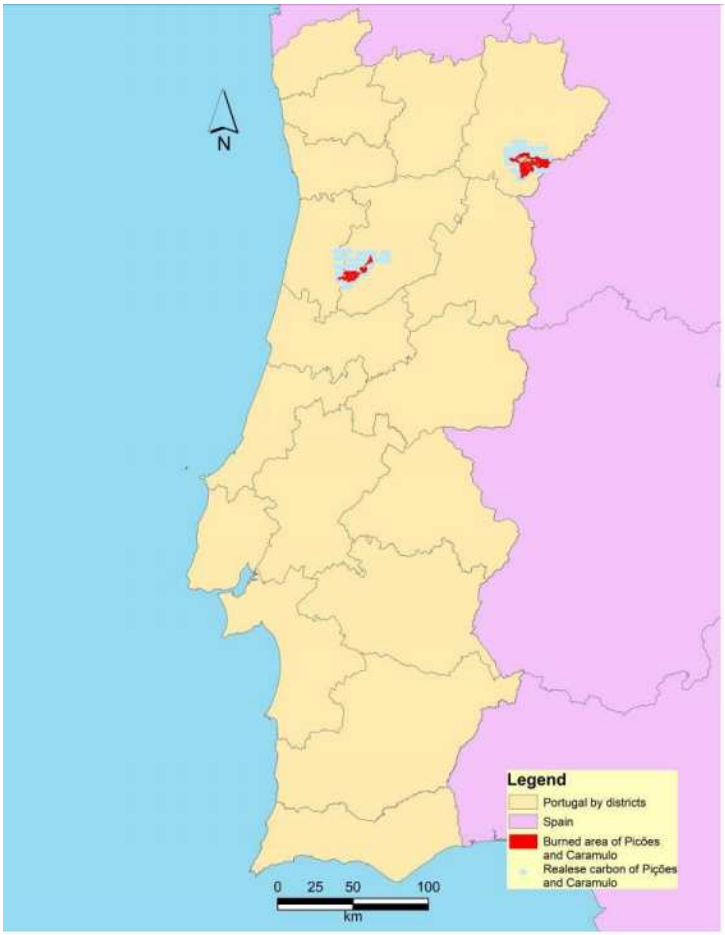

Figure 5 - Localization of two forest fires (Alfandega da Fé and Caramulo). The burnt area measure in red and the FRP product for the same days in blue

Latitude and Longitude of centre of pixels of LSA SAF products are available (geolocation), making possible to map products. For each of the selected wildfire periods already indicated, (8 to 11 July 2013 for Alfandega da Fé and 21 to 31 August 2013 for Caramulo) Carbon data was used to map fires in the correspondent area.

It is possible to observe (Figure) the very good fit of the areas: burnt area prepared by ICNF (*Instituto de Conservação da Natureza e Florestas*) and LSA SAF Carbone map estimated after the integration of the FRP product for the correspondent period of the fires and areas, using all 15 minutes LSA SAF FRP.

Limits for the selection were established:

- Alfândega da Fé: Latitude from 41º 8'N to 41º 18'N, longitude from -6º 59'W to -6º 40'W (Figure 3).
- Caramulo: Latitude from 40º 32'N to 40º 42'N, Longitude from -8º 20'W to -8º 0' W (Figure 4).

3. Results and Discussion

Figure 6 (A and B) shows the evolution of the amount of Carbon released into the atmosphere corresponding to the integrated value (15 minutes), for the each of the two study areas, Alfandega da Fé and Caramulo, for July and August respectively. Analyzing the figures it can be observed a large amount of carbon released into the atmosphere by forest fires from 8 to July 11 in the area of Alfandega da Fé and, on days 21 to 31 August (mainly in 29 and 30), in the Caramulo region.

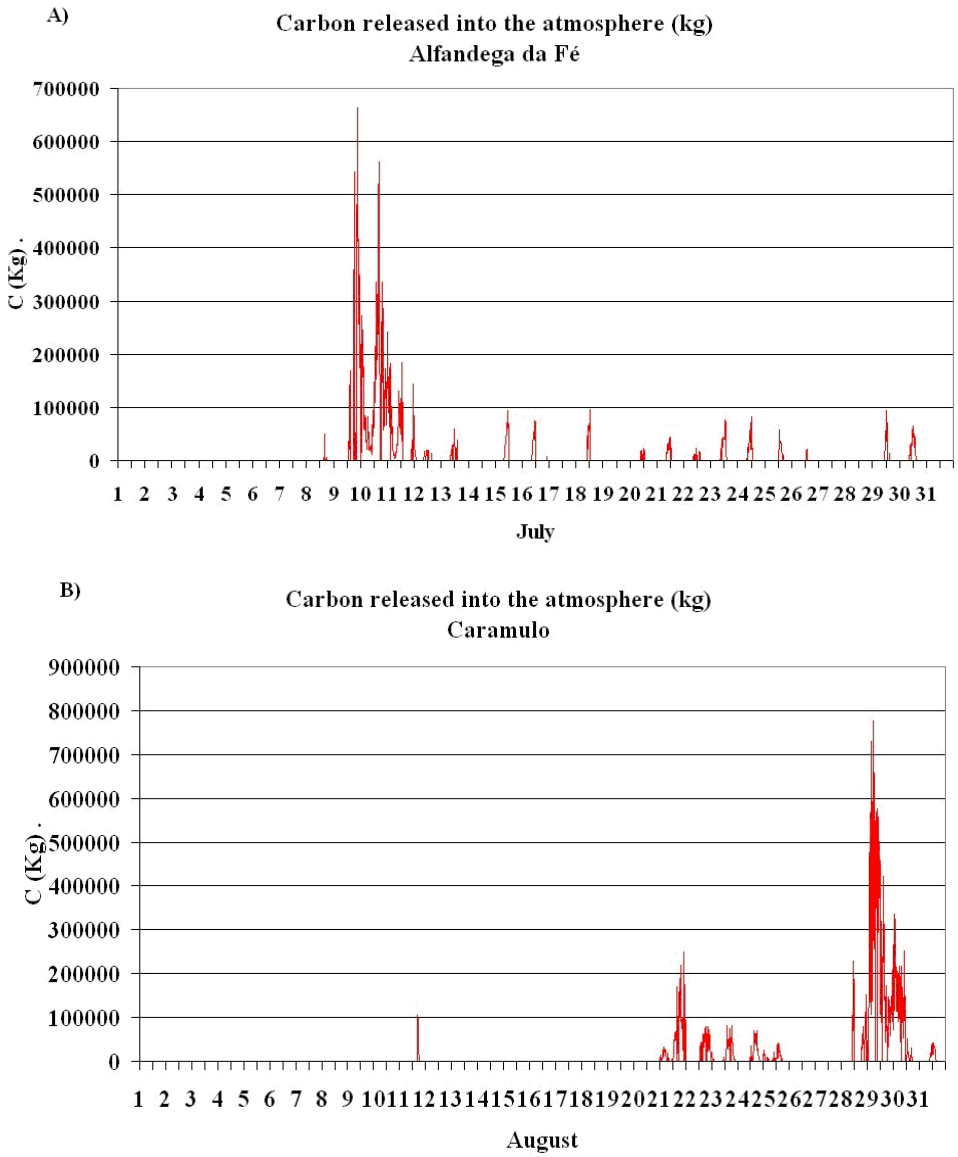

Figure 6 - Daily evolution of the equivalent amount of CO2 released into the atmosphere by forest fires across the Alfandega da Fé area before defined (A) and Caramulo area before defined (B) (red, tons)

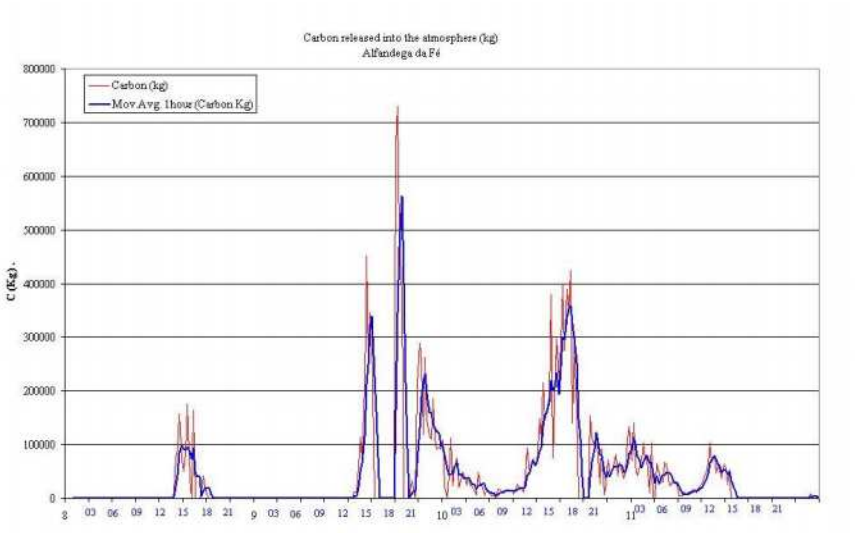
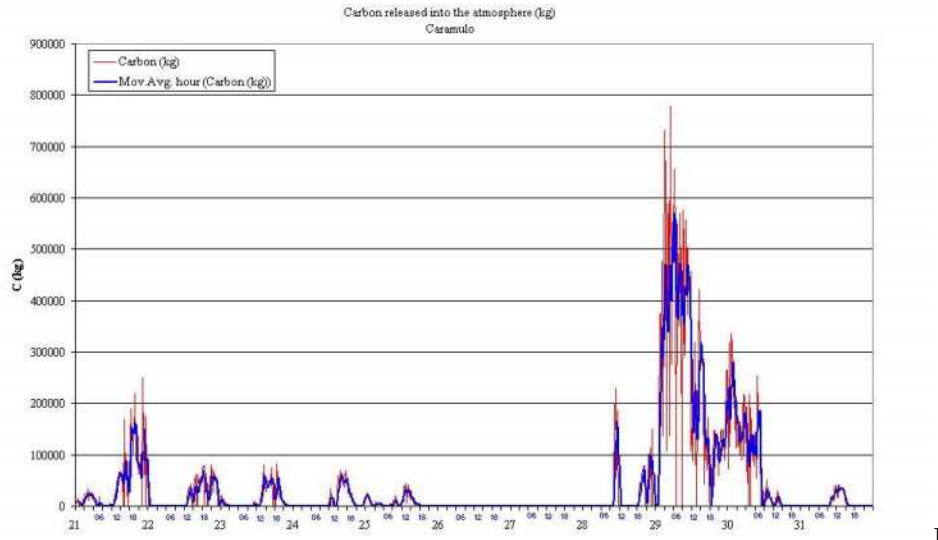
Figure 7 (A and B) shows also the evolution of Carbon released into atmosphere around the periods of maximum emission: Alfandega da Fé (8 to 11 July 2013) and Caramulo (21 to 31 August 2013). A moving average of one hour (in blue) was also included. It is possible to verify that Carbon emission was very high, with a maximum of more than 664 tons of Carbon in 15 minutes, released at 21:00 of 9 July 2013 in Alfandega da Fé and a maximum of more than 777 tons released in 15 minutes on 29 August 2013 at 05:00.



A



B

Figure 7 - The same of Figure 5 during the periods 8 to 11 July and 21 to 31 August, 2013 (red) and moving average of one hour (blue)

The daily evolution of burned areas can be associated to pixels where there are values of Carbone, ie, where it is possible using remote observation, detection of forest fires associated with biomass burning. Figure 8A and B shows the overlay of information about daily evolution of the area burned by forest fires, and pixels. The colour is giving the information about the day of occurrence.

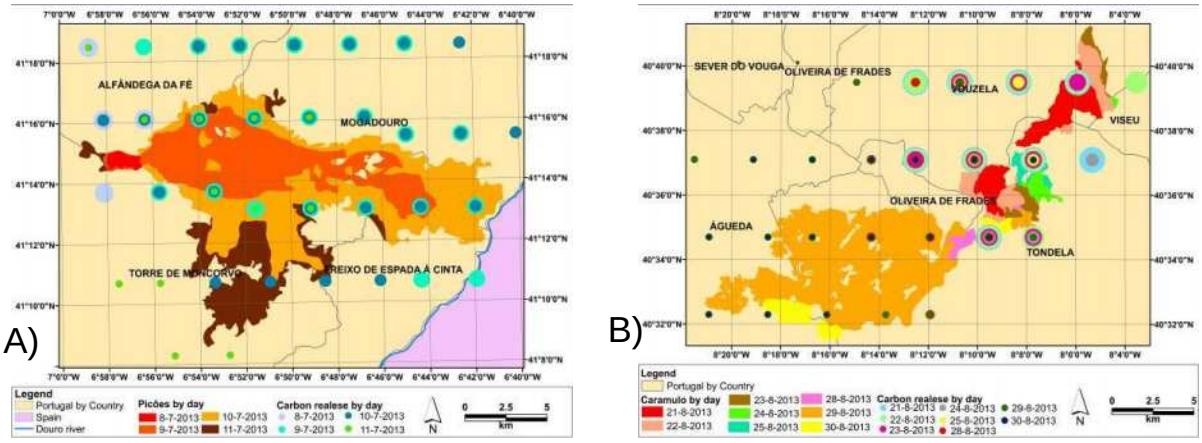


Figure 8- The daily evolution of burnt area for Alfandega da Fé (Picões), (A) and Caramulo (B) and the pixels with FRP values for each day

Note that the location is placed on the centre of the pixel but the fire can be in any place inside of the pixel (or even out the limits of the pixel). Also, geometric correction of the input MSG image can have some impact (geometric corrections done by EUMETSAT) when trying to use in applications near the pixel size. Nevertheless, analyzing Figure 8A and 7B, it is possible to verify that the evolution of spot fires follow the wildfire. For example, in Picões (Alfandega da Fé), Figure 8A, the fire started in further west, on the 8th of July, and it is possible to observe pixels with values of Carbone in light blue in the Figure 8A. On following days (9 and 10), the forest fire migrate to the river eastward. This behaviour is also accompanied by the evolution of Carbone released. On day 11, the wildfire occurs further south, being also accompanied by the Carbone released. Due to the error associated with the pixel size and the geolocation error, associated to remote sensing technique, the pixels with values of Carbone are not always over wildfire.

Conclusion

It is possible to conclude that:

- Results obtained so far shows a good correlation between burnt areas and Carbone (or CO_2) released in the atmosphere;
- In the case of the two large fire events in 2013 this is especially true.
- The monitoring Carbon (or CO_2) release in the atmosphere during forest fires, seems good and shall be used as an environmental tool.
- It seems possible to used the estimation of Carbon (or CO_2) released into the atmosphere as an economic way of estimating burned area, with enough quality to be used in NRT (*Near Real Time*).

Abstract

The paper presents a state of the art in the research area of ground based wildfire surveillance systems with special emphasis on their latest generations proposed and developed in the last couple of years. We have focused primarily on novel, more efficient algorithms for wildfire detection, but other topics like fusion of video based systems with other wildfire detection systems and their integration with Geographic Information Systems (GIS) systems has also been analyzed. Our particular focus was on research carried out in our Department. Last but not least, we give our opinions and assumptions about future development of such systems.

Keywords*: wildfires, forest fires, smoke and fire detection, wildfire monitoring, wildfire surveillance, augmented reality, GIS, wildfire monitoring network, fusion of video data.*

Introduction

Wildfires are still a constant threat to ecological systems, as well as human safety, causing rapid reduction of forest stand. Many efforts in fire prevention and protection are aimed to reduce not only the number of fires, but also the fire damage. It is well known that early fire detection and quick and appropriate intervention are the most important measures for wildfire damage minimization. Once a wildfire has expanded, it is very difficult to control and extinguish. Therefore in countries that have a great wildfire threat, there are a lot of efforts to organize appropriate and efficient wildfire surveillance. Wildfire surveillance1 is still mostly based on a traditional human wildfire observers, specially trained people located on selected spots with a good visual coverage of protected area, usually equipped only with binoculars, maps and communication units. Their task is to detect wildfire in the incipient stage, try to locate it on the map and to alert the appropriate fire department. In fire season human observers are engaged 24 hours a day and they are exposed to isolation, extreme weather conditions, especially high temperatures and a need for continuous concentration.

Therefore, since 1932 when the inventor called Osborne designed a swing-lens panoramic camera used by USDA Forest Service for wildfire detection (Kresek, 2007), until today a lot of research was done with the aim of photo and video based systems in wildfire detection to make the observers' job less

[1] *Concerning wildfire observation two terms could be encountered – wildfire surveillance and wildfire monitoring. They are often thought as synonymous, but there is a certain difference in their meaning and a lot of discussions about these differences. More or less in all discussions people agree that they are identical in the fact that they collect routinely information on phenomena, but surveillance is more than monitoring. Under surveillance the information collected are analyzed, interpreted and action taken while in monitoring the action might not necessarilly be there, depending on the purpose of this monitoring. The other difference is that term surveillance is mostly used when information is collected primarily by vision sensors, and in monitoring it is not necessary to have a vision sensor at all and instead any other kind of sensors could be used. As our focus is primarily on vision based systems in this paper we will use the term wildfire surveillance.*

strenuous and easier. These research efforts were particularly intensive after 80s, thanks to development of video technology. At the beginning, that was only dislocation of the observer to the observation center and installment of pan, tilt, zoom controlled video cameras on monitoring spots, but quite soon more advanced systems have been proposed with the ability of automatic wildfire detection (Cappellini *et al*., 1989). Human observer no longer needs to constantly look at the monitor. His/her job is now to check and verify whether the raised alarm is real or false. Such automatic systems could be used not only for early fire detection, but also for distant video presence, a task very important for preventive inspection of the protected area as well as for fire-fighting coordination when the fire starts, so they are usually called automatic wildfire surveillance systems and to emphasize that they are located on the ground automatic ground based wildfire surveillance systems.
Since the end of the 80s, a few generations of such systems have been developed, designed and deployed, not only as experimental, but also as real working systems (Kührt, 2001) (Dedeoglu *et al*., 2005) (De Dios *et al*., 2008) (Stipaničev *et al*., 2010). Improvements have occurred on different parts and functions, both on hardware and software level. This paper focuses on the last generation of such systems that have been proposed in the last couple of years. Our attention is particularly focused on:

a) Algorithms for wildfire smoke and fire detection, resulting in significant improvement of detection features,

b) Fusion of video detection in various electromagnetic ranges, as well as fusion of video detections with other sensor types,

c) Close integration of wildfire surveillance and monitoring and systems with Geographic Information Systems (GIS), resulting in new features in both fire detection and distant video presence modes,

d) Synergy effect of wildfire observer network consisting of mutually connected individual wildfire observers working together in cooperation.

The paper presents a state of the art in this research area with emphasis on the research carried out in our Department in the last couple of years (Stipaničev *et al*., 2010) (Šerić *et al*., 2011) (Jakovčević *et al*., 2013) (Bugarić *et al*., 2014). We have worked and we are working on almost all of the topics listed above, both on the experimental, laboratory level but also on practical implementation.

Improvements in algorithms for wildfire smoke and fire detection, resulting in significant improvement of detection features

Vision based wildfire detection systems are mainly focused on smoke detection during the day and fire detection during the night. Since 80s, a lot of different algorithms have been proposed based on different smoke and fire visual characteristics. In this review we have been focused on recent works since 2011. Review of the previous works in this field could be found in (Jakovčević *et al*., 2011).
Most of the methods for smoke detection are based on the moving region detection as the first step of the detection process. Ashish at al. proposes an algorithm (Ashish *et al*., 2013) based on the background subtraction method introduced by Collins at al. (Collins *et al*., 1999). In detected regions, color is used as discriminatory characteristic where smokes colored pixels are expected to have small aberration in red, green and blue channels from the average value of all three channels. Another distinctive characteristic of smoke is perimeter to area ratio that is expected to be above the predefined threshold. Finally, suspicious regions that satisfy above given conditions are checked against dynamic property of the smoke that it continuously moves in upward direction. Brovko *et al*. (Brovko *et al*., 2013) proposed an algorithm based on motion and contrast, with wavelet transform applied as a preprocessing step to reduce the image size and to remove high frequencies details. Slowly moving areas are detected by frame differencing of 3 consecutive frames. Model for blending semitransparent objects with background is introduced with:

$$I_{t+1}(x,y) = b \times F_{t+1}(x,y) + (1 - b) \times B_t(x,y) \quad (1)$$

where $I_{t+1}(x,y)$ is the current frame, β is the blending parameter and $B_t(x,y)$ is the background from the previous step. As soon as frame $I_{t+1}(x,y)$ is obtained, foreground can be estimated from equation (1). Smoke propagation direction based on optical flow calculation is used as a final test for suspicious regions.

Complex wildfire smoke detection technique is proposed by Labati *et al*. (Labati *et al*., 2013) based on the previous work by Genovese *et al*. (Genovese *et al*., 2011) using computational intelligence methods to dynamically adapt to the environment. Proposed algorithm can be summarized in the following steps: moving region detection, smoke-color analysis, sharp edge detection, growing region detection, rising region detection, perimeter disorder analysis and feature set computation. Moving region detection is based on the work of Collins *et al*. (Collins *et al*., 1999). Two different background images are estimated. The first one is updated at every frame and the second is updated with a period of 1 second. Two background images are used to extract slow moving regions. A matrix D_M representing the motion of every pixel is computed according to:

$$D_M(x,y,t) = \begin{cases} 0, & if \left| B_f(x,y,t) - B_s(x,y,t) \right| \le T_l \\ \left(\left| B_f(x,y,t) - B_s(x,y,t) \right| - T_l \right) / (T_h - T_l), & if\ T_l \le \left| B_f(x,y,t) - B_s(x,y,t) \right| \le T_h \\ 1, & if\ T_h \le \left| B_f(x,y,t) - B_s(x,y,t) \right| \end{cases} \quad (2)$$

where $0 < T_l < T_h$ are fixed threshold values. In the next step color feature matrix is computed based on the work of (Toreyin *et al*., 2009) and pixels not satisfying predefined conditions are discarded. Sharp edge detection step aims to search high differences in the luma channel of adjacent frames, usually not present in the regions containing smoke. Growing region matrix is computed as the difference between the moving regions at the time instants *t* and *t-1* and only positive values of growth are considered to avoid excessive data fluctuations. Finally, rising value of the moving pixel and the perimeter disorder is computed. Two different algorithms use the computed features set. In *Algorithm A* the features are extracted for every pixel of each frame of the frame sequence and in *Algorithm B* the features are extracted globally for each frame. Feature selection algorithm based on kNN is applied separately for different scenarios. Obtained features are used as inputs for computational intelligence and statistical classifiers.

Park *et al*. (Park *et al*., 2013) proposed an algorithm for wildfire smoke detection using spatial-temporal bag-of-features (BOF) technique. Slow moving regions are extracted by key-frame detection, followed by rejection of non-smoke colored blocks based on probability density function of smoke color model learned from the training data. For the remaining suspicious blocks, combining the candidate blocks with 100 corresponding blocks in previous frames creates a spatial-temporal 3D volume. Histogram of optical flow (HOF) is extracted as a temporal feature and histogram of gradients (HOG) extracted from the current block is used as a spatial feature. Random forest classifier trained from the training data is used as a final confirmation of smoke.

Vipin (Vipin, 2012) proposed a rule-based system for forest fire detection. Fire-colored regions are detected by processing input images in RGB and YCbCr color spaces. Avgerinakis *et al*. (Avgerinakis, 2012) proposed an algorithm based on temporal HOGHOF descriptors and color energy. Separation of moving from static pixels is based on the assumption that real motion introduces deviation from the Gaussian distribution of motion vector induced by noise. Moving blocks are constructed in regions

where at least 50% of pixels are detected as moving. HOG descriptors are calculated for moving blocks and HOF is constructed from previous set of frames. Extracted HOG and HOF descriptors from the training set are used to train SVM classifier. When a frame with smoke is detected, second stage of the algorithm takes place, where statistics based on the color energy of the candidate blocks are analyzed to determine whether they contain smoke or not.

Algorithm proposed by Lee *et al*. (Lee *et al*., 2012) is based on hybrid motion segmentation using frame differencing and Gaussian mixture model. For the regions with detected motion spatial and temporal features are extracted. Spatial wavelet analysis detects loss of energy in high frequencies is followed by temporal energy analysis differencing sudden loss of energy corresponding to rigid objects from the gradual loss of energy which may represent smoke. Color information is used as the third characteristics for identifying smoke in a video. Based on the empirical analysis, authors assume that smoke affects every component in the RGB color space. However, it does not drastically change the configuration of the normalized rgb color system. Described features extracted from the training data set are combined and used to train SVM classifier. Final verification of the smoke is based on temporal consistency. The alarm is raised if smoke is detected for over 50% of a predefined time interval. In the study presented by Ko *et al*. (Ko *et al*., 2012) moving regions are detected using key-frame differencing. Features extracted from the training data are used to train two random forest (RF) classifiers. One is trained using temporal features, namely: average hue, saturation, intensity and skewness of the hue, average wavelet energy and skewness of the wavelet energy and spatial motion orientation from the preceding 100 frames. Histogram of gradients (HOG) from the current block is used to train the other classifier. A candidate block is declared as smoke block if the average probability of two RF classifiers in a smoke class is maximum.

Surit and Chatwiriya (Surit, 2011) proposed a technique based on frame differencing. Moving blocks are examined and confirmed as smoke based on color. Habiboglu *et al*. (Habiboglu *et al*., 2011) proposed an algorithm based on two background models, where one is optimized to detect fast moving objects used to differentiate ordinary objects from smoke-like moving regions. Set of thresholds in YUV color space is used to further filter non-smoke from smoke colored pixels. Slow moving region detection was based on GMM background models. Background model optimized to detect fast moving objects is used to differentiate ordinary objects from smoke-like moving regions. Set of thresholds in YUV color space is used to further filter non-smoke from smoke colored pixels. For each pixel satisfying the color condition a set of covariance descriptors is extracted, including luminance, chrominance, intensity and its temporal derivatives. The video is divided into blocks that do not overlap in spatial domain but there is 50% overlap in time domain. SVM classifier is trained for classification. Similar technique based on the covariance descriptors and SVM classification was also proposed for flame detection (Habiboglu *et al*., 2012).

Last but not least let us mention the work of our Department concerning improved algorithms for wildfire smoke detection. Interesting and promising research work was integration of context information in wildfire detection, together with motion, chromatic, texture and shape analysis (Jakovčević *et al*., 2011). Visual context analysis was performed by region merging segmentation, classification and applying context rules based on shape analysis. The phase of classification into classes smoke, low clouds and fog, sun and light effects, water surface and sky, distance landscape and vegetation, was not used for detection itself, but as a validation process for false alarms reduction. Fig 1 shows an example of input and classified image.

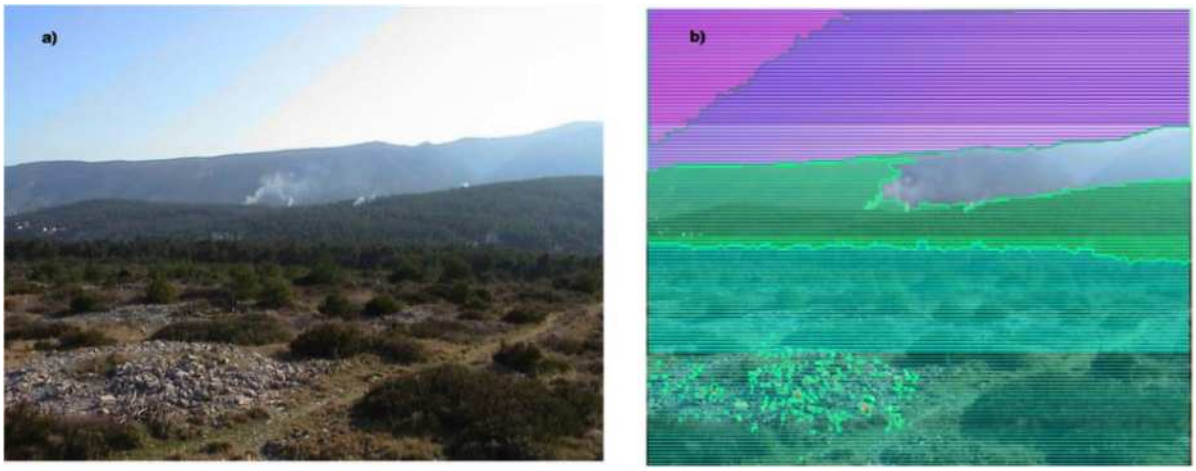

Figure 1. a) Input image and b) classified image used in visual context analysis

Fusion of video detection in various electromagnetic ranges and fusion of video detections with other sensor types

Sensory data fusion is today one of the top themes in artificial perception inspired by human perception. Humans usually use the fusion of data from more than one sensor in order to understand their surroundings. Usually the fusion processes are divided in low level or data fusion, intermediate level or feature fusion and high level or decision fusion (FireSense, 2010). Low level fusion or data fusion combines various raw data to produce new raw data having additional information in comparison with input data. Intermediate fusion or feature fusion is a fusion of features primarily extracted from row data. High level fusion or decision fusion is performed on the decision making level when various sources are used only for final decision making. In wildfire surveillance all three fusion types could be used and realized as fusion of video data captured in various electromagnetic ranges, usually visible and IR spectra and fusion of video data with other sensors data, particularly meteorological sensors data. Fig 2 shows an example of smoke visibility during typical hot summer day in visible and far IR spectra.

The research presented in (Verstockt *et al*., 2012) describes a multi-sensor approach to smoke detection using visible and thermal imaging. The information from both sensors is analyzed in order to extract moving objects that could potentially represent smoke. The silhouette of the moving objects is examined in order to determine the appearance of smoke in the scene. In order to implement this type of multi-sensor detection process, images for two different sources have to be registered. The registration is performed using a contour-mapping algorithm where the rotation, scale and translation of moving objects are discovered.

Figure 2. Smoke visibility during typical hot summer day in visible spectra (left) and far IR spectra (right)

Another approach, presented in (Torabnezhad *et al*., 2013), describes a new method of smoke detection based on fusion of information from IR and visible sensors, since each source alone cannot provide the full information about the potential event. The method is designed for smoke detection on short distances. The smoke is not visible in the IR images, so this feature is used to distinguish between smoke and objects/phenomena visually similar to smoke. The method consists of two phases. In the first phase the input from both sources is used to generate a potential-smoke mask. The mask from the visual source is obtained using background subtraction and a smoke color model, while the mask from the IR source is obtained using hot object segmentation where due to invisibility of smoke in the IR image the smoke pixels are not segmented as hot objects. The potential smoke mask is built using these two masks as input. The second step is based on disorder measurements and energy calculation in order to reduce false alarms. The authors characterize the method as very effective and accurate.
Work presented in (Verstockt *et al*., 2010) describes a new multi-sensor fire detection system operating on ordinary video and long wave infrared (LWIR) thermal images. The detection process consists of several phases. When dealing with thermal images, the detector extracts hot objects using dynamic background subtraction and histogram based segmentation. Similarly, when dealing with ordinary video, moving objects are extracted using dynamic background subtraction. Both types of objects, hot and moving, are further analyzed using flame features based on specific geometric, temporal and spatial disorder characteristics of flame regions. By combining probabilities of visual and thermal features, according to authors it is possible to detect fire at an early stage.
Salah *et al*. (Salah *et al*., 2011) describes an FP7 project dealing with protection of cultural heritage sites from the risk of fire and extreme weather conditions. The fire protection is provided using a fusion of information obtained from IR and visible images. The main problem with this type of approach is the image registration between two different sources. The objective is to discover the correspondences between images. When the correspondences have been found the images can be transformed into the same reference so it is possible to achieve information fusion. The process of registration is challenging because the wavelengths of the IR and visible spectrum are different, so the general approaches such as SIFT and RANSAC do not work properly in this case. Authors have discussed several different registration approaches and proposed explicit alignment of lines derived from edge pixels. The individual extracted points could not always match correctly, so a Hough transform is used to generate lines. Using four of the generated lines it is possible to obtain perspective transformation matrix used for registration. The paper does not present explicit results for the fire detection process.
Although detection of wildfires using fusion of video data is most common, there are some drawbacks to this approach, primarily fusion of video based systems and other sensor types. Various types of sensors are used in wildfire detection, primarily meteorological sensors like temperature, pressure, humidity, wind and sun radiation sensors, but chemical sensors sensing carbon monoxide, carbon

dioxide and nitrogen dioxide are also used. The main problem in video - sensors data fusion is the correct fusion application for heterogeneous sensor types. Interesting example of smoke video detection and meteorological information fusion were presented by Štula *et al*. (Štula *et al*., 2011) where fuzzy cognitive maps with 4 concepts: current wind, conclusion on alarm (true/false), false alarms generated in the last 24 hours and current humidity was used for false alarms reduction in image post-processing phase.
Fire detection on Wild-land Urban Interface (WUI) using wireless sensor network was studied in SCIER project (Sekkas *et al*., 2010). The system architecture consists of three layers: Sensors, Local Area Control Unit (LACU) and Computing Subsystem. Sensors that are measuring temperature, humidity and vision sensors are organized into local clusters. LACU is responsible for administration of local sensor network. First level of fusion is performed on local cluster by calculating cumulative sum (CUSUM test) of local sensors and assigning basic probability of fire to each of them. Computing subsystem perform second level of fusion. Data from all LACU units are fused using Dumpster-Shafer evidential theory.
In (Šerić *et al*., 2011) authors proposed framework for multi sensor data fusion based on vision sensor and environmental sensors with goal of forest fire detection and false alarm reduction. The framework utilizes formal theory of perception and describes data fusion aiming to detect sensors and network failure (syntactic and semantic data validation) and occurrence of wildfire phenomenon. The system is also interesting, because it is entirely based on software agent's architecture. Software agents and intelligent software agents are responsible for everything from image and data collection to final wildfire recognition.

Integration of wildfire surveillance and monitoring systems with GIS

GIS can be of great benefit for wildfire surveillance, regardless of whether it is used in the phase before, during or after the wildfire (pre-fire, fire and post-fire). Geographic position of wildfire, as well as the time of ignition, is of vital importance in many aspects of human and material safety.
In the 'pre-fire phase' GIS could be used to calculate the probability of fire occurrence. Wildfire risk index is a numerical indicator that defines the level of fire risk and as such is associated with a certain geographic area. For this reason, GIS is the right tool that could be used to develop advanced wildfire risk models. We have developed a site-specific wildfire risk index (SWRI) that is focused on the micro-location and based on climatological and meteorological parameters, vegetation, terrain configuration and anthropogenic parameters (Bugarić *et al*., 2014).
SWRI could be quite useful in wildfire surveillance systems, particularly in its automatic mode for more successful wildfire detection. An example is recent work of Bugarić *et al*. (Bugarić *et al*., 2014) where it was shown how any existing smoke detection methods could be improved by the automatic adaptation of smoke detection parameters based on SWRI. Almost every existing smoke detection method depends on various detection parameters that could be manually edited and change to adapt the algorithm and particularly its sensitivity, on the current weather situation. Normally this is a job of system operators, but in practice we could encounter that operators are not very keen to interact with detection procedure and change parameters. One of the possible solutions is automatic adaptation of smoke detection parameters. In our approach it was based on GIS and Augmented Reality (AR). GIS was used for calculation of SWRI and augmented reality scene calibration. The idea was to find link between real world scene and digital elevation model based on GIS. Then the calculated SWRI map in GIS could be transformed to word scene as Fig 3 shows and applied for adaptation of detection parameters. On all those image parts where fire risk index is high the detection algorithm sensitivity will be also higher and vice versa where there is small fire risk index, for example on river parts the algorithm sensitivity could be lowered to zero.

Figure 3. Original image of detection area and synthetic AR image of the same view with superimposed site-specific wildfire risk index

Augmented Reality based mixing of real images and GIS produced data could be used not only for automatic adjustment of motion detection sensitivity, but also to selective blurring of input images based on point distance from the camera, definition of the minimal candidate region size and dynamics analysis based on detected region growth.

Augmented reality in combination with GIS could be useful in manual mode of wildfire surveillance and monitoring systems as well. The important fact is that these systems are geo-referenced, so for every pixel in the image the corresponding geo-coordinate is known and vice versa. Therefore, in manual mode, relevant GIS information such as toponyms, compass, geographic coordinates or altitudes could be presented on a real-time video stream. Another important capability of GIS, useful in the phase before the wildfire, is interpreting and visualizing the current weather conditions, such as wind speed and direction, temperature or humidity. These data could be of great importance in the case of organizing fire-fighting activities. Figure 4a shows an example of dynamic presentation of meteorological data where weather information is automatically and dynamically retrieved from a Croatian Meteorological and Hydrological weather server several times a day. Important is to note that this feature is of equal importance also in the fire phase when it is important to predict the future fire behavior.

Visibility of any point manually chosen on the map could be easily verified using simple trigonometry and Digital Elevation Models. Note that visibility maps and elevation profiles could also be generated using GIS, as this feature is suitable for better understanding of what is visible in the camera image. Another important feature that GIS systems provide is the determination of azimuth, elevation and field of view of the actual video camera viewing as Fig 4b shows.

Figure 4. a) Superposition of dynamic meteorological data on GIS maps and b) presentation of cameras azimuth and field of view on GIS map

When wildfire is spotted the 'fire phase' start. For wildfire damage minimization it is important to have a rapid and well-organized response. Apart from the information concerning the current weather conditions, knowledge about the wildfire features is equally important as it may affect the final outcome. These features include the time and geographic coordinates of the ignition, the way in which the wildfire spreads, real-time tracking of the fire front and the current location of fire-fighting units in the field.

After a successful detection of the wildfire, determining the ignition point and displaying it on the map could be done using 'alidade'-like devices such as Osborne Fire Finder or DragonPlot (Guth et.al., 2005). However, more advanced methods using vision based wildfire surveillance and GIS could be used. Almost all wildfire surveillance systems on the market have this ability, either as cameras azimuth ray intersection with digital elevation model, triangulation if few cameras could see the fire location or based as afore mentioned AR systems that we have developed (Bugarić *et al*., 2014). It has the ability to extract geographic coordinates by simply clicking on any pixel on real life image using AR based pre-calculated image templates where for every image pixel its corresponding lat-long-height coordinate is determined.

Figure 5. a) Simulated wildfire spread shown on GIS map and b) superimposed in real time on real camera view using Augmented Reality methods

Wildfire propagation modeling and simulation is another feature for wildfire surveillance, useful in pre-fire and fire phase. Based on vegetation characteristics, landscape and meteorological conditions the future fire spread could be simulated in appropriate time steps. Fig 5a shows result on one such simulation for SE winds. In pre-fire phase it could be used for training and in fire phase for proper intervention planning and management. Augmented Reality could be used for superposition of fire spread simulation results on real life image as Fig 5b shows.

Synergy in wildfire observance networks

Aristotle coined that "The whole is more than the sum of its parts." This sentence was later used to describe the synergy, the effect that exists between parts of a system working together in a cooperative effort. Therefore, having a wildfire observance network of mutually connected individual wildfire observers working together in cooperation, could give the overall effect greater than the sum of their individual effects. Cooperation of individual wildfire observers could be used to improve automatic wildfire detection as well as to enhance manual camera PTZ control.
