Preface

Forest fires remain a challenge to firefighters, scientists, managers, decision makers, and citizens, in many parts of the World. Conditions brought by a changing climate associated to other trends in land use and fuel management policies along the past years indicate that extreme fire behaviour episodes may occur more frequently than in the past, bringing even more challenges to all.

During the past twenty to thirty years the international fire research community grew in number, quality and diversity of scientific areas involved worldwide. This is reflected in the number of scientific publications and meetings dedicated to forest fires.

The International Conference on Forest Fire Research, that has its seventh edition in 2014 in Coimbra (Portugal), aims to serve its purpose of being a platform to present and discuss the latest results of scientific research on various areas of forest fire management. Almost 300 extended abstracts were submitted for the conference, on the following topics:

- Economic Issues
- Evaluation and management of burned areas
- Fire at the Wildland Urban Interface
- Fire Behaviour
- Fire Detection and Monitoring
- Fire Ecology
- Fire Management
- Fire Safety
- Fire Suppression and New technologies
- Forest Fire Risk assessment and Climate Change
- Forest management and Fire Prevention
- Human and Institutional factors
- Large Fires
- Remote Sensing

Following a process of dedicated evaluation and selection by the Conference Scientific Committee the full papers were put together in this Book.

I hope that this Book may serve the purpose of keeping a record of the recent research in these fields and to illustrate the role that is played by the scientific community in the face of the challenges that these new times bring to fire science. I am sure that it will inspire and provoke more investigation and collaboration.

In the name of the Organizing Committee of the Conference I wish to thank all the authors for their valuable work and for their participation.

I wish to thank Dr. Mike Flannigan for having accepted, once more, the role of Head of the Scientific Committee, who with the help of a group of selected experts revised the submitted abstracts and selected them. Their work was very important to keep the high level of quality that has been the standard of this Conference and I wish to thank the reviewers also.

I would like to express my personal thanks to all the members of the Organizing Committee and in particular to my colleagues of the Local Committee and the Secretariat for all their support, work and dedication during the preparation of the Conference. They carried the largest part of the work load that included the performance of the large and small tasks that are required to put this Conference together and therefore they deserve thanks from all of us.

Chapter 1
Fire Behaviour and Modelling

A Comparative Study of Parameter Estimation and State Estimation Approaches in Data-Driven Wildfire Spread Modeling

Abstract
The objective of this work is to demonstrate the ability of the FIREFLY data-driven wildfire simulator to forecast the fire spread behavior over complex terrain topography. The prototype simulator features the following main components: a level-set-based fire propagation solver that adopts a regional-scale viewpoint, treats wildfires as propagating fronts, and uses a description of the local rate of spread (ROS) of the fire as a function of vegetation, topographical and meteorological properties based on Rothermel's model; a series of observations of the fire front location; and a data assimilation algorithm based on an ensemble Kalman filter (EnKF). The data assimilation algorithm also features a choice between a parameter estimation (PE) approach in which the estimation targets are the input parameters of the ROS model, and a state estimation (SE) approach in which the estimation targets are the spatial coordinates of the discretized fire front. This study shows the extension of the FIREFLY data-driven simulator to complex terrain topography. The fire propagation is represented by time-evolving two-dimensional fronts along the horizontal plane in order to remain consistent with the formulation of the PE-/SE-based EnKF algorithms that were initially developed for flat terrain configuration. While evaluated on synthetic cases in this study, the performance of the EnKF algorithm is shown to be preserved in the case of complex terrain. Thus, this study emphasizes the potential of data assimilation to dramatically increase wildfire simulation accuracy in real-world wildfire events.

Keywords: *Data assimilation, Ensemble Kalman Filter, Wildfire, Fire modeling, Terrain topography*

Introduction

The challenges found on the route to developing quantitative fire models are two-fold. First, there is the classical modeling challenge associated with providing accurate mathematical representations of the multi-physics multi-scale processes that involve biomass pyrolysis, combustion, flow dynamics as well as atmospheric dynamics and chemistry (Sullivan 2009a, 2009b). Second, there is the less common data challenge associated with providing accurate estimates of the input parameters required by the models (Viegas 2011). Current regional-scale fire models are limited in scope because of the large uncertainties associated with the accuracy of physics-based models, because also of the large uncertainties associated with many of the environmental conditions that are required as input parameters to the fire problem (Rochoux 2014). A possible approach to overcome the limitations found in numerical simulations of wildfire spread as well as to develop predictive models that are compatible with operational applications is data assimilation (DA). This approach takes advantage of recent progress made in airborne remote sensing that is promising for real-time monitoring of the fire front location (Paugam *et al*. 2013). DA offers a convenient framework for integrating fire sensor observations into a computer model along with the estimated modeling/observation uncertainties with the goal to provide optimal estimates of the control variables and thereby to improve predictions of fire spread behavior. The application of DA and inverse modeling has recently been explored in the area of wildfire research (e.g. Mandel and Beezley 2007; Lautenberger 2013; Rochoux *et al* 2013). The key idea is that, when used alone, neither measurements nor computer models can provide a reliable and complete description of the real state of the physical system.

The present study is an extension of our previous work in Rochoux *et al* (2013, 2014a, 2014b) and Rochoux (2014), in which a prototype data-driven wildfire spread simulator capable of forecasting the wildfire spread behavior was developed. The prototype simulator features the following main components: a level-set-based fire propagation solver (Rehm and McDermott 2009) that treats wildfires as propagating fronts and uses a description of the local rate of fire spread (ROS) as a function of vegetation, topographical and meteorological conditions based on the model due to Rothermel (1972); a series of observations of the fire front location; and a DA algorithm based on the ensemble Kalman filter (EnKF) to account for some of the non-linearities in the mapping between control space and observation space. The DA algorithm also features a choice between a parameter estimation (PE) approach in which the control variables are the input parameters of the ROS model (Rochoux *et al* 2014a) and a state estimation (SE) approach in which the control variables are the spatial coordinates of the fire front (Rochoux *et al* 2014b). This study presents the extension of the FIREFLY-based data-driven wildfire spread simulator to problems with complex terrain topography; the formulation of the PE-/SE-based DA strategies is not affected by the increasing complexity of the wildfire spread model. The paper is organized as follows. The data-driven wildfire spread model (including the fire spread model with complex terrain topography and the DA algorithms) is presented in Section 2; examples for each component of the data-driven simulator are also provided. Its performance is evaluated for synthetic DA experiments in Section 3.

Methodology: Data-driven wildfire spread model

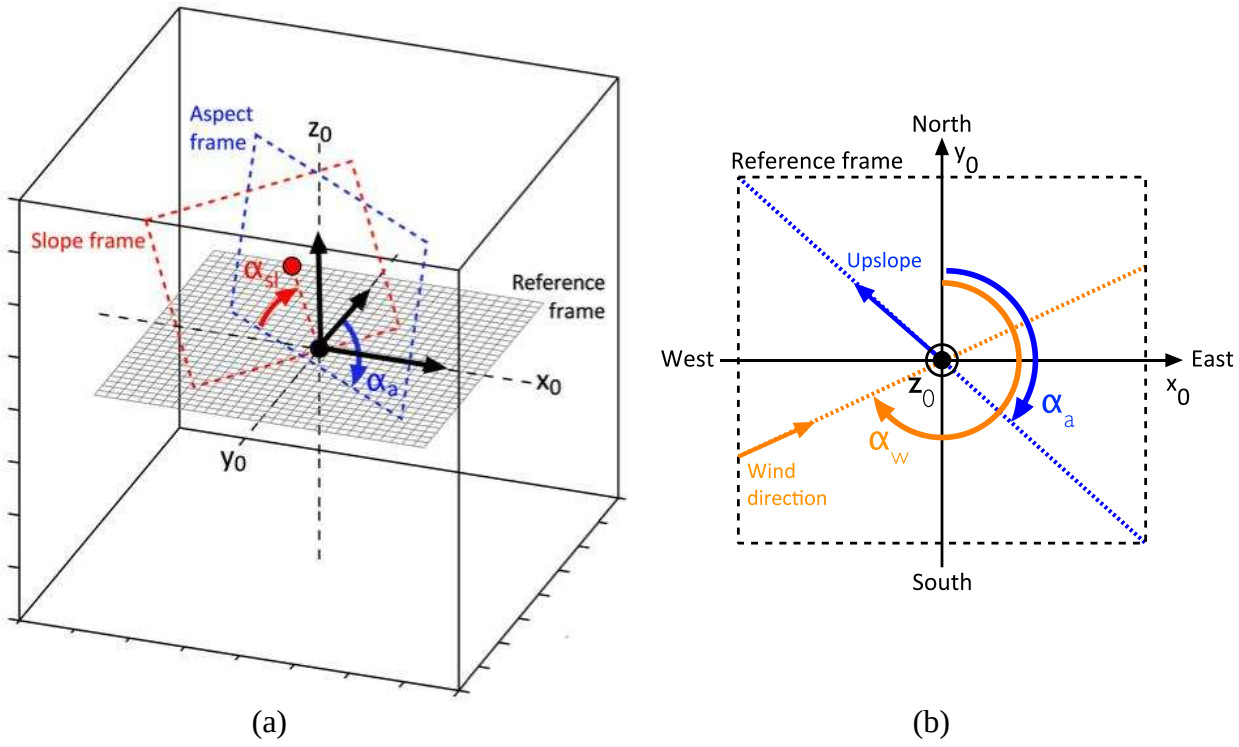
As any current operational fire spread simulator, FIREFLY adopts a regional-scale perspective. This implies that wildfires are assumed to feature a front-like geometry at scales ranging from a few tens of meters up to several kilometers and may be described as a line that propagates normal to itself into unburnt vegetation and over complex topography, at a ROS denoted by Γ_{3D}.

Forward model: Fire spread model

2.1.1. *Geometrical considerations*

A rectangular Cartesian coordinate system (x_0, y_0, z_0) is introduced to geolocalize the propagation of the fire front over complex terrain topography. (x_0, y_0) represents the horizontal plane, with the x_0-axis pointing towards the East direction and the y_0-axis pointing towards the North direction; the z_0-axis is the vertical direction (z_0 = 0 m represents the horizontal plane, where the terrain elevation h is zero). The reference frame is illustrated in Figure 1a.

Based on Sharples (2008) and Lautenberger (2013), the terrain topography is locally characterized in FIREFLY by a pair of angles noted (α_a, α_{sl}), see Figure 1a. α_a [°] is the terrain aspect angle indicating the downslope direction and is defined in a clockwise representation, where 0° indicates the North direction (i.e. the y_0-direction). α_{sl} [°] is the terrain slope angle, taking values between 0° (flat terrain) and 90° (vertical wall). The direction from which the wind blows is noted α_w [°] and is defined in a clockwise representation, where 0° indicates the North direction, see Figure 1b. In this framework, the direction of fire propagation is noted α_{fr} [°].



(a) (b)

Figure 1. Formalism to include terrain topography in FIREFLY. (a) Three-dimensional reference frames, where (x0, y0) represents the horizontal plane, where αa represents the aspect angle direction (i.e. the downslope direction) and where αsl represents the terrain slope angle; the blue and red planes are perpendicular. (b) Two-dimensional horizontal plane (x0, y0) with the aspect angle direction αa and the wind direction angle αw.

The pair of local parameters (α_a, α_{sl}) can be retrieved from altimetry elevation data $h \equiv h(x_0, y_0)$ as follows (Vico and Porporato 2009, Emery *et al* 2013):

$$\begin{pmatrix} \sin\alpha_a \\ \cos\alpha_a \end{pmatrix} = -\frac{1}{\tan\alpha_{sl}} \begin{pmatrix} \partial h/\partial x \\ \partial h/\partial y \end{pmatrix}, \quad (1)$$

with:

$$\tan\alpha_{sl} = \sqrt{\left(\partial h/\partial x\right)^2 + \left(\partial h/\partial y\right)^2}. \quad (2)$$

In FIREFLY, the terrain elevation h corresponds to input data that are interpolated at each grid point of the computational domain. The calculation of its gradient is performed through a classical centered finite difference scheme.

2.1.2. *Extension of the Rothermel's model to wind and slope effects*

The original Rothermel's ROS model (noted Γ_{1D}) that was developed for one-dimensional upslope and/or upwind fire propagation is of the following form:

$$G_{1D} = G_0(1 + F_w^* + F_{sl}^*), \quad (3)$$

where Γ_0 [m s^{-1}] is the no-wind no-slope ROS, and where the 1-D coefficients $\Phi_w^* \equiv \Phi_w^*(\mathbf{u}_w)$, $\Phi_{sl}^* \equiv \Phi_{sl}^*(\alpha_{sl})$ represent the wind and slope correction coefficients to account for the additional effects of

wind and slope on the propagating speed of the head fire. Note that the wind correction coefficient depends on the surface wind velocity vector noted $\mathbf{u}_w$ [m s^{-1}], which can be provided for instance by meteorological forecasts.

Following choices made by Lautenberger (2013), a modification of the wind and slope contributions to the Rothermel-based ROS is introduced to account for wildfire spread in other directions than the uphill/upwind direction. The 2-D wind and slope correction coefficients in the modified Rothermel's formulation are noted Φ_w and Φ_{sl}, respectively. The modification of the slope correction coefficient Φ_{sl} relies on the following assumptions: (1) when the fire propagates in the upslope direction (i.e. $\alpha_{fr} = \alpha_a + 180°$), the slope contribution to the ROS is maximum (i.e. $\Phi_{sl} = \Phi_{sl}^*$); (2) if the fire propagation occurs in the normal direction to upslope or downslope (i.e. $\alpha_{fr} = \alpha_a \pm 90°$), the slope does not contribute to the fire front propagation; and (3) if the fire propagates in the downslope direction such that $\alpha_{fr} \in [\alpha_a - 90°, \alpha_a + 90°]$, the ROS is forced to Γ_0, meaning that the fire cannot propagate at a lower ROS than the no-slope no-wind Γ_0. The modification of the wind correction coefficient Φ_w relies on similar arguments. Thus, the Rothermel's formulation of the wind- and slope-aided ROS (noted Γ_{3D}) becomes:

$$\Gamma_{3D} = \Gamma_0 \max(1, 1 + \Phi_w + \Phi_{sl}), \tag{4}$$

with the following expressions for $\alpha_{fr} \notin [\alpha_a - 90°, \alpha_a + 90°]$:

$$\Phi_{sl} = \cos\left(\alpha_{fr} - (\alpha_a + \pi)\right) \Phi_{sl}^*, \tag{5}$$

$$\Phi_w = \cos\left(\alpha_{fr} - (\alpha_w + \pi)\right) \Phi_w^*. \tag{6}$$

Γ_{3D} corresponds here to the evaluation of the ROS in the slope frame (see Figure 1a); this value is projected onto the reference frame (x_0, y_0, z_0) to obtain the ROS Γ_{2D} required by the FIREFLY level-set solver to propagate the fire front on the horizontal plane (x_0, y_0) along its normal direction $\mathbf{n}_{fr}$. Based on geometrical considerations, the projected ROS Γ_{2D} reads:

$$\Gamma_{2D} = \Gamma_{3D} \left(1 + \tan^2(\alpha_{sl}) \cos^2(\alpha_a - \alpha_{fr})\right)^{-\frac{1}{2}}. \tag{7}$$

The derivation of the formulation in Eq. (7) can be found in Emery *et al* (2013). Figure 2 shows the variations of the slope-aided ROS Γ_{2D} evaluated using Eq. (7), with respect to the slope angle α_{sl} (horizontal axis) for different aspect angles α_a (colorbar) varying between 0° (dark-blue-plain line) and 90° (brown-plain line). For $\alpha_a = 0°$, the fire spreads in the upslope direction with a ROS reaching up to 1 m/s for a slope angle α_{sl} above 65°; the effect of the slope is considerable since the ROS Γ_{2D} can be multiplied by a factor up to 25 compared to the no-slope no-wind ROS $\Gamma_0 = 0.048$ m/s. On the contrary, for $\alpha_a = 90°$, the fire propagates in the transverse direction to the slope, implying that the slope does not modify the ROS and $\Gamma_{2D} = \Gamma_0 = 0.048$ m/s.

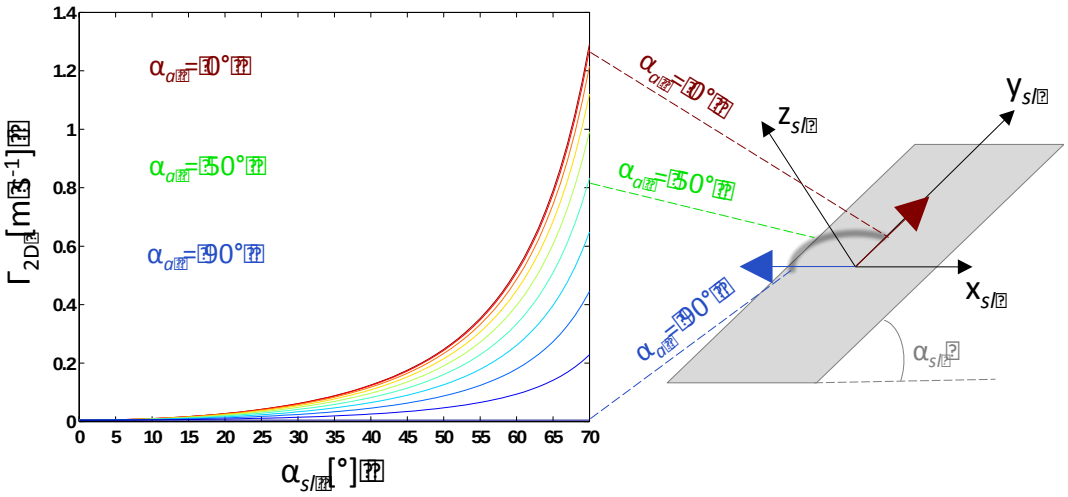


Figure 2. Slope-aided ROS Γ_{2D} with respect to the terrain slope angle α_{sl} (horizontal axis) for different values of the terrain aspect angle α_a (represented by the colorbar) for a no-wind plane configuration and Γ_0 = 0.048 m/s.

2.1.3. *Level-set solver*

FIREFLY tracks the time-evolving fire front location on the horizontal plane (x_0, y_0) using a level-set-based solver, see Figure 3. A progress variable $c \equiv c(x,y,t)$ is introduced as a flame marker: $c = 0$ in unburnt vegetation, $c = 1$ in burnt vegetation, and the contour line $c_{fr} = 0.5$ is identified as the flame front.

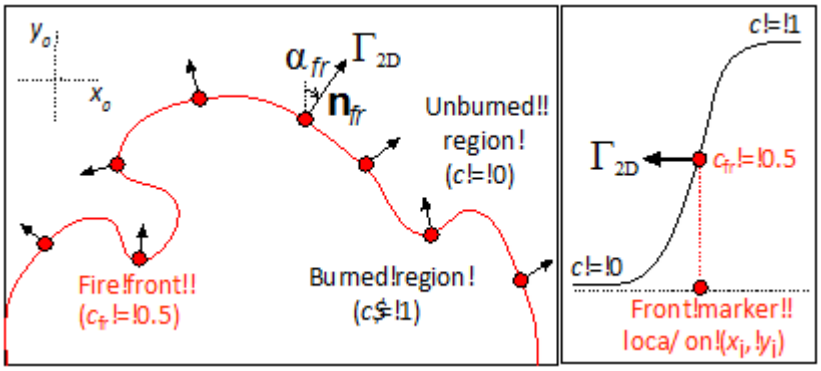

Figure 3. Schematic of FIREFLY. (a) Propagation of the contour line c_{fr} = 0.5 onto the horizontal plane (x_0, y_0), Γ_{2D} measures the local ROS of the fire along the normal direction to the front n_{fr} (defined by the direction angle of fire propagation α_{fr}). (b) Profile of the spatial variations of the progress variable c across the fire front, (x_i, y_i) representing the location of the ith fire front marker.

The progress variable field c is calculated as a solution of the propagation equation:

$$\frac{\partial c}{\partial t} = G_{2D} |\nabla c|, \qquad (8)$$

where $\Gamma_{2D} \equiv \Gamma_{2D}(\mathbf{u}_w, \alpha_{sl}, M_v, \Sigma_v, \beta_v, \delta_{v,\ldots})$ calculated by Eq. (7) is defined along the local normal direction to the fire front $\mathbf{n}_{fr} = -\nabla c/|\nabla c|$ (see Figure 3) and depends on the local environmental conditions such as the biomass fuel moisture content M_v [-], the biomass fuel particle surface-to-volume ratio Σ_v [m^{-1}], the biomass fuel packing ratio β_v [-] and the biomass fuel layer thickness δ_v [m].

Equation (8) is solved by using a second-order Runge-Kutta scheme for time-integration and a second-order total variation diminishing scheme with a Superbee slope limiter for spatial discretization, following choices made by Rehm and McDermott (2009). Convergence of the numerical method was demonstrated in Rochoux (2014).

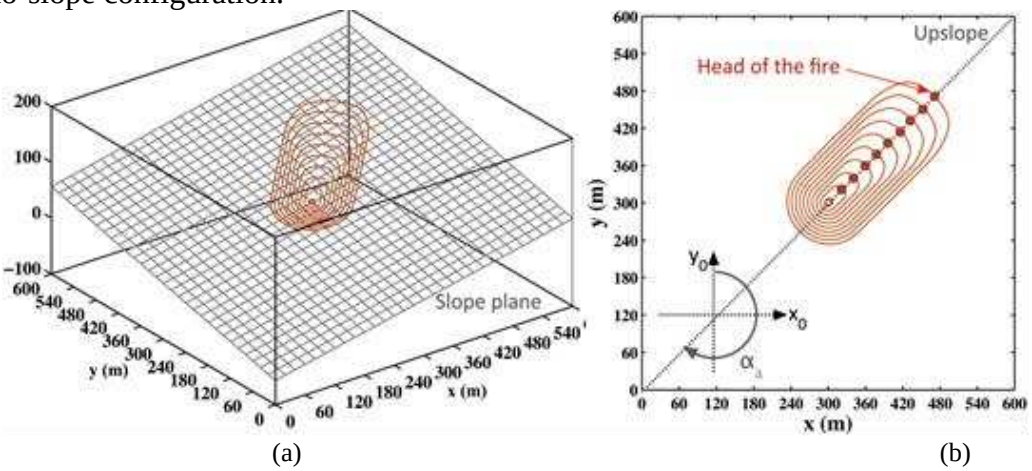
2.1.4. *Reconstruction of the simulated fire front*

The instantaneous location of the fire front at time t is extracted by geolocalizing the contour line $c_{fr} = 0.5$ and satisfies: $c(x_i, y_i, t) = c_{fr}$ for every marker i of the front, with $i \leq 1 \leq N_{fr}$ (N_{fr} being the total number of simulated markers along the fireline). Two steps are required for this reconstruction of the simulated fire front. First, the algorithm extracts the contour line $c_{fr} = 0.5$ from the two-dimensional progress variable c with respect to the computational grid resolution on the horizontal plane (x_0, y_0) in FIREFLY. Second, this algorithm discretizes the contour line $c_{fr} = 0.5$ with a fixed number (N_{fr}) of equally-spaced markers. Thus, the outputs of FIREFLY are the two-dimensional coordinates of the N_{fr} front markers. Further technical details on the contour line algorithm are provided in Rochoux (2014).

2.1.5. *Examples of fire propagation over terrain topography*

Two synthetic test cases are presented to illustrate the effects of non-uniform terrain topography on the fire front location as simulated by FIREFLY. This terrain topography corresponds to first, an inclined plane and second, a terrain elevation $h(x_0, y_0)$ typical of mountainous regions.

Inclined plane. The fire spread is simulated for a uniform biomass fuel characterized by $\delta_v = 1$ m, $M_v = 15$ % and $\Sigma_v = 11500$ m^{-1}. The terrain is a uniform inclined plane, tilted by $\alpha_{sl} = 15°$ with respect to the horizontal plane, whose aspect angle is $\alpha_a = 225°$ and whose dimensions are 600 m × 600 m (with a mesh step size $\Delta x = \Delta y = 1$ m). The initial condition is described by a circular front centered at ($x_0 = 300$ m, $y_0 = 300$ m) and of radius $r_0 = 5$ m; there is no external flow ($u_w = 0$). FIREFLY is integrated during 1000 s (with a time step $\Delta t = 0.5$ s). Results presented in Figure 4 show that the slope induces a constant propagation in the upslope direction, while the spread at the back of the fire remains very limited. The effective simulated ROS of the head of the fire is equal to 0.264 m s^{-1}, which is consistent with the theoretical value 0.261 m s^{-1} provided by the 0-D Rothermel's model Γ_{1D} (see Eq. 3). The no-slope ROS Γ_0 is equal to 0.068 m s^{-1}; the slope induces a propagation that is 4 times faster than in a no-slope configuration.



(a) (b)

Figure 4. Time-evolving location of the simulated fire fronts at 100 s intervals on a slope plane with the aspect angle $\alpha_a = 225°$ (a) Three-dimensional representation. (b) Projected representation onto the horizontal plane (x_0, y_0).

Mountainous region. A simulation of wildfire spread induced by complex terrain topography is performed for moderate wind conditions (0.75 m s^{-1}, 315°); the biomass fuel is uniformly-distributed over the 200 m x 200 m field, with $\delta_v = 1$ m, $M_v = 20$ % and $\Sigma_v = 10000$ m^{-1}. The initial condition is

described by a circular front centered at (x_0 = 100 m, y_0 = 100 m) and of radius r_0 = 5 m. FIREFLY is integrated during 1500 s. Figure 5 illustrates the growth of the burnt area over time (at 300 s time intervals). Even though the validation of FIREFLY for the treatment of the wind and slope effects remains to be performed against real-world wildfire events, this simulation is consistent with the main features of wildfire spread: the largest ROS is obtained in the upslope direction (the effect of terrain elevation on the fireline behavior is high compared to the effect of moderate wind, partly due to the high terrain elevation in one corner of the domain).

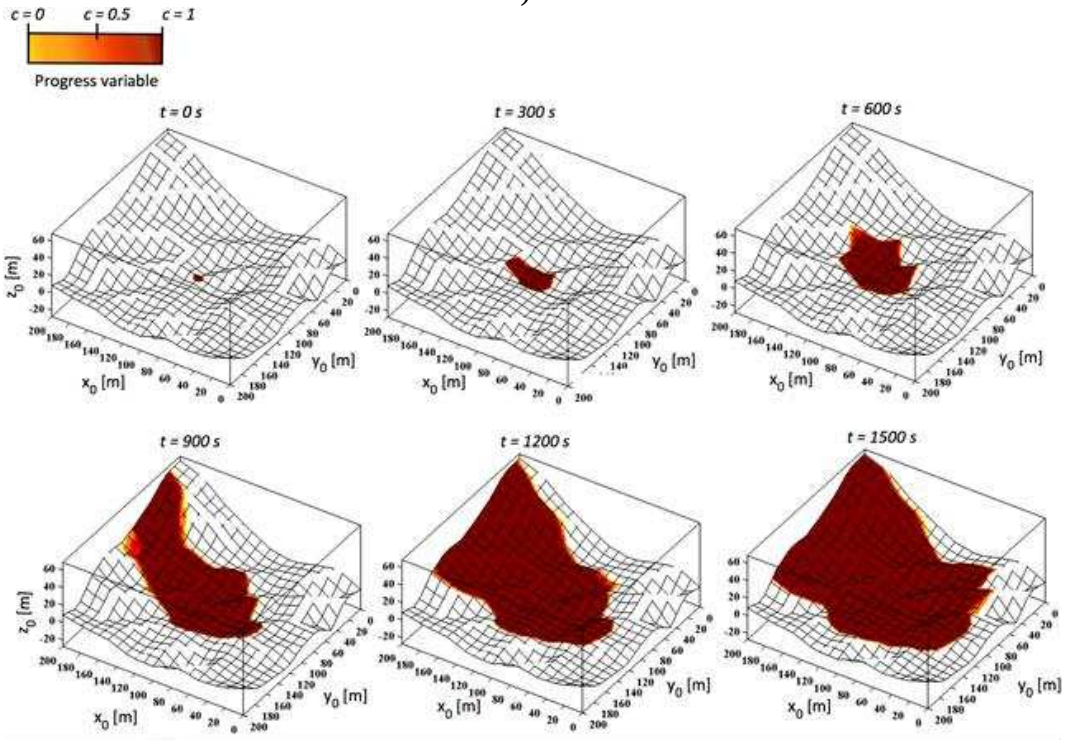


Figure 5. Growth of the burnt area from t = 0 s to t = 1500 s, simulated with FIREFLY over a complex terrain topography; moderate horizontal wind conditions (0.75 m s^{-1}, 315°);

Data assimilation algorithms: parameter estimation versus state estimation

2.2.1. *Model counterparts of the observations*

The correction provided by the DA algorithms relies on a comparison between the (FIREFLY-based) predicted and observed fire front locations at time *t*. The predicted fire front is a high-resolution discretized line described by a set of N_{fr} markers. Since observations of the fire front position are likely to be provided with a much coarser resolution and since they may cover only a fraction of the fire front perimeter, the observed fire front is a discretized line with a set of N_{fr}^o markers, with N_{fr}^o much lower than N_{fr}. In the following, we assume for simplicity that $N_{fr}^o = (N_{fr} / r)$ where *r* is an integer taking values much larger than 1. A selection operator is applied to the simulated fire front in order to pair a subset of N_{fr}^o markers along the simulated fire front with the N_{fr}^o markers along the observation fire front, associating each marker of the observation fire front with its closest neighbor along the simulated fire front.

2.2.2. *Ensemble Kalman filter*

For both parameter estimation (PE) and state estimation (SE) approaches, the EnKF algorithm is sequentially; each assimilation cycle consists of two successive steps (see Figure 6): (1) a prediction step (forecast) in which the system is evolved from time *(t-1)* until time *t* (the next observation time) through an integration of the FIREFLY fire spread model for a large sample N_e of control variables, each realization leading to a new prediction of the fire front location; (2) an update step (analysis) in

which new observations are considered at the analysis time t and the ensemble of forecast realizations is modified consistently with the observations in order to reduce uncertainties in FIREFLY predictions. The new ensemble of N_e realizations is obtained by the application of the classical Kalman filter equation, assuming that the errors on the control variables and on the observations follow Gaussian probability density functions. One advantage of the EnKF algorithm is that the mapping between the control variables and the observation space is estimated stochastically. Thus, the EnKF algorithm is able to handle model non-linearities.

In the PE approach, the control vector includes the n input parameters of the Rothermel-based ROS model that are subject to uncertainties and to which FIREFLY is sensitive (Rochoux *et al*. 2014a). In the SE approach, the control vector is made of the coordinates of the N_{fr} front markers along the simulated fire front such that $n = 2N_{fr}$ (Rochoux *et al*. 2014b). The main difference between PE and SE approaches relies on the definition of the observation operator. In the SE approach, the observation operator is limited to the selection operator introduced in Section 2.2.1. Since in the PE approach the observation operator maps the environmental parameters onto the model counterparts of the observations, it also includes the integration of the FIREFLY fire spread model (this aspect emphasizes the need for a DA approach that accounts for model non-linearities).

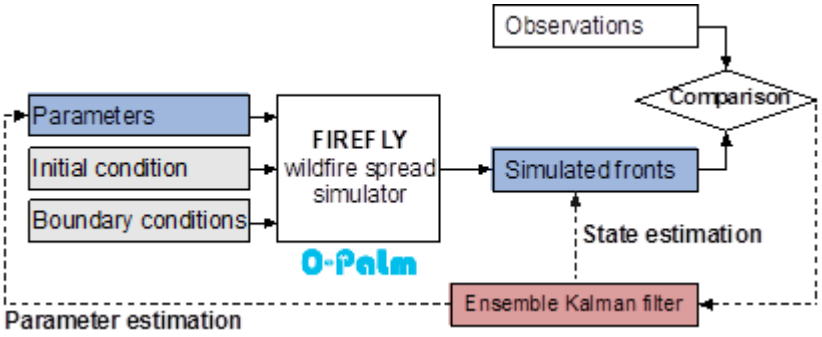

Figure 6. DA flowchart for PE and SE approaches over one assimilation cycle based on the OpenPALM dynamic coupler (www.cerfacs.fr/globc/PALM_WEB/); control variables are colored in blue.

2.2.3. *Validation of the ensemble Kalman filter*

We present results from a validation test in which observations are taken from an experimental database corresponding to a controlled grassland fire (personal communication and unpublished data). This validation test corresponds to a real reduced-scale (4 m x 4 m), flat, open-field grassland lot burning in which the ROS takes values on the order of 1 cm s^{-1} under moderate wind conditions. The properties of the grass are (approximately) known: $\delta_v = 0.08$ m, $M_v = 22$ % and $\Sigma_v = 11500$ m^{-1}. The mean wind conditions are also approximately known: $u_w = 1$ m/s and $\alpha_w = 307$ degrees. The fire spread is recorded during 350 s using a thermal-infrared camera; the fire front (represented by $N_{fr}^o = 40$ markers) is defined at the 600 K iso-temperature contour at 14 s intervals, from $t_0 = 50$ s to $t_4 = 106$ s. In the PE approach, 4 parameters are used as control variables: the fuel moisture content and particle surface-to-volume ratio as well as the wind magnitude and direction angle. These parameters are varied around mean values and with prescribed uncertainties; the EnKF ensemble contains $N_e = 1000$ members. In the SE approach, the control variables are the spatial coordinates of the discretized fire front. An ensemble of $N_e = 100$ members is produced based on assumed uncertainties in the input parameters of the ROS model (i.e., the fuel depth, moisture content and particle surface-to-volume ratio as well as the wind magnitude and direction angle) as well as assumed uncertainties in the initial fire location at t_0.

Figure 7a presents the averaged fire front position at time $t_4 = 106$ s, using the PE and SE ensembles as predicted from a numerical integration of FIREFLY, and with an EnKF update performed at time $t_3 = 92$ s. The numerical integration is performed N_e times for all members of the EnKF ensemble but only the mean predictions are plotted in Figure 7a. It is shown that the mean forecast significantly

underestimates the observed ROS. In contrast, Figure 7b shows that the mean analysis (i.e. a simulation with an EnKF update at current time t_4) successfully reduces the distance between model predictions and observations; this result is achieved by an adjustment of the ROS model parameters in the PE approach or directly of the fire front position in the SE approach.

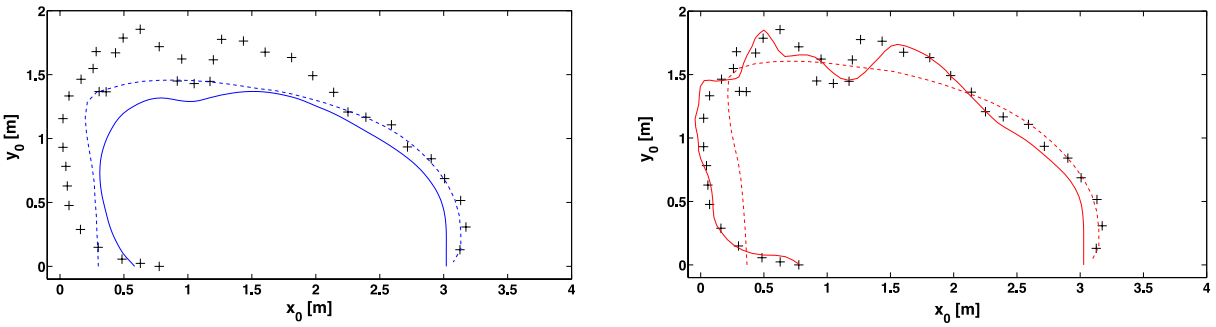

Figure 7. Comparison between simulated (lines) and observed (symbols) front positions at time t_4 = 106 s on the horizontal plane (x_0, y_0). The simulated front position is the mean position calculated as the average of the EnKF ensemble; dashed lines (solid lines) correspond to the PE-based (SE-based) simulations. (a) Forecast (with an EnKF update at t_3 = 92 s). (b) Analysis (with an EnKF update at t_4 = 106 s).

In spite of the quality of the PE-based or SE-based correction, the mean forecast, while still significantly more accurate than the simulations without DA, remains limited. The mean predictions presented in Figure 7a have the benefits of an EnKF update performed at earlier time t_3; however, some of these benefits are lost at time t_4 due to the limited persistence of the initial condition for the SE-based forecast and due to the temporal variability of the errors in the environmental conditions for the PE-based forecast. We find that in this configuration, the PE algorithm provides better forecasts than the SE algorithm but this ranking is problem-dependent. While a DA approach provides excellent forecasting performance at short lead-times, the assimilation frequency (i.e., frequency at which the analysis is renewed by observations) needs to be adjusted to the persistence of the initial condition and/or to the temporal variability of the errors in the environmental conditions.

Evaluation of the performance of the data-driven simulator for complex terrain topography

An anisotropic case of wildfire spread subject to moderate wind conditions is considered for the complex terrain topography illustrated in Figure 5 for a deterministic run. In the present DA test, observations are synthetically generated using a similar deterministic run over the time window [0; 750 s], called *true solution* of the FIREFLY fire spread model, with specified values of the environmental conditions (referred to as the *true parameters* in Table 1); random errors characterized by a 1-m standard deviation (STD) are then added to the true solution to obtain the location of the observation markers ($N_{fr}^{o} = N_{fr} = 100$) at time 750 s (there is a single observation time over [0; 750 s]). Since this observation error STD is low relatively to the size of the fireline perimeter, the objective here is to evaluate the ability of the EnKF algorithm to retrieve the true location of the fire front.
An ensemble of $N_e = 320$ forecasts is produced over the time window [0; 750 s], based on assumed uncertainties in a subset of ROS model parameters, specifically in the fuel layer depth δ_v, the fuel moisture content M_v, the fuel particle surface-to-volume ratio Σ_v and the wind properties (u_w, α_w). Thus, uncertainties are due to variations in 5 parameters, whose mean and STD are presented in Table 1. Note that the perturbed parameters remain spatially-uniform for each ensemble member. Note also that this large ensemble is necessary to accurately describe the spatial variability in the errors in the SE approach as well as to dissociate the effects of each control parameter on the fireline position in the PE approach. Figure 8a presents a comparison between the true and forecast fire front locations at time t = 750 s (the forecast estimates between PE and SE approaches are equivalent). Due to

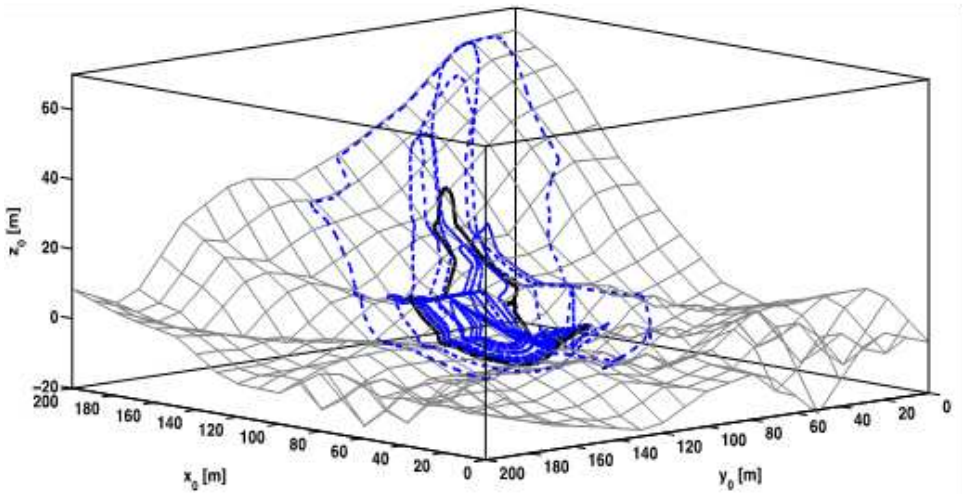
uncertainties in the ROS model parameters and the presence of heterogeneous terrain topography, the shape of the simulated fire fronts significantly varies between the members (with a burnt area varying between 500 and 10000 m^2).
The EnKF update is performed at time 750 s, either for the PE approach or for the SE approach. While the SE approach leads to a direct adjustment of the fire front location, the PE approach works by an adjustment of the ROS model parameters; the 5 perturbed parameters (δ_v, M_v, Σ_v, u_w, α_w) are used as control variables**.** Figure 8b compares the mean analysis estimate obtained at the same time 750 s using a PE-based EnKF update (red dashed line) and a SE-based EnKF update (red solid line). These analysis estimates are compared to observations (black crosses) and to the mean forecast estimate (blue solid line). For both PE and SE approaches, the analysis estimates feature a much reduced scatter around the true location of the fire front than the ensemble of forecast estimates. At time 750 s, the mean distance between the (PE-/SE-based) mean ensemble estimate and the observations is reduced by a factor of at least 20. Thus, both PE and SE approaches are able to retrieve an accurate estimation of the fire front location, even though the prior information is subject to high levels of uncertainties and the terrain topography is complex. Note that as for the real case presented in Figure 7, the SE approach is more effective at retrieving the topology of the front at the analysis time than the PE approach; the latter provides valuable information on the input parameters to forecast the front at future lead-times (see Rochoux *et al*. 2014a, 2014b for further details).

Table 1. Properties of the ensemble forecast in the control space; anisotropic OSSE test

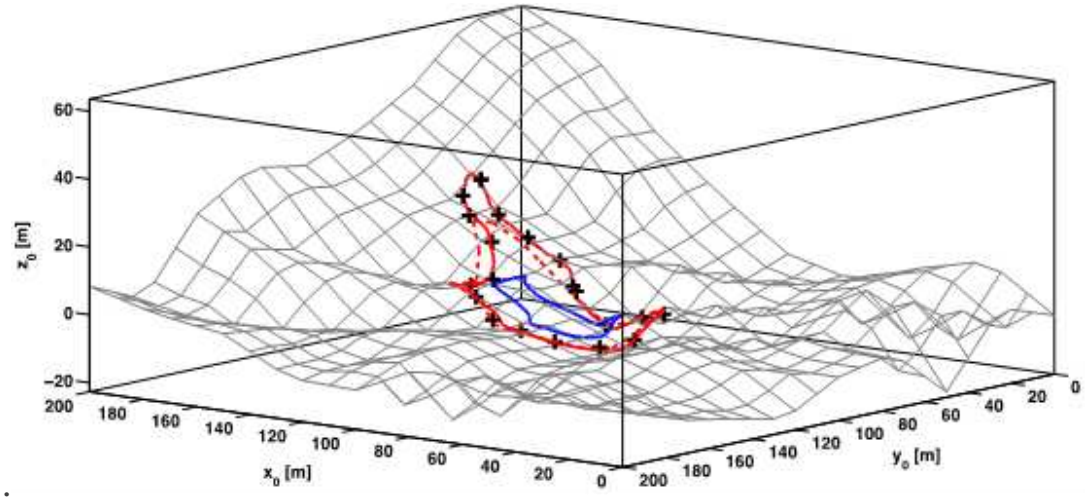
	True	Forecast (mean/STD)		PE-based analysis (mean/STD)	
δ_v	0.30 m	0.20 m	0.10 m	0.26 m	0.06 m
M_v	10 %	14.0 %	4.0 %	11.7 %	3.6 %
Σ_v	11500 m^{-1}	10000 m^{-1}	4000 m^{-1}	13078 m^{-1}	2436 m^{-1}
u_w	0.75 m s^{-1}	0.65 m s^{-1}	0.20 m s^{-1}	0.83 m s^{-1}	0.15 m s^{-1}
α_w	315°	315°	45°	288°	28°

Conclusions

This study presents a prototype data-driven wildfire simulator capable of correcting inaccurate predictions of the fire front position and of subsqequently providing an optimized forecast of the wildfire behavior over complex terrain topography. The simulator features a regional-scale wildfire spread model FIREFLY coupled with an EnKF-based data assimilation algorithm and a parameter estimation (PE) approach or a state estimation (SE) approach. The study assumes that observations of the fire front location are available at frequent times but possibly provide an inaccurate and incomplete description of the fire front. The results obtained for a controlled grassland fire indicate that the forecasting performance of a PE approach or a SE approach may be limited to short lead-times. Future plans include the development of a dual SE/PE approach that could partly overcome these limitations. The PE approach could be extended to the case of weak spatial variations of the spread-rate model parameters. Assuming that the errors on the parameters vary slowly in time, the PE-based correction can reasonably be used for forecast, thus allowing for mid- to long-term forecast. In addition, the SE correction could be used for short-term forecast in order to locally correct the shape of the fire front. Future plans also include the evaluation of the PE/SE-based estimation strategy for real-world regional-scale wildfire hazards, in order to design the observation requirements (in terms of spatial and temporal resolutions) to obtain reliable forecasts of wildfire spread.



(a) Forecast step at time 750 s



(b) Analysis step at time 750 s.

Figure 8. Comparison between simulated (lines) and observed (symbols) front positions at time 750 s; single assimilation cycle. (a) Forecast step: comparison between the true front location (black solid line) and the ensemble of forecast estimates (blue dashed lines). Only a subset of the ensemble is shown here for clarity purposes (b). Analysis step: comparison between observations (black crosses) and the mean analysis estimate: the dashed line (the solid line) corresponds to the PE-based (SE-based) analysis (with an EnKF update at 750 s and starting from the same initial condition as the forecast at time 0). Only a subset of observation front markers is shown here for clarity purposes.

Acknowledgments

The financial support provided by the Agence Nationale de la Recherche under the IDEA project grant ANR-09-COSI-006 (2010-2013) and by the LEFE-MANU grant (INSU-CNRS program, 2011-2013) was greatly appreciated. The authors also gratefully acknowledge Ronan Paugam and Martin Wooster (King's College London) for sharing the experimental data, Florent Duchaine and Thierry Morel (CERFACS) for support on Open-PALM.

Abstract
A homogeneous 40-year (1972-2013) hourly 4-km gridded climate dataset for Victoria, Australia is being generated using a combination of mesoscale modeling, global reanalysis data, surface observations, and historic observed rainfall analyses. The primary purposes of this dataset are optimizing planned burning and land management strategies, and scenario planning for major fire events. Outputs include fire weather and fire danger variables. The output data are created using the Weather Research and Forecast (WRF) model. Error correction techniques are applied to minimize any model biases. Outputs provide an almost limitless opportunity for hitherto unavailable analyses – fields of percentiles of forest fire danger index (FDDI) values, analysis of periods exceeding thresholds at any location, inter-annual and regional variations of fire season characteristics, analysis of prescribed burning windows, of atmospheric dispersion climates, and various atmospheric stability measures that might affect fire behaviour, and to assess climatologies of more esoteric mesoscale weather events, such as mountain waves, that may affect fire behaviour. This presentation describes the generation of the dataset, shows examples of output, and highlights use and relevance for fire management.

Keywords*: Fire weather, fire danger, climatology, dynamical downscaling*

Introduction

There is a need for a detailed understanding of the climatology of fire weather across the Australian landscape if strategic decisions to ameliorate the sometimes-extreme impacts of bushfires on the socio-economic wellbeing of the community are to be based on sound scientific evidence, and if variability and trends in this climatology are to be correctly interpreted. This paper describes the methodology by which a 1972-present high temporal- and spatial-resolution climatology of Victoria's fire weather is being developed. The climatology is intended to combine hourly values of meteorological variables on a regular, high spatial resolution, grid over Victoria, Australia with drought factors based on the Australian Water Availability Project (AWAP) rainfall and temperature analyses (Jones *et al*. 2009) to generate hourly gridded fields of Forest Fire Danger Index (FFDI).
The dataset will provide baseline climatology information for risk management assessments and climate change adaptation planning. The benefits of the dataset to the Victoria Department of Environment and Primary Industries and others include:

- Provides a high-resolution temporally and spatially complete record of temperature, humidity, wind, precipitation, drought and fire danger.
- Allows for analyses at local through regional through state scales.
- Shows interannual and decadal variability for the elements produced, as well as climate trend.
- Quantitatively links climate variability and trend to impacts from fire, heat waves, drought, etc.

- Provides a historical baseline that can be used in comparison studies with downscaled regional or place-based future climate data.
- Serves as input data for decision-support tools to obtain historic baselines.
- Provides quantitative climate values to help test agency strategies and predict ecological outcomes.
- Helps determine if assumptions that go into policy and operations are supported by what is known about the climate record.
- Helps determine the extent that fire management responses have been "driven" by climate versus other forcing factors (e.g., political, economic, public perceptions).

Specific fire management relevance and uses include, but are not limited to:

- Estimating climate related bushfire risk
- Estimating number of days suitable for planned burning
- Input into the allocation of fire management resources - including planned burning
- Bushfire case study analysis, refinement and improvement of burning prescriptions
- Development of climate envelopes for vegetation communities
- Development of weather predictions for "fire use" decision making, and future bushfire climate predictions for strategic planning
- Providing hourly high-resolution weather input for fire spread models

In situ observation networks more typically than not have inhomogeneities in time and space. Thus, there are some considerable barriers to basing a climatology on long-term meteorological observations, as shown by the relatively low number of reliable, long-term observation records available for such analyses (see Lucas *et al*. 2007). This has significant implications for fire weather applications. The bulk of the observations are based near population centres, and so do not necessarily reflect the conditions in the forests where the bulk of major bushfires occur, and which are concentrated in the slopes and valleys of the ranges through central and eastern Victoria. To fulfill bushfire management agency needs, an ideal climatology would be based on a homogeneous high-resolution temporal (i.e., hourly) and spatially gridded fire weather and fire danger dataset. This paper briefly describes the model configuration, running strategy, and quality control/assessment procedures we are using in developing such a dataset for Victoria.

Methods

The mesoscale model used is the Weather Research and Forecasting (WRF) model described by Skamarock *et al*. (2008). It is a well-supported and widely used non-hydrostatic model that includes a wide range of choices of physical parameterization schemes. Three integration domains are used in our configuration (Figure 1) with grid spacings of 36 km (outer mesh), 12 km (middle mesh), and 4 km (inner mesh). Each nest has 33 vertical model levels. Initial state and lateral boundary conditions for the outer mesh are provided by 6- hourly interval global reanalyses. Choices of physical parameterization packages selected are listed in Table 1.

We utilize two global reanalyses for initial state and lateral boundary conditions to start each WRF integration and nudge fields through the 15-day process. The National Centers for Environmental Prediction (NCEP) FNL (Final) Operational Global Analysis (NCEP 2000) data are on 1-degree by 1-degree grids prepared operationally every six hours, and was used for the 2000-2013 period. The ERA-Interim (Dee *et al*. 2011) reanalysis dataset is being used prior to 1999.

There are logistical and data set quality benefits in performing longer (multi-day) rather than shorter (1-2 day) integrations as it is desirable not to have too many discontinuities at the commencement of

each new integration due to the need for the inner mesh to "spin up" from the smooth global reanalysis fields. One would intuitively expect that the model solution would drift somewhat from reality with time, although the use of analysis lateral boundary conditions rather than the forecast conditions used in operational forecast models should reduce this effect somewhat. After considerable testing, we chose to generate the data using 15-day integrations, but with the first day of each integration treated as a spin-up period and thus discarded. Therefore days 2-15 of each integration become Days 1-14 of each two-week data set period.

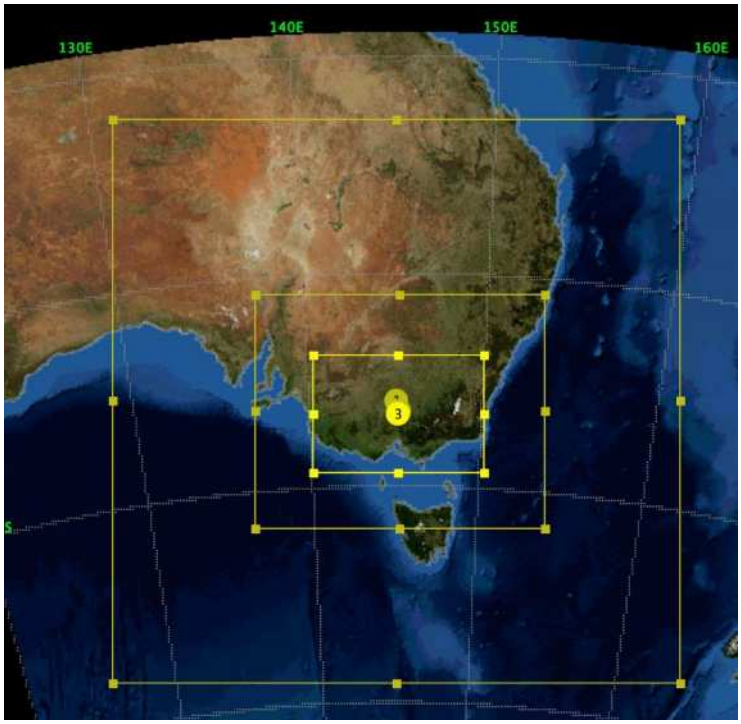

Figure 1. Map showing the three integration grids used in our configuration of the WRF model. Outer grid spacing 36-km, middle 12-km and inner mesh 4-km.

Table 1. List of physical parameterisations used in this WRF configuration.

Microphysics: Thompson *et al.* scheme: A new scheme with ice, snow and graupel processes suitable for high-resolution simulations (8).

*Longwave Radiation***:** RRTM scheme: Rapid Radiative Transfer Model. An accurate scheme using look-up tables for efficiency; it accounts for multiple bands, trace gases, and microphysics species.

*Shortwave Radiation***:** Goddard shortwave: Two-stream multi-band scheme with ozone from climatology and cloud effects.

*Land Surface***:** Noah Land Surface Model: Unified NCEP/NCAR/AFWA scheme with soil temperature and moisture in four layers, fractional snow cover and frozen soil physics.

*Planetary Boundary layer***:** Yonsei University scheme: Non-local-K scheme with explicit entrainment layer and parabolic K profile in unstable mixed layer.

*Cumulus Parameterization***:** Kain-Fritsch scheme: Deep and shallow convection sub-grid scheme using a mass flux approach with downdrafts and CAPE removal time scale.

*Diffusion Option***:** Simple diffusion: Gradients are simply taken along coordinate surfaces.

*K Option***:** 2d Deformation: K for horizontal diffusion is diagnosed from just horizontal deformation. The vertical diffusion is done by the PBL scheme.

The 15-day integrations and model field nudging has produced remarkably small biases. Figure 3 shows cumulative distribution functions (CDFs) for a combined 30 observation dataset and corresponding model grid point for each station for the 10-year period 2004-2013. This includes all hours and days during this period. Further analyses are being undertaken to assess diurnal, seasonal and elevation biases.

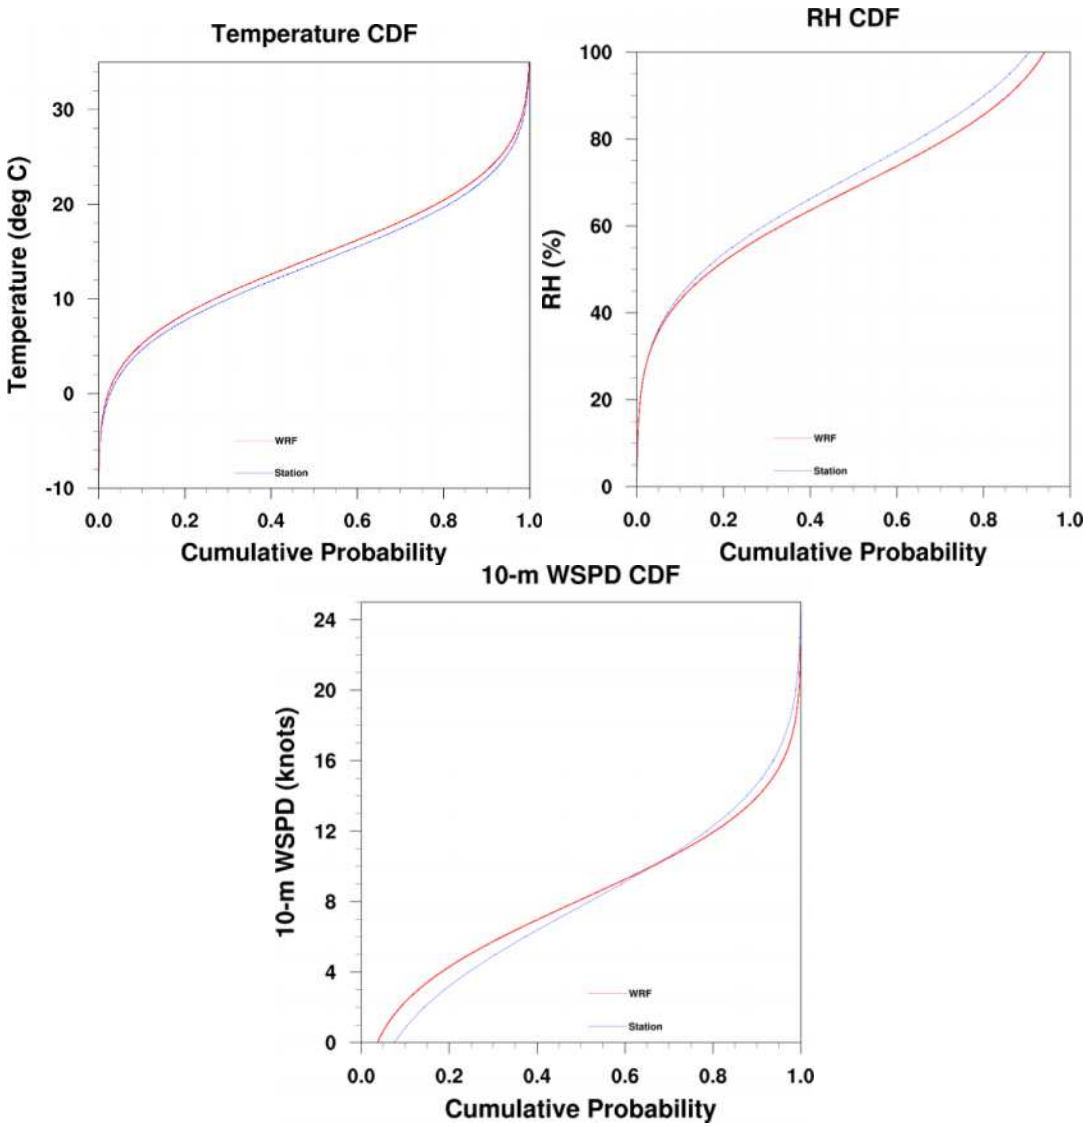

Figure 3. Cumulative distribution functions for 30 stations and corresponding model grid points for all hours and days 2004-2013 for temperature, relative humidity and wind speed.

Results

The surface data from WRF of primary interest include hourly temperature, relative humidity, wind speed, wind direction, Forest Fire Danger Index (FFDI) and precipitation. Daily data of interest include precipitation, Keetch-Byram Drought Index and the Drought Factor. Not surprisingly, a dataset of this size allows for the production of extensive statistics, graphics and analyses. Here we provide a few examples.

Figure 4 shows example maps of 2-m temperature, 2-m relative humidity and 10-m wind speed for 0500 UTC on 22-Jan-2006, a day of extreme fire danger over Victoria. At 0500 UTC a dry cold front has moved onshore in Victoria's west.

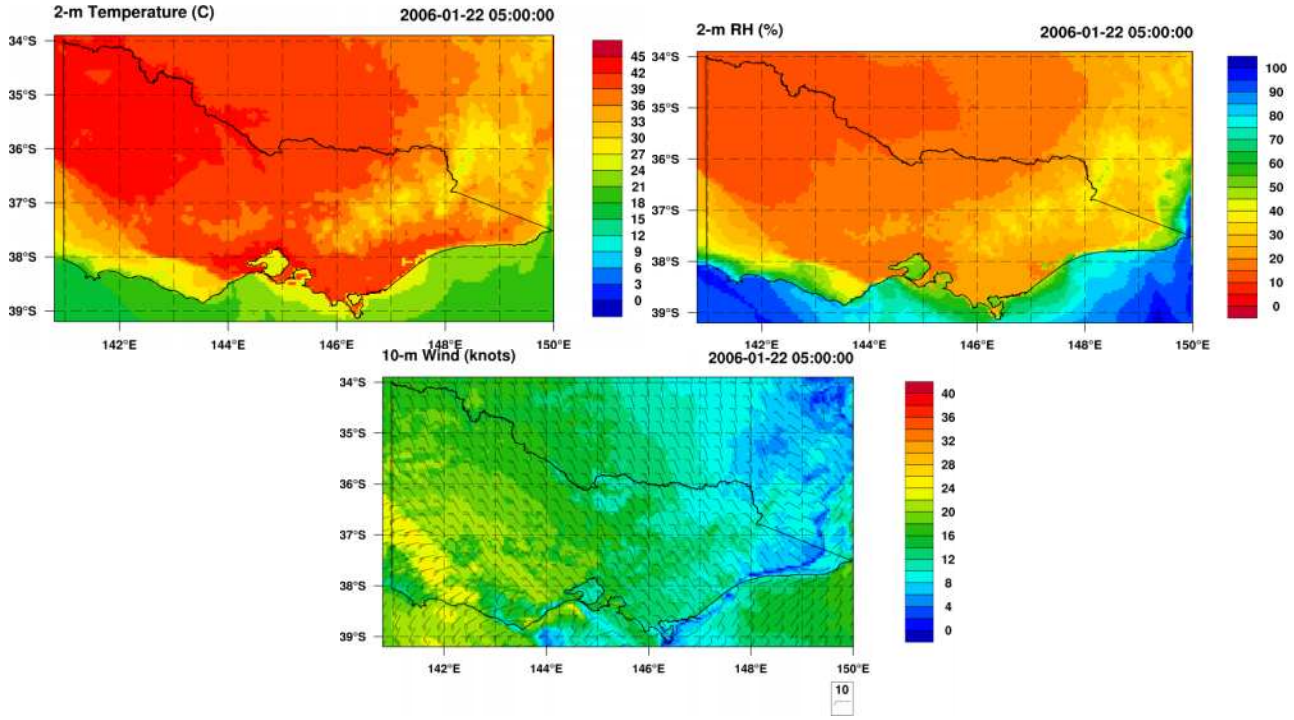

Figure 4. Example maps of 2-m temperature, 2-m relative humidity and 10-m wind speed for 22-Jan-2006.

Figure 5 shows an example of the diurnal cycle of January mean relative humidity by comparing 0500 and 1700 UTC.

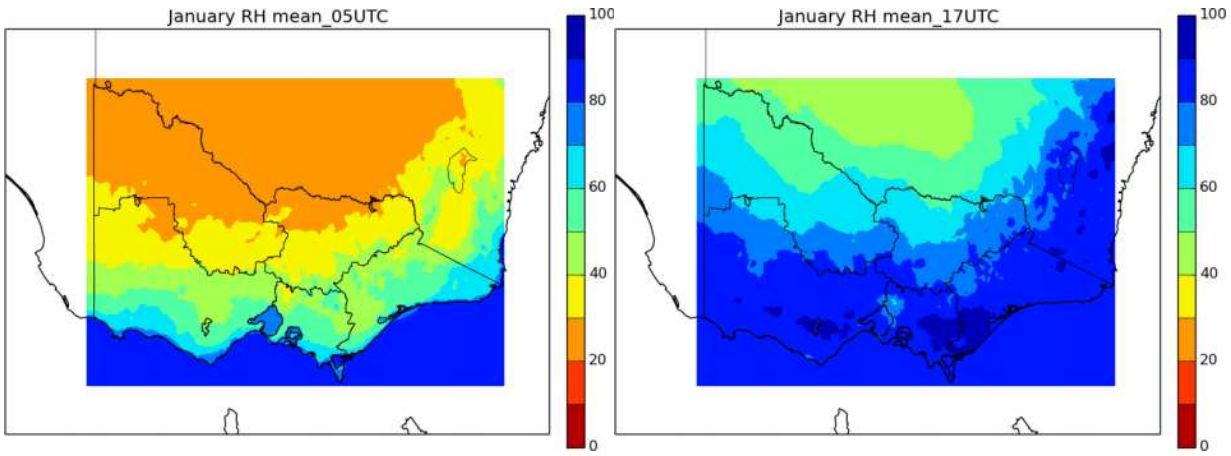

Figure 5. Example maps of January mean relative humidity highlighting the diurnal cycle by contrasting 0500 and 1700 UTC, respectively.

Figure 6 shows the maximum value of the FFDI for the December-February climatological season. The coastal and topographic effects are obvious, and the area of FFDI greater than 125 south of the ranges and west of Melbourne is notable.

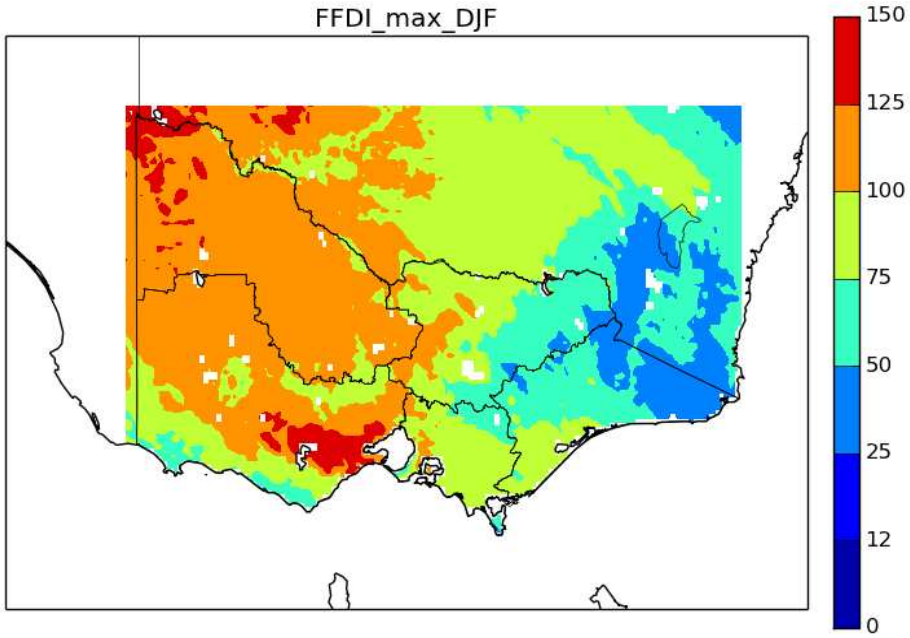

Figure 6. Example map of the climatological maximum FFDI value for the December-February season.

Summary

As of this writing, a 22-year climatology (1992-2013) has been completed. The full dataset is anticipated for completion by the end of 2014. While hourly 4-km surface variables are the primary priority of this project, the fact that the WRF model outputs hourly 3-dimensional fields of all atmospheric variables means that there is the opportunity to assess the climatology of above-surface weather on fire activity that has never been possible at this scale over Victoria before. These studies include the effect of atmospheric stability on fire behavior using indices such as those described by Mills and McCaw (2010), and the potential to perform climatological assessments of foehn/mountain wave events such as those described by Sharples *et al*. (2010) and Badlan *et al*. (2012), or other mesoscale systems that are difficult to analyse climatologically from the observational record.

A numerical study of crown fires spread using a conjugate formulation

Valeriy Perminov

Tomsk Polytechnic University, Russia 634050, Lenin Avenue, 30, valerperminov@gmail.com

Abstract
The aim of the present paper is to study the behaviour of crown forest fires propagating through crown canopy and to study the mutual influence of crown forest fires and boundary layer of atmosphere using numerical simulation with a physics-based model. It is a coupled atmosphere/crown fire behavior model and is based on conservation of mass, momentum, species and energy. The boundary-value problem is solved numerically using the method of splitting according to physical processes. It allows investigating dynamics of forest fire initiation and spreading under influence of various external conditions: a) meteorology conditions (air temperature, wind velocity etc.), b) type (various kinds of forest combustible materials) and their state (load, moisture etc.).

***Keywords**: forest fire, mathematical modelling, control volume, numerical solution*

Introduction

Fires spreading in crowns are often more intense than fires spreading through surface vegetation. As a result, they are more difficult to suppress, produce higher heat fluxes and more smoke. They can interact with boundary layer of atmosphere that leads to dangerous fire behaviour. The end goal is to develop a range of computationally efficient tools to help land managers and others assess forest fire risk to communities and homes. A suitably validated physics-based approach has the potential to account for realistic variations in the environmental. Considering that, natural investigations of these problems are merely impossible, methods of mathematical modelling are urgent.

Physical and mathematical model

Considering domain consist of two parts: boundary layer of atmosphere and forest. Let us examine a plane problem of radiation-convection heat and mass exchange of forest fuels in all forest strata with gaseous combustion products and radiation from the tongue of flame of the crown forest fire The fire source is modeled as a plane layer of burning forest fuels with known temperature and increasing area of burning**.** It is assumed that the forest during a forest fire can be modeled as a homogeneous two-temperature multiphase non-deformable porous reactive medium [1]. Temperatures of condensed and gaseous phases are separated out. The first includes a dry organic substance, moisture (water in the liquid-drop state), condensed pyrolysis and combustion products (coke, ash) and mineral part of forest fuels. In the gaseous phase it is separated out only the components necessary to describe reactions of combustion (oxygen, combustible products of pyrolysis of forest fuels and the rest inert components). Let the coordinate reference point x_1, $x_2 = 0$ be situated at the centre of the forest fire source at the height of the roughness level, axis $0x_2$ directed upward, axis $0x_1$ directed parallel to the Earth's surface to the right in the direction of the unperturbed wind speed (Fig.1).

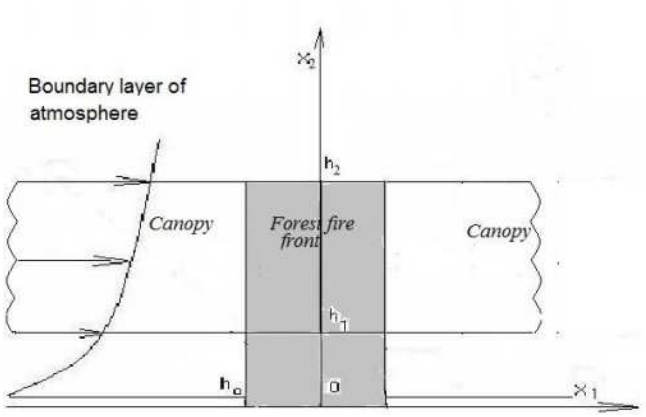

***Figure 1.** Scheme of the domain*

The problem formulated above is reduced to a solution of the system of equations (1)-(6):

$$\frac{\partial \rho}{\partial t} + \frac{\partial}{\partial x_j}(\rho v_j) = \dot{m},\ j = 1,2,\ i = 1,2; \tag{1}$$

$$\rho \frac{dv_i}{dt} = -\frac{\partial P}{\partial x_i} + \frac{\partial}{\partial x_j}(-\rho \overline{v_i' v_j'}) - \rho\, sc_d\, v_i\, |\vec{v}| - \rho g_i - \dot{m} v_i; \tag{2}$$

$$\rho c_p \frac{dT}{dt} = \frac{\partial}{\partial x_j}(-\rho c_p \overline{v_j' T'}) + q_5 R_5 - \alpha_v (T - T_S) + k_g (cU_R - 4\sigma T^4); \tag{3}$$

$$\rho \frac{d\, c_\alpha}{\partial t} = \frac{\partial}{\partial x_j}(-\rho \overline{v_j' c_\alpha'}) + R_{5\alpha} - \dot{m} c_\alpha,\ \alpha = 1,...,5; \tag{4}$$

$$\frac{\partial}{\partial x_j}\left(\frac{c}{3k}\frac{\partial U_R}{\partial x_j}\right) - (k + k_s) c U_R + 4\sigma(k_g T^4 + k_s T_s^4) = 0; \tag{5}$$

$$\sum_{i=1}^{4} \rho_i c_{pi} \varphi_i \frac{\partial T_S}{\partial t} = q_3 R_3 - q_2 R_2 - k_S (cU_R - 4\sigma T_S^4) + \alpha_V (T - T_S); \tag{6}$$

$$\rho_1 \frac{\partial \varphi_1}{\partial t} = -R_1, \rho_2 \frac{\partial \varphi_2}{\partial t} = -R_2,\ \rho_3 \frac{\partial \varphi_3}{\partial t} = \alpha_c R_1 - \frac{M_c}{M_1} R_3, \rho_4 \frac{\partial \varphi_4}{\partial t} = 0; \tag{7}$$

$$\sum_{\alpha=1}^{5} c_\alpha = 1, P_e = \rho R T \sum_{\alpha=1}^{5} \frac{c_\alpha}{M_\alpha}, \vec{v} = (v_1, v_2), \vec{g} = (0, g).$$

The system of equations (1)–(8) must be solved taking into account the following initial and boundary conditions:

$$t = 0: v_1 = 0, v_2 = 0, T = T_e, c_\alpha = c_{\alpha e}, T_s = T_e, \varphi_i = \varphi_{ie}; \tag{8}$$

$$x_1 = -x_{1e}: v_1 = V_e, v_2 = 0,\ T = T_e,\ c_\alpha = c_{\alpha e}, -\frac{c}{3k}\frac{\partial U_R}{\partial x_1} + cU_R/2 = 0; \tag{9}$$

$$x_1 = x_{1e}: \frac{\partial v_1}{\partial x_1} = 0, \frac{\partial v_2}{\partial x_1} = 0,\ \frac{\partial T}{\partial x_1} = 0,\ \frac{\partial c_\alpha}{\partial x_1} = 0, \frac{c}{3k}\frac{\partial U_R}{\partial x_1} + cU_R/2 = 0; \tag{10}$$

$$x_2 = 0: v_1 = 0, (\rho v_2)_0 = h_0 \dot{m}_0,\ T = \begin{cases} T_e + (T_0 - T_e)\exp(-((x_1 - x_{10})/\Delta)^2)t/t_0, t \le t_0 \\ T_e + (T_0 - T_e)\exp(-((x_1 - x_f)/\Delta)^2), \quad t > t_0 \end{cases},$$

$$x_f = \omega(t - t_0),$$

$$-\rho D_t \frac{\partial c_\alpha}{\partial x_2} + \rho v_2 c_\alpha = h_0 \bar{R}_{5\alpha}, -\frac{c}{3k}\frac{\partial U_R}{\partial x_2} = \frac{k_0 h_0}{2}(4\sigma T_S^4 - cU_R); \quad (11)$$

$$x_2 = x_{2e}: \frac{\partial v_1}{\partial x_2} = 0, \frac{\partial v_2}{\partial x_2} = 0, \frac{\partial T}{\partial x_2} = 0, \frac{\partial c_\alpha}{\partial x_2} = 0, \frac{c}{3k}\frac{\partial U_R}{\partial x_2} + cU_R/2 = 0; \quad (12)$$

Here and above $\frac{\mathrm{d}}{\mathrm{d}t}$ is the symbol of the total (substantial) derivative; α_v is the coefficient of gas exchange; t is time; x_i, v_i, (i = 1, 2) are the Cartesian coordinates and the velocity components; x_f is a right boundary coordinate of the surface forest fire source in a wind direction; k_0 is the radiation absorption coefficient in the ground cover, h_0 is the thickness layer in the ground cover; $\Delta = \Delta_0 + 2\omega t$ is the size of the surface fire source, Δ_0 is the initial value of the characteristic size, ω is the normal rate of surface fire spread, t_0 is the time of fire source formation (characteristic time of setting the maximum temperature in the source or the time of ignition), T_0 and T_e are the maximum temperature in the surface fire source and the ambient temperature; index α=1,2,...,5, where 1 corresponds to the density of oxygen, 2 - to carbon monoxide *CO*, 3 - to carbon dioxide and inert components of air, 4 - to particles of black, 5 - to particles of smoke. The thermodynamic, thermophysical and structural characteristics correspond to the forest fuels in the canopy of a pine forest [1].

It should be noted that this system of equations describes processes of transfer within the entire region, which includes boundary layer of atmosphere and forest: crown and the space between the underlying surface and the base of the forest canopy. Because of the characteristic sizes of problem for boundary layer of atmosphere and forest are different; it may be more convenient to divide our domain into two parts. Therefore we can solve this problem using a conjugate formulation. Besides for the second domain the horizontal sizes of forest massif more than height of forest, system of equations of general mathematical model of forest fire was integrated between the limits from height of the roughness level - 0 to top boundary of forest crown. Thus the solution of this problem is reduced to the integration of two systems of differential equations taking into account the correspondence initial and boundary conditions (8)-(12) and condition of conjugation between two domains [1].

Method solution and results

The boundary-value problem is solved numerically using the method of splitting according to physical processes. In the first stage, the hydrodynamic pattern of flow and distribution of scalar functions was calculated. The system of ordinary differential equations of chemical kinetics obtained as a result of splitting was then integrated. A discrete analogue was obtained by means of the control volume method using the SIMPLE like algorithm [2]. Fields of temperature, velocity, component mass fractions, and volume fractions of phases were obtained numerically. At $V_e \neq 0$, the wind field in the forest canopy interacts with the gas-jet obstacle that forms from the forest fire source and from the ignited forest canopy and burn away in the forest canopy. The isotherms of gas phase components moved in the forest canopy by the action of wind. It is concluded that the forest fire begins to spread. The results of the calculation give an opportunity to consider forest fire spread for different wind velocity, canopy bulk densities and moisture forest fuel. Figures 2 a,*b* present the distribution of temperature of gas phase above the crown $\bar{T}(\bar{T} = T/T_e, T_e = 300K)$ (1- 2., 2 – 2.5, 3 – 3, 4 – 4., 5 – 5.) for wind velocity V_e= 5 m/s in different instants of time: I - t=13 sec., II - t=16 sec, III - t=20 sec., IV - t= 23 sec and V - 25

sec. (Fig.2a) and 10 m/s (Fig.2b) (I - t=9 sec., II - t=11 sec, III - t=13.5 sec., IV - t= 15.5 sec.). The distribution of velocity fields is presented also (Fig.3a,b).

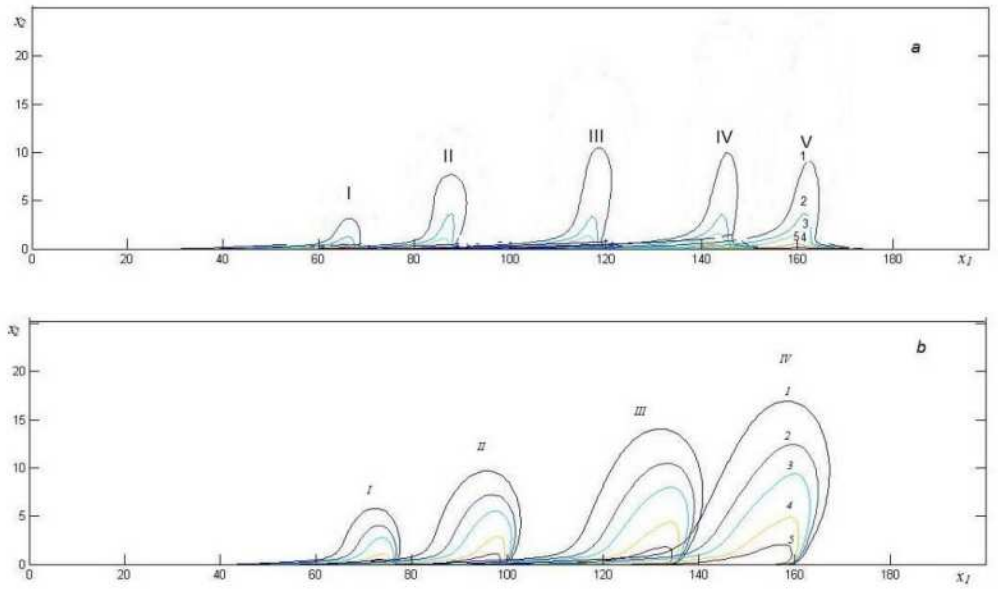

Figure 2. . Field of isotherms of the forest fire spread (gas phase).

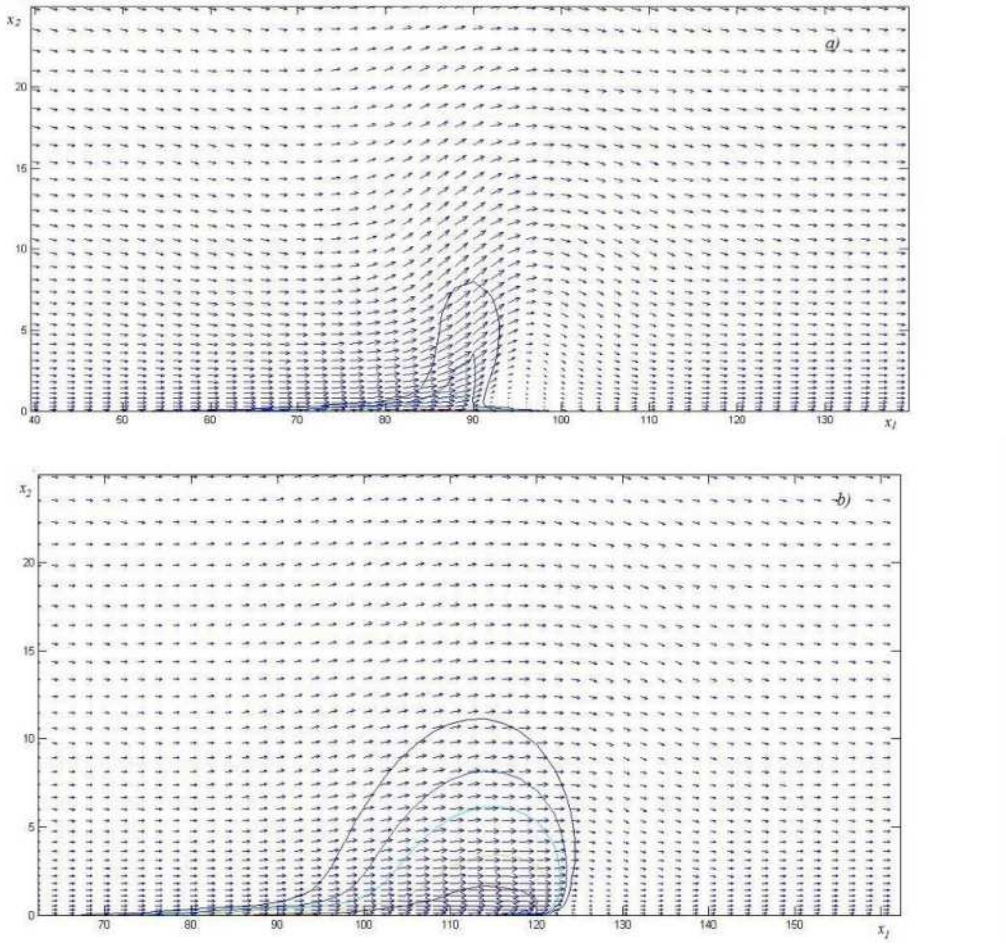

Figure 3- . Fields of velocities for wind: a)V_e=5 m/s(t=16 s)and b) V_e =10m/s (t=10 s).

Figures 3 a and b represent vector fields of velocities and isotherms for different instants of time when a wind velocity V_e= 5 m/s at a height x_2=10 m(Fig.3a) and . It is seen that the effect of the wind results in the tongue of flame defection from the vertical. The wind field above the forest fire front interacts with the gas-jet obstacle that forms from the crown forest fire source. Recirculating flow forms beyond the zone of heat and mass release (Fig.3a), while on the windward side the movement of the air flowing past the ignition region accelerates. But in the second case there is no recirculation flow, because a strong wind destroys it (Fig.3b).

Conclusion

Results of calculation give an opportunity to describe the different conditions of the crown forest fires spread taking account different weather conditions, state of forest combustible materials, which allows applying the given model for prediction and preventing fires. It overestimates the rate of crown forest fire spread that depends on crown properties: bulk density, moisture content of forest fuel, wind velocity and the influence of boundary layer of atmosphere. The model proposed here gives a detailed picture of the change in the temperature and component concentration fields with time, and determine as well as the influence of different conditions on the crown forest fire spreading for the different cases of inhomogeneous of distribution of sources of forest fires initiation. The results of calculation of the rate of crown forest fires are agreed with the laws of physics and experimental data

Abstract
Prescribed fire is a commonly used practice for managing wildland fire spread and intensity. However, due to limits in the current scientific understanding of wildland fire behavior in general, it is difficult to predict the effectiveness and efficiency of a particular regimen of prescribed fire-based fuel treatments in a given environment. As part of a larger project intended to aid in such an assessment, the first in a series of experimental prescribed fires was conducted. Efforts were made to both quantify various aspects of fire behavior and to obtain an accurate measure of pre- and post-fire fuel loadings. This paper focuses on an initial investigation of the fire behavior, as this is necessary for contextualizing the level of fuel treatment achieved. In particular, the range of observed surface fuel consumption and fireline intensities is discussed, the role of ambient wind conditions is considered, and a qualitative assessment of canopy fuel consumption is presented.

Keywords*: Fire behavior, prescribed fire, fuel treatments, fire intensity*

Introduction

Hazardous fuel reduction treatments are important for both the mitigation of wildland fire risk and the support of suppression efforts. In the United States, significant financial resources have been directed to this goal, with an average of $500 million spent by the Federal Government each year from 2002-2012 (Gorte 2011). However, rigorous experimental measurement and proper metrics to measure the success of fuel reduction measures are lacking. As stated by Omi and Martinson (2002), "the lack of empirical assessment of fuel treatment performance has become conspicuous". While the aforementioned report found that fuel treatments were able to modify extreme fuel behavior, questions remain as to the intensity and repetition of treatment needed in a given ecosystem to maintain a desired condition. Further, the success of a certain treatment may not be consistent for different ecosystems or treatment techniques (Gorte 2011). More work is clearly needed to understand and evaluate the effectiveness of these types of treatments.
One technique used to accomplish the reduction of hazardous fuels is prescribed fire, and is the focus of this work. When attempting to develop efficient and effective fire-based fuel treatment strategies, a proper understanding of fire behavior is particularly important. Managers must be able to understand

how a prescribed fire will behave, given a particular set of conditions, as well as predict the subsequent impact on fuel loading. In an effort to improve this understanding, a Joint Fire Science Program (JFSP) funded project is being conducted. This project takes a dual experimental and numerical approach. It aims to use a series of well-instrumented prescribed fires as a source of direct measurements, which can both provide a quantitative analysis of fire behavior and fuel reduction, as well as comparison criteria for use in the development of physical fire behavior models. Such models have the potential to be effective tools for the continued investigation of both general fire behavior and specific topics, such as fuel treatment effectiveness, without requiring extensive experimentation.

The work here pertains specifically to the first of the experimental prescribed fires. The measurement of wildland fire behavior properties is not a novel concept, as can be seen in experiments like those of Santoni *et al*. (2006), Viegas *et al*. (2006), Morandini and Silvani (2010), and Frankman *et al*. (2013). However, the number of such experiments is limited, and each is specific to a particular set of conditions. This work will help to strengthen the scientific understanding of fire behavior by adding to the collection of available measurements. Additionally, due to the focus on fuel reduction, the detail to which pre-fire fuel loading, fire behavior, and post-fire fuel loading are studied and can be correlated is rather unique. This experiment was also designed from the outset so that measurements would be both easily translatable to model inputs and comparable to model outputs.

Though a variety of different measurements were taken, the results analyzed in this paper represent an initial effort to describe the history of the fire spread and its general characteristics. Focus is put on estimates of fireline intensity, the role of ambient wind conditions, and basic characteristics of canopy fuel consumption.

Methods

Study site

The experimental fire was conducted in the Pinelands National Reserve (PNR) of New Jersey, United States. The PNR spans approximately 445,000 ha, and is the site of an active fuel management program by the New Jersey Forest Fire Service (NJFFS) and federal wildland fire managers. Prescribed fires are employed by the NJFFS with the explicit intent of reducing fuel loads and thus mitigating fire risk. These managers, for the most part, rely on professional judgment when planning the intervals and geographic position of these fires. The climate is classified as cool temperate, with mean monthly temperatures of 0.3 in January and 24.3 °C in July, and mean annual precipitation is 1159 mm. The terrain consists of plains, low-angle slopes, and wetlands, with a maximum elevation of 62.5 m. A burn block covering an area of 16.6 acres was used for the experiment, and can be seen outlined in Figure 1. The forest canopy in the block was comprised primarily of Pitch Pine (*Pinus rigida* Mill.), with intermittent oaks (*Quercus* spp.). The understory contained a mixed shrub layer of huckleberry (*Gaylussacia* spp.), blueberry (*Vaccinium* spp.), and scrub oaks (*Quercus* spp.). The perimeter of the block was comprised of access roads, with a narrower track running through the center of the block. These were created to facilitate access for the management of prior prescribed burns.

2.2. Measurement techniques

Point measurements of fire behavior were made using a combination of 4 overstory towers, 12 understory towers, and 3 Fire Behavior Packages (FBP), each supporting various instruments. Each overstory tower provided measurements of turbulence (3D sonic anemometer) at a height of 12.5 meters, and a vertical array of air temperature (8 K-type thermocouples) at even 1.5 m intervals from 0.5 to 11.0 meters. Dataloggers were buried in waterproof boxes and a sampling rate of 10 Hz was used. Each understory tower provided measurements of upward radiative flux (downward facing radiometer) at a height of 6.0 meters, vertical velocity (bi-directional pressure probe) at a height of 6.0

meters, and a vertical array of temperature (5 K-type thermocouples) at even 1.5 m intervals from 0 to 6.0 meters.

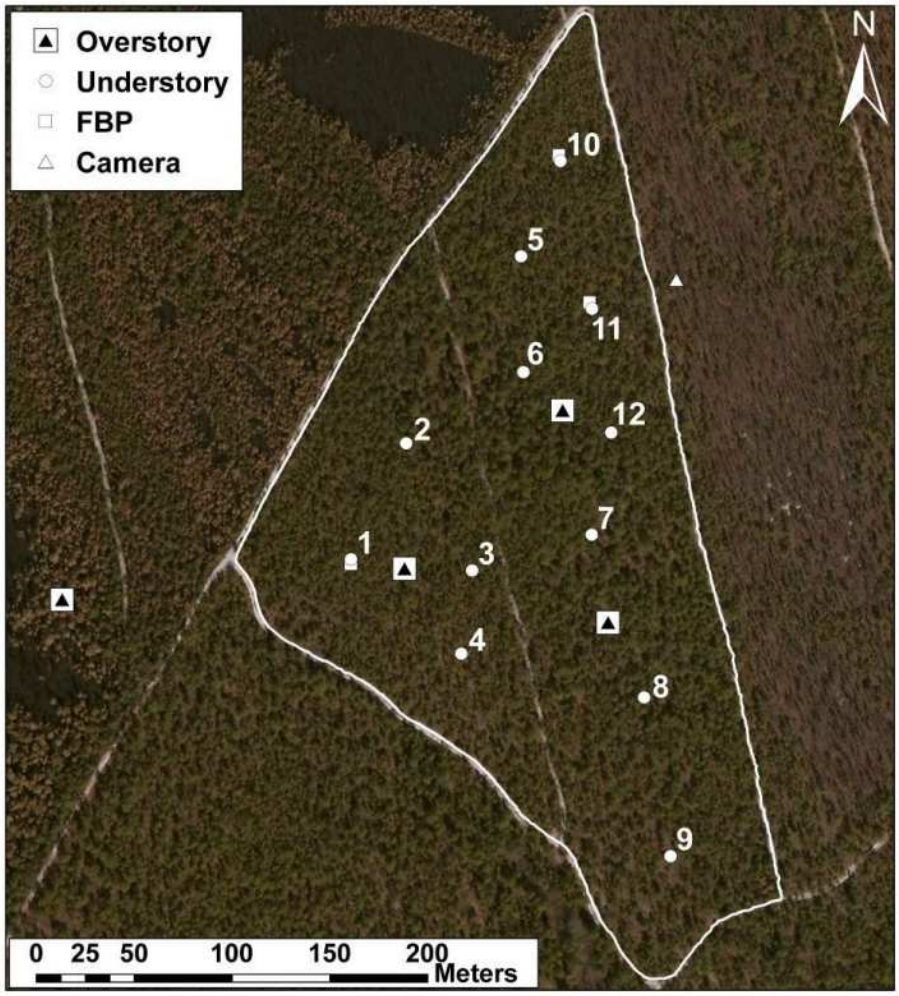

Figure 1. Layout of instrumentation in the study site with understory tower numbers labeled.

Dataloggers were located in protective enclosures at the top of the towers and a sampling rate of 0.5 Hz was used. Each FBP provided measurements of total and radiative incident heat flux (dual radiometer), horizontal and vertical velocity (2 bi-directional pressure probes), and temperature (K-type thermocouple), all at a height of roughly 1 meter (Butler *et al*. 2010). Dataloggers were housed in a protective enclosure and a sampling rate of 10 Hz was used. All instruments were distributed within the area to be burned, excluding one overstory tower, which was situated to the west in order to measure ambient conditions during the time of the fire. Exact instrument locations can be seen in Figure 1. In addition to point measurements, sequential aerial IR images of the fire were recorded from an aircraft using Rochester Institute of Technology's Wildfire Airborne Sensor Program (WASP) (McKeown *et al*. 2011). The WASP records data in short-wave (1.0-1.7 μm), mid-wave (3.0-5.0 μm), and long-wave (8.0-9.2 μm) infrared spectral bands, as well as the visible spectrum (0.4-0.9 μm). Images were time-stamped and georeferenced. Of the above instrumentation, this paper only discusses measurements obtained with the sonic anemometers and the aerial IR camera. As a visual reference, several cameras were placed within and around the burn block. The camera discussed here was placed outside of the site, looking east towards Understory 11 at a distance of about 45 meters.

Field measurements of surface fuel loading were obtained by destructive sampling of the forest floor and shrub layer in 1 m^2 clip plots. 36 of these measurements were made (3 surrounding each understory

tower) both pre- and post-fire, in order to give an indication of surface fuel consumption. Measurements from the litter layer (O_i horizon) were divided into categories of fine fuel, reproductive material (pine cones, acorns, and catkins), 1-hr wood, 10-hr wood, and 100-hr wood, while measurements from the shrub and oak layer fuels were divided into categories of foliage, 1-hr wood and 10-hr wood. It should be noted that a destructive sampling technique inherently excludes colocation of pre- and post-fire measurements. Remote measurements of both pre- and post-fire canopy fuel loading were conducted using an airborne Light Detection and Ranging (LiDAR) technique. This data will allow the generation of a 1 m x 1 m resolution canopy height model, as well as 3D canopy bulk density (CBD) profile at a resolution of 10 m x 10 m x 1 m. CBD will be calibrated to profiles from an upward-sensing LiDAR unit in twelve 20 m x 20 m plots within the burn area. This unit has been previously calibrated to represent profiles of CBD using equations developed through destructive harvest by Clark *et al*. (2013). As this calibration is currently ongoing, only a qualitative discussion of the relative reduction in canopy fuel loading will be given.

2.3. Measurement techniques

In order to characterize the type of fire observed, it is useful to estimate the quantity known as fireline intensity (*I*), which indicates the energy release rate per unit length of fire front (Byram 1959). Fireline instensity is often calculated as $I = H \cdot \Delta m \cdot R$, where R is the rate of spread [$m \cdot s^{-1}$], Δm is the mass of fuel consumed [kg], and H is the heat yield of the fuel. In this study, H is taken as 18700 $kJ \cdot kg^{-1}$ (Alexander 1982). This value of H is the low heat of combustion and is an estimate based on an average value for a number of different fuel species. However, studies have shown that the typical variation between species is only on the order of ±10% (Byram 1959, Van Wagner 1972). Corrections may also be considered to account for completeness of combustion and mass consumption during smouldering combustion, after the fire front passage, but for the purposes of the study this basic value is sufficient. As canopy fuel consumption estimates are not yet available, only the physical measurements of surface fuel consumption were used. Thus, the quantity will be referred to as surface fireline intensity (I_{surf}). Finally, due to the inability to collocate pre- and post-fire physical fuel samples, as mentioned in Section 2.2, consumption estimates for larger fuel elements were considered unreliable, as they were sparsely distributed. For example, 100-hr fuel will likely not be completely consumed, but if no such fuel is located in the post-fire sample plot before the fire, calculation of the difference would suggest that total mass in the pre-fire plot was consumed. Therefore, only fine fuel (primarily needle litter), 1-hr forest floor wood, and 1-hr oak and shrub layer material was used to calculate I_{surf}. Further, thin fuel was considered to be the main contributor to fire intensity. Spread rates were obtained from the aerial IR imagery.

2.4. Burn conditions

The fire was conducted on March 5th, 2013. Ignition was carried out by the NJFFS using a drip torch along the northwest road, moving from northeast to southwest over a roughly 8 minute period, starting at 11:53 (EST). The real-time location of the drip torch on this road was tracked by GPS. Due to safety concerns caused by rapid fire growth, a secondary ignition line was subsequently created along the southwest road. The duration of the fire was determined to be approximately 1 hour, though much of the block was consumed within the first 20 minutes. During this 1 hour period, mean ambient temperature was around 7 °C and mean relative humidity was 39%. Fuel moisture content (FMC) was measured for different classes of vegetation during the burn, details of which can be seen in Table 1. Samples were taken from the stand immediately to the north of the burn block.

Table 1. Measurements of fuel moisture content (FMC ± relative standard deviation) for fuel collected during the time of the fire.

Location	Fuel Type	Sample size	FMC [%]
Canopy (Pitch Pine)	Live needles	7	114.4 ± 2%
	Live stems (1-hr)	7	85.2 ± 8%
Understory	Shrub stems (1-hr)	8	60.9 ± 9%
	Oak stems (1-hr)	5	61.2 ± 12%
Forest Floor	1-hr wood	7	15.3 ± 16%
	10-hr wood	10	30.9 ± 52%
	Needle litter	8	22.5 ± 50%
	Oak leaf litter	7	15.7 ± 45%

Results

3.1. General fire spread

Between the time of 11:56:59 (EST) and 12:38:45 (EST), 16 IR images were captured by the WASP as the plane made passes overhead and allowed the mapping of fire progression (Figure 2). The contours displayed in Figure 2 were obtained by tracing along the sharpest gradient of pixel intensity recorded for each long-wave image. Only 7 of the 16 contours are shown, as these represent the fire behavior of interest for this study. These will be referred to as P2-P8 hereinafter.

The primary fire front, originating from the northwest road, spread as a head fire in a southeasterly direction. It did not completely merge with the secondary (backing) fire front until sometime between fire contour P5 and P6. At certain locations the fire contours sharply dips back to a point which appears to lag behind in the direction of spread (Figure 2). In many places, this feature can be attributed to the narrow track which ran along the center of the block, as can be seen in Figure 1. This track acted functioned as a fuel break, because the only fuel consisted of a thin and intermittent litter layer. However, the resulting discontinuities in the fire front coalesced with continued fire spread, as can be seen when comparing contour P5 to P6 in Figure 2. Other irregular features of the fire contours, such as along the west portion of P3, may be due to fuel heterogeneity, discontinuity in the ignition line, or some combination of the two.

3.2. Local surface fire intensity

Given that each understory tower was surrounded by 3 mass consumption field sample plots, and fire contours were available across the entire burn block, it was possible to calculate local surface fireline intensity to get an indication of the range of fire behavior. A selection of locations are shown in this report, which are, moving from north to south, understory towers 10, 5, 11, and 1. These were chosen as initial sites to investigate as they were situated in a region of headfire which was unaffected by the backfire. Spread rates at each of these locations were determined by measuring distances between fire contours in ArcGIS. Each distance was measured 15 times along a segment of around 60 meters of fire front in order to both minimize measurement uncertainty and to give a general indication of the relative homogeneity of local fire spread. A summary of the calculations for each location, resulting in surface fireline intensity, is presented in Table 2.

At the location of Understory 10, near the northern corner of the plot and the start of the ignition line, the lowest intensities were found (of the locations considered). Estimated values fall between 500-1300 $kW \cdot m^{-1}$. This was a result of both low mass consumption and slow fire spread, as can be seen in Table 2.

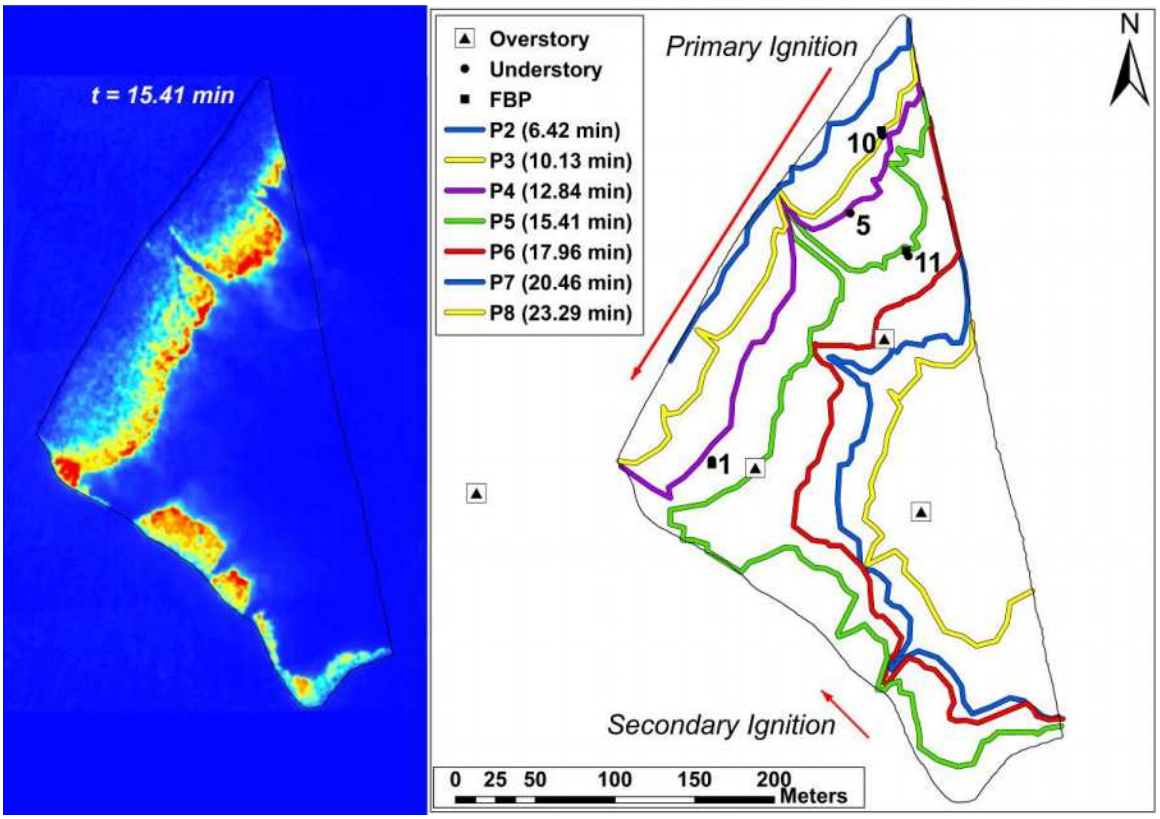

Figure 2. (Left) Example IR image from the WASP (P5). (Right) Progression of the fire front, extracted from IR imagery. The fire progressed from West to East, with consecutive fire contours labeled P2-P8. The time of each contour is given in minutes after the start of ignition.

Table 2. Summary of Δm (± maximum relative difference in the 3 samples), R (± relative standard deviation), and I_{surf}. Values of I_{surf} are rounded to the nearest 100 kW·m^{-1}.

Location	Δm [kg·m^{-2}]	Distance	R [m·s^{-1}]	I_{surf} [kW·m^{-1}]
Understory 10	0.73 ± 41%	P2-P3	0.095 ± 7%	1300 ± 52%
		P2-P4	0.074 ± 10%	1000 ± 51%
		P2-P5	0.073 ± 9%	1000 ± 50%
		P3-P4	0.039 ± 36%	500 ± 77%
		P3-P5	0.055 ± 28%	700 ± 69%
		P4-P5	0.074 ± 49%	1000 ± 90%
Understory 5	0.90 ± 9%	P3-P4	0.088 ± 28%	1500 ± 37%
		P3-P5	0.164 ± 7%	2800 ± 16%
		P4-P5	0.245 ± 9%	4100 ± 18%
Understory 11	1.32 ± 8%	P4-P5	0.245 ± 9%	6000 ± 17%
		P4-P6	0.222 ± 3%	5500 ± 11%
		P5-P6	0.191 ± 7%	4700 ± 15%
Understory 1	1.03 ± 6%	P3-P4	0.166 ± 15%	3200 ± 21%
		P3-P5	0.178 ± 16%	3400 ± 22%
		P4-P5	0.177 ± 10%	3400 ± 16%

Of particular note is a region of slow spread between P3 and P4. There was a deceleration of the fire here, with a 41% reduction in mean spread rate from P2 to P3. The spread increased again from P4 to P5, though increased heterogeneity is observed (± 49% deviation) which is likely due to gaps in fuel loading. The deceleration and acceleration is believed to be partially a result of ambient wind, and will be discussed later.

The Understory 5 and 11 locations are considered together, as they are roughly in line with each other in the direction of fire spread. Surface fireline intensities are considerably higher in this region, ranging from 1500-6000 $kW \cdot m^{-1}$. Here again, a slowing of the fire occurred between P3 and P4. Although the placement of mass consumption measurements does not allow for an accurate measure of intensity from P2 to P3 in this part of the block, the mean spread is between P3 and P4 is a 26% reduction from the P2 to P3 value (0.119 $m \cdot s^{-1}$). There is an increase of fire intensity moving from P3 to P5, with both higher spread rate and higher mass consumption measured at Understory 11. Indeed, of all regions examined in this study, both quantities are at a maximum in this location. Between P5 and P6 there is another slight reduction in spread.

To give a qualitative indication of the type of fire being measured, Figure 3a shows a frame of video footage. The camera was directed towards Understory 11, though it shows fire behaviour closer to the perimeter of the parcel. This region predominantly experienced a surface fire with localized torching into the tree crowns. Fire spread, however, was not supported continuously from crown to crown. Instead, vertical flame spread up the tree trunks resulted in brief periods of crown fuel consumption for individual trees.

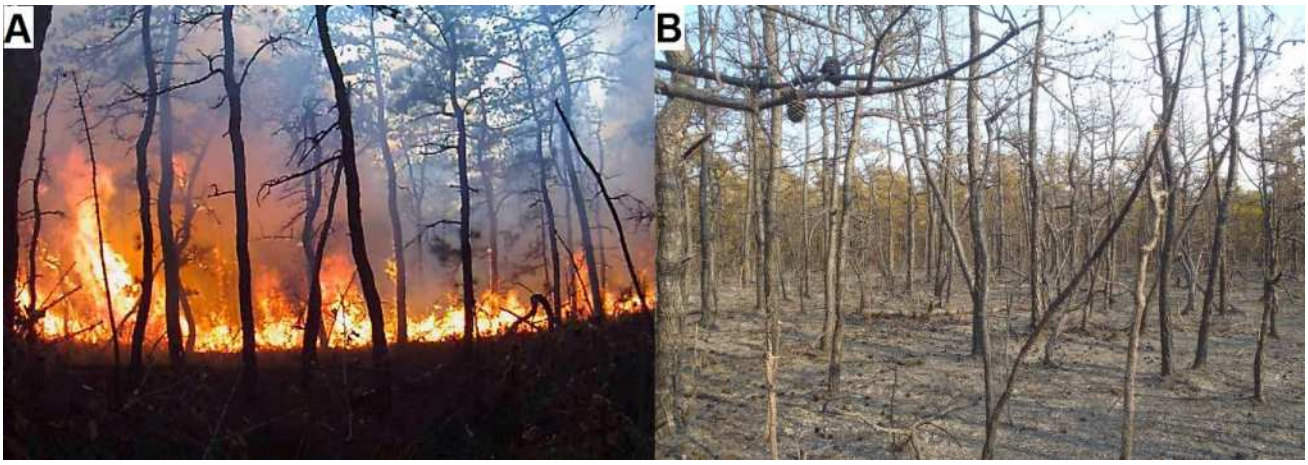

Figure 3. Examples of visual data. (a) Image from camera facing east towards Understory 11 (distortion is due to the wide angle lens used), and (b) image of post-fire fuel consumption in the vicinity of Understory 1.

Understory 1 experienced surface fireline intensities in the range of 3200-3400 $kW \cdot m^{-1}$, which fall between the values at Understory 10 and those at Understory 5 and 11. This region exhibited the most consistent fire behavior, with no obvious accelerations or decelerations. Additionally, observations of significant crown involvement were reported in this area, particularly near P3, close to the ignition line. This is confirmed by post-fire photographs of the region, where very little crown vegetation remains compared to other sections of the burn block (e.g. Figure 3b). However, the location described was to the northwest of Understory 1, beyond the measurements of surface fuel consumption, so the behavior pictured is not well reflected in the values of Table 2.

3.3. Wind

Wind is a critical factor to consider when analyzing the behavior of any wildfire. In the case of this experiment, the focus was first directed to the ambient winds measured by the sonic anemometer on the Overstory Control tower to the west. The magnitude of the horizontal winds at this location is

shown in Figure 4a. The curve was obtained by applying a loess-type moving average filter to the instantaneous values, in order to show the dominant wind gusts more clearly. Over the interval plotted, the average unfiltered horizontal wind is 1.8 $m \cdot s^{-1}$, with a peak magnitude of 6.4 $m \cdot s^{-1}$. Table 3 shows the mean horizontal wind magnitude at the Overstory Control tower for different intervals of fire spread. The instantaneous horizontal wind direction measured at the Overstory Control tower is shown in Figure 4b. Points where horizontal wind magnitude is less than 0.5 $m \cdot s^{-1}$ have been omitted from this figure, as low winds are more susceptible to rapid fluctuations in direction, which do not represent the dominant wind direction and make the data more difficult to interpret.

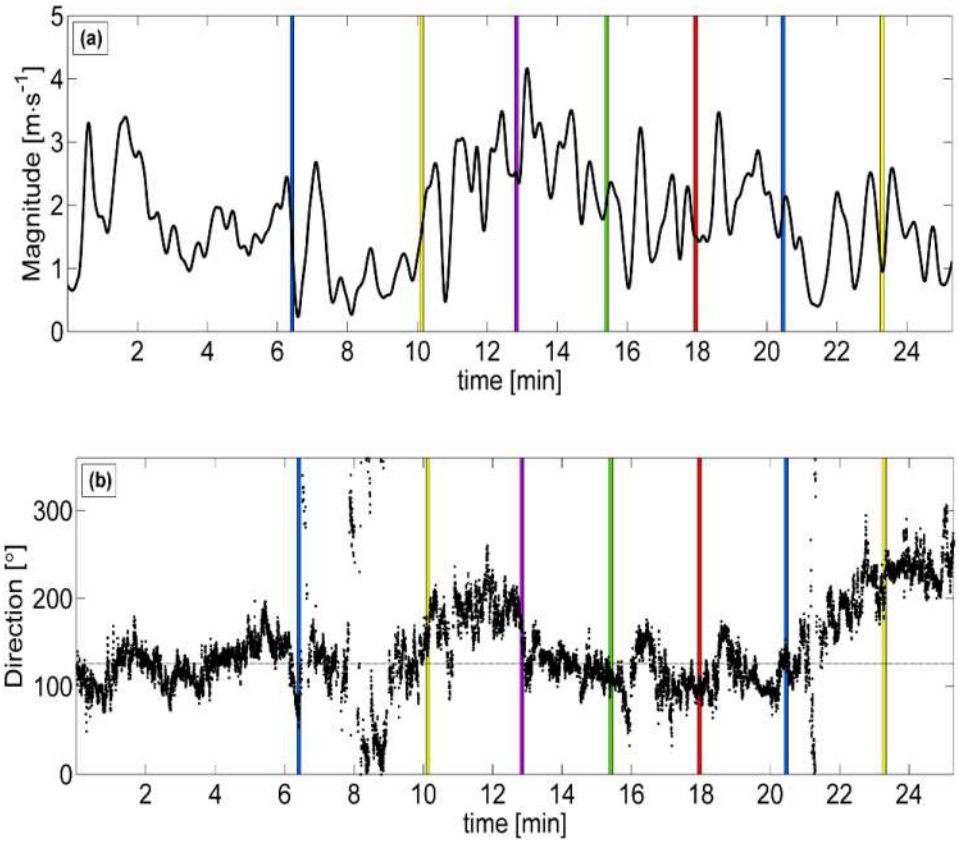

Figure 4. (a) Magnitude and (b) direction of horizontal winds at the sonic anemometer on the Overstory Control tower. Colored lines correspond to the time of fire contours P2-P8 (refer to Figure 2). Time is given in minutes from the start of ignition. Direction is given in compass degrees (clockwise from north). The horizontal line in figure (b) represents the general direction of fire spread.

From this information it can be seen that, as the fire built from ignition, winds were coherent to the direction of initial fire spread (estimated from fire contours as roughly 125°). Between P2 and P3, the wind is reduced somewhat and this corresponds to a shift in direction. From P3 to P4, where a reduction in fire spread was noted at the northeastern section of the burn block, the wind does pick up again, but the direction is oblique to fire spread by about 60°. From P4 to P5, where fire spread was high across the entire block, ambient wind is both relatively strong and consistent with fire spread. It is during this interval that the peak value of 6.4 $m \cdot s^{-1}$ was measured. This wind direction persists until around P7, where a shift is again observed.

Table 3. Mean horizontal magnitude of winds at the sonic anemometers (height of 12.5 m) on the Overstory Control and Overstory West towers.

Interval	Control Magnitude [$m \cdot s^{-1}$]	West Magnitude [$m \cdot s^{-1}$]
Ignition – P2	1.8	1.6
P2 – P3	1.0	2.3
P3 – P4	2.4	2.2
P4 – P5	2.7	3.0
P5 – P6	1.8	3.3
P6 – P7	2.1	2.5
P7 – P8	1.4	2.4

To understand the local influence of the fire on wind conditions within the study site, a comparison is made to the instantaneous horizontal wind direction measured at the Overstory West tower. This data is shown in Figure 5 (with low-velocity data omitted, following the previous convention). Mean horizontal magnitudes are also summarized in Table 3. Deviations from measurements at the Overstory Control tower appear to be fire induced and result from combination of low ambient winds and strong fire behavior. From the ignition to P2, a period of relatively weak ambient wind corresponds with a swing in local wind direction towards the north, where the fire has already established. A similar shift is observed as the fire reaches P3, with even lower ambient winds. From P3 to P4, as the ambient wind shifts to the south, the local wind has more of a westerly direction. This is likely caused by entrainment to the fire plume, which at this point is approaching the Overstory West tower from the northwest. Between P4 and P5, the dominant direction follows the ambient, but the scatter in this data is much greater. This is due to the fact that the anemometer has now started to be impacted by the turbulent plume. Data during this period should be treated with some caution, as the temperature rating of the device only extends to 50 °C. Following the pass of the fire front at P5, the local winds align with the direction of fire spread for the rest of the time shown. The direction is also roughly in line with ambient winds, but the higher magnitude locally suggests there is still an influence of entrainment to the plume.

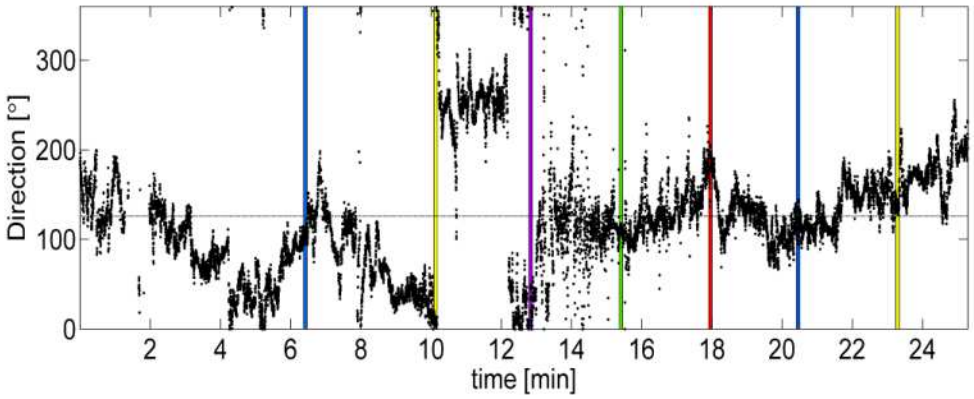

Figure 5. Direction of horizontal winds at the sonic anemometer on the Overstory West tower. Colored lines correspond to the time of fire contours P2-P8 (refer to Figure 2). Time is given in minutes from the start of ignition. Direction is given in compass degrees (clockwise from north). The horizontal line represents the general direction of fire spread.

3.4. **Canopy consumption**

An examination of canopy fuel consumption is also very important to assessing fire behavior. Although the LiDAR data cannot yet be used to obtain direct measures of mass consumption, a

qualitative analysis of the data can still provide valuable information. The percent difference in the pre- and post-fire data was obtained over the 10 m x 10 m x 1 m measurement grid. Transects of this data, which follow the direction of fire spread and pass through grid cells containing understory towers of interest, are shown in Figure 6. Note that because the transects are at an angle to the rectilinear LiDAR grid, the cells shown in Figure 6 have a horizontal extent greater than 10 m.

A comparison of the transects reveals that the Understory 10 and 5 had relatively little canopy fuel consumption, corresponding to the lower surface fireline intensities. In both cases, as the fire reached roughly 40-60 m from the ignition line, a transition to canopy fuel consumption occurred. This type of canopy fuel involvement continued as the fire spread from Understory 5 to Understory 11. The transect for Understory 1 shows somewhat different fire behavior. Canopy fuel is quickly involved in the fire, with this initial region corresponding to the area photographed in Figure 3b. This type of behavior appears to persist along the distance shown, with some small variability, such as a drop in consumption around 40 m.

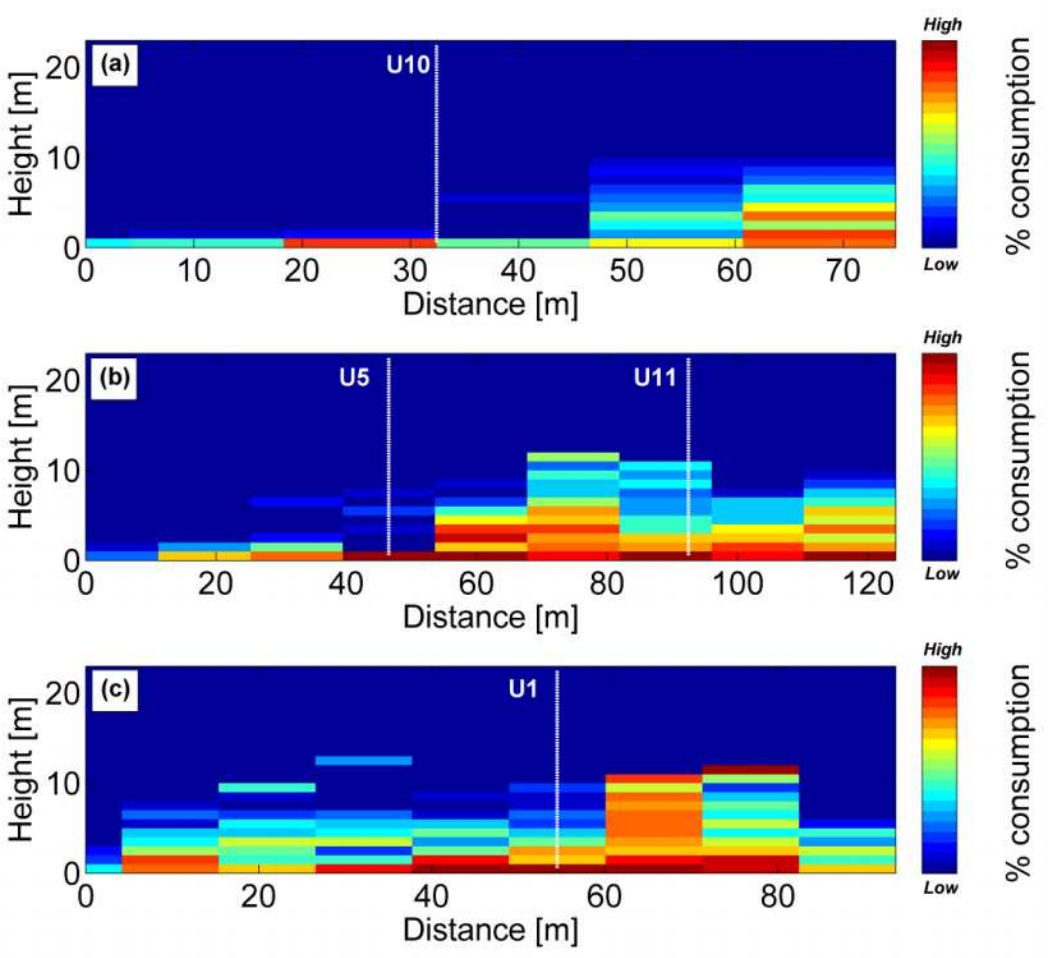

Figure 6. Percent canopy consumption estimated from uncalibrated LiDAR data. Transects are shown in the direction of fire spread for (a) Plot 10, (b) Plot 5 and 11, and (c) Plot 1. Distance is given in meters from the ignition line.

Discussion

The features of fire spread examined in this initial study help quantify the type of fire which was observed. Surface fireline intensities, which range from 500-6000 $kW \cdot m^{-1}$, can be compared to other fires, such as those summarized in Morandini and Silvani (2010). Spread rates reported for several shrubland fires fall within the range of 0.003-0.4 $m \cdot s^{-1}$, which is comparable to those determined here.

However, for the shrubland fire intensities presented by Morandini and Silvani (2010) the upper range was 48000 $kW \cdot m^{-1}$. Wind speed in these studies was within the range of 0-7.9 $m \cdot s^{-1}$, which is again comparable. It should be noted that the measurements discussed from this experiment were made above the canopy, and the drag of the canopy vegetation will cause lower values at the level of the shrubs. The considerably higher intensities can be traced back to the fuel loading. As expected, shrub layers in the open environments of the report tended to be denser than the shrub layer of a forested environment, such as the PNR. Values as high as 25 $kg \cdot m^{-2}$ were found in these previous experiments. Therefore, a prescribed fire which consumes a significant percentage of the shrub layer will be less intense in the environment studied here. However, in the case of this experiment, surface fuels are not the only contributors, and, when considering total fireline intensity, the inclusion of canopy fuel consumption will play a significant role in some areas.

In order to complete this investigation, a full study of canopy fuel structure and consumption will be critical. The different regimes discussed previously in Figure 6 are of particular interest. The transition from surface fire to canopy fuel involvement near Understory 5 is reflected in the fact that surface fireline intensity nearly tripled as the fire passed through this region (see Table 2). However, such a transition is not obvious in the surface fireline intensities near Understory 10. This can be attributed to the fact that the physical fuel samples at this location were taken in the region before the transition. At Understory 1 the more consistent canopy consumption can be seen in the low variation of surface fireline intensity. Examination of the pre-fire canopy arrangement will help provide insight into the presence of transitions. It may be that spatial features of the fuel density played as much or more of a role than wind in causing changes in local fire behavior.

Mean wind speed in this experiment was relatively low compared to what might be considered severe wildland fire conditions. For example, during a famously catastrophic fire in the PNR in 1963, peak wind gusts exceeding 22 $m \cdot s^{-1}$ were measured (Hughes 1987). Despite this, it appears that shifts in wind direction and magnitude may have affected certain observed aspects of fire behavior. One example is the reduction and then increase in fire spread which was observed between P3 and P5, towards the northeast corner of the block. This corresponded with a roughly 60° swing in wind direction. As discussed previously, the fire here did not have significant canopy fuel involvement. Therefore, it is likely that the less intense fire was susceptible to the influence of ambient wind. Conversely, fire spread was quite consistent in the region of Understory 1 during this time. The fire near Understory 1 should be less influenced by ambient winds, however, due to the stronger convective plume where canopy fuels are invloved. The ongoing study of the impact of wind on fire behavior must take into account the fact that measurements shown were taken at 12.5 m, and not within the understory. However, with the largely even topography and fuel loading, shifts above the canopy should correspond to shifts in the lower winds at the level of the shrub layer.

Many other aspects remain to be studied as well. Measurements of upward radiant flux, vertical velocity, and turbulent statistics at understory tower locations will supplement the comparison of variations in fire behavior throughout the burn block. Continued analysis of video footage will also help in interpreting the LiDAR data. The regions in which canopy fuels were involved in fire spread are clearly seen in the Figure 6. However, whether this represents localized torching supported by the surface fire, as shown in Figure 3a, or if true continuous crown fire spread was experienced in some locations, requires further investigation.

Conclusions

This work represents an initial effort to understand the behavior of an experimental fire and the fire spread dynamics. A time series of aerial IR imagery, destructive field sampling of fuel loading and consumption, as well as wind measurements were analyzed, along with a preliminary qualitative discussion of LiDAR data. Several features of fire behavior were identified:

- Observations revealed a predominantly surface fire, with localized torching of tree crowns.
- The involvement of canopy fuels in fire spread was identified with LiDAR measurements, and a clear transition from a pure surface fire was revealed in some locations.
- Ambient winds were relatively low. Wind is believed to have influenced low-intensity surface fire spread, and to have played a role in the aforementioned transition, but had little impact on more intense fire behavior.
- As the fire grew, local winds within the study site appeared to be dominated by fire induced flow, both preceding and following the passage of the fire front.

This analysis will expand, as additional measurements are integrated to provide a more complete description of the behavior. However, the results presented in this investigation give a qualitative baseline and a first understanding of the dynamics of the fire spread. Once coupled with total fuel consumption across the entire burn block, an assessment of the level of fuel reduction, given this type of fire, can be made. In addition, fire contours, spread rates, surface fuel consumption, and wind measurements will all become comparison points for future efforts to model this fire.

Acknowledgements

The authors wish to thank the Joint Fire Science Program (JFSP) for funding this research effort (project #12-1-03-11). Dr. Filkov was supported by the Tomsk State University Competitiveness Improvement Program and the Russian Foundation for Basic Research (project number 14-01-00211-a). The authors would also like to thank the NJFFS for their cooperation in the planning and execution of the experimental fires, as this was critical to the success of the project.

An update on the WindNinja surface wind modeling tool

Bret Butler, J. Forthofer, N. Wagenbrenner

USDA Forest Service, Rocky Mountain Research Station 5775 W US Highway 10 Missoula MT 59808, USA

Abstract
The WindNinja surface wind modeling tool is being used throughout the world to support wildland fire management. It continues to be updated and improved. Recent improvements include the capability to initialize simulations based on meso-scale weather forecast data or direct observations, an improved tool for accessing elevation data, and access to a momentum solver. This paper describes current status of the tool and planned enhancements.

***Keywords**: Fire behavior, prescribed fire, fire modeling*

Introduction

The temporal and spatial variability in near-surface winds is one of the primary environmental factors influencing wildland fire behavior (Rothermel 1972; Albini 1981; Williams 1982; Linn *et al.* 2007). Historically, fire managers have relied on expert judgment, point measurements, or weather forecasts to estimate local winds (Butler *et al.* 1998; USDA Forest Service and USDI Bureau of Land Management 2002). These methods can lead to large errors in estimated wind speed and direction and subsequently to corresponding uncertainty in fire growth simulations, especially in complex terrain. Others have identified the need for computationally efficient decision support systems for applications involving hazardous chemical or biological releases into the atmosphere and battlefield tactical situations (Davis *et al.* 1984; Homicz 2002; Ling and Shuming 2003; Vaucher and Luces 2011). In order to be useful as a decision support tool for operational fire management, the model must meet several constraints: 1) minimum level of required technical expertise (i.e. not necessarily extensively trained in meteorology); 2) short computational time (i.e. less than 1 hour); 3) minimum computing hardware (i.e. can be run on low cost laptop computers), 4) fine spatial resolution (~ 100 m) of winds at 3 to 10 m above ground level. This paper provides an update on a high resolution surface wind model called WindNinja which meets these constraints (Forthofer *et al.* in press).
WindNinja is a mass-conserving diagnostic model designed for simulating fine-scale, terrain-driven winds. It is widely used in North America to simulate winds in support of wildland fire management. The model seeks to minimize the change from an initial wind field while conserving mass. Details regarding the technical foundation of the model are provided in Forthofer *et al.* (in press). The model can be run via a simple graphical user interface (Figure 1) or a command line interface. Required inputs include a digital elevation model, an initial wind field, and vegetation information. Model outputs are gridded surface or volume wind fields in the following formats: .kmz for viewing in Google Earth, .shp and .asc for viewing in GIS applications, .atm for input to FARSITE and FlamMap fire spread models, and .vtk for viewing in 3-D visualization applications. WindNinja is typically run on domain sizes of up to 50 x 50 km and resolutions on the order of 100 m. Typical simulation times are around 10-30 seconds.
Here we outline the current status of the model with an overview of (1) new features including a diurnal slope flow parameterization, initialization using numerical weather model forecast data, a non-neutral atmospheric stability parameterization, and automated download of terrain data; (2) model validation work with newly collected field observations; and (3) ongoing work including incorporation of an

optional momentum solver, a new GeoPDF output format option, and development of a WindNinja mobile application.

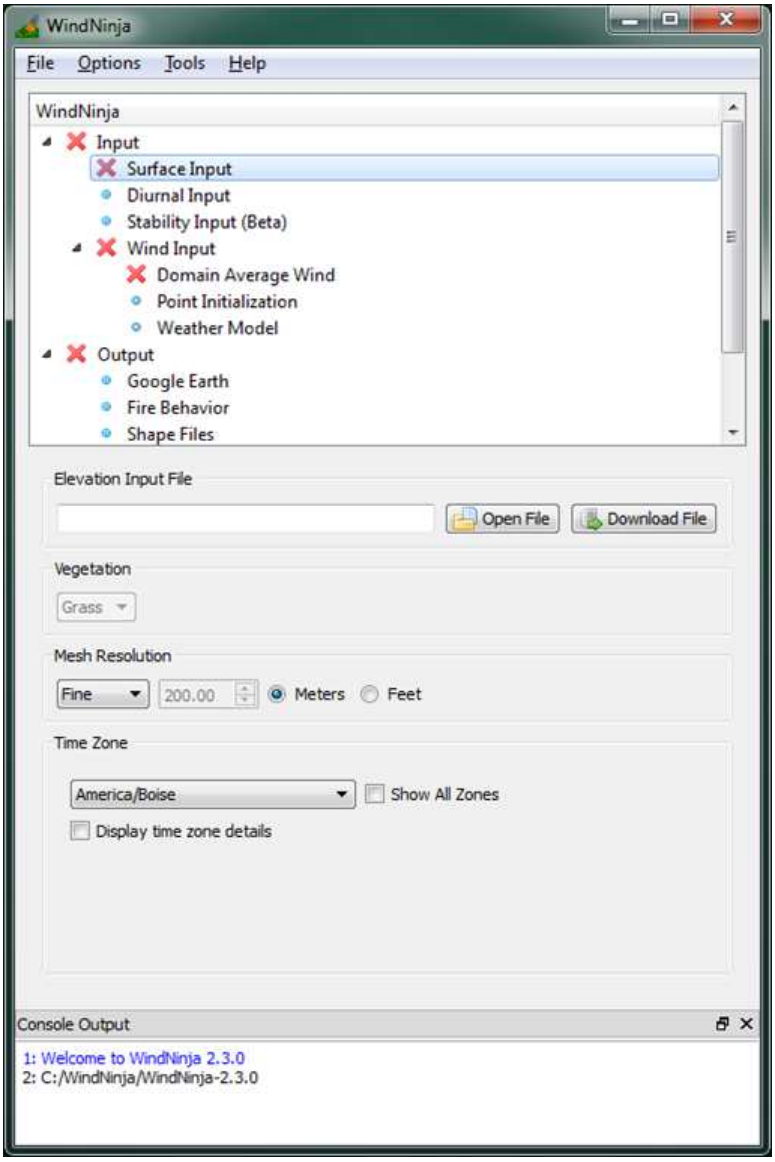

Figure 1. WindNinja graphical user interface.

New features

Diurnal slope flow

An optional diurnal slope flow parameterization has been added to the WindNinja model to simulate local thermally-driven upslope and downslope flows (Forthofer *et al.* 2009). The diurnal slope flow model simulates slope flows induced by local surface heating and cooling. These types of slope flows are most important when gradient wind speeds are low and thermally-induced effects outweigh the mechanically-induced effects on the flow.

The technical foundation of the diurnal slope flow model is described in (Forthofer *et al.* 2009). It includes a micrometeorological model based on (Scire and Robe 1997; Scire *et al.* 2000) which estimates atmospheric stability, surface heat and momentum fluxes, and boundary layer height.

Incident solar radiation is computed within each surface cell using the algorithm from the National Renewable Energy Laboratory (Rymes 2011) and a custom terrain shadow computation. The slope flow model is a one-dimensional model of buoyancy-driven flow along a slope. The magnitude of the slope flow is calculated at each surface grid cell as a function of acceleration distance (distance to ridgetop or valley bottom), percent slope, surface and entrainment drag parameters, and surface sensible heat flux. The direction of slope flow within each cell is exactly upslope or downslope and the depth of the slope flow is assumed to be 5% of the elevation difference to the ridge or valley. Once calculated, the slope flow component in each cell is added to the initial wind field and then the WindNinja solver is run to generate the final mass-conserving flow field.
Since incident solar radiation must be computed, use of the slope flow model requires that the following additional input parameters be specified: date, time, cloud cover, and air temperature. If the simulation is initialized with a weather model forecast, this information is obtained automatically from the weather model data, otherwise it must be supplied. Validation of the diurnal slope flow model with field observations is described below.

Weather model initialization

WindNinja allows initialization with a number of weather model forecasts. Numerical weather models compute gridded predictions of *u*, *v*, *w*, pressure, moisture, and heat on 3-D computational domains. They include sophisticated schemes for boundary-layer dynamics, cloud microphysics, and land-surface interactions. They typically simulate large areas (regional to continental scale), employing computational grids with horizontal resolutions of 4 km or larger. Because of the large computational expense required to simulate detailed physical processes over such large areas, it is not possible to run these types of models at a fine enough resolution to capture local terrain effects on the flow. In contrast, WindNinja is designed to simulate fine-scale winds that are dominated by mechanical terrain modification and local slope flows induced by local surface heating and cooling. Weather model forecasts linked with higher-resolution wind models can produce more accurate surface wind forecasts (Beaucage *et al.* 2014), as synoptic-scale forces and planetary boundary layer processes are resolved by the weather model to generate an initial wind field which is then downscaled by the higher resolution wind model that better resolves individual terrain features. The effect of downscaling weather model surface wind predictions with WindNinja is discussed below.
WindNinja includes built-in support for downloading and initialization with the following forecasts provided by the National Centers for Environmental Prediction: National Digital Forecast Database (NDFD), North American Mesoscale Model (NAM), Rapid Refresh Model (RAP), and Global Forecast System (GFS) (Table 1). Additionally, limited support has been added for the following forecasts via the command line interface: Weather Research and Forecasting (WRF-ARW) (netCDF format), historical NAM (GRIB2 format), and High Resolution Rapid Refresh (HRRR) (GRIB2 format). WindNinja only supports reading and initialization with these additional models, and does not offer download support, so the user must obtain these forecasts from another source.
WindNinja uses the 10-m wind speed and direction, cloud cover, and 2-m temperature from the weather model forecast. Only this subset of variables is downloaded from the full forecast for each output time step so the data transfer is very fast (typically just a few seconds). WindNinja performs an individual WindNinja simulation for every output time step in the weather model forecast. During each WindNinja run, the coarse-scale weather model forecast data is interpolated to the finer-scale WindNinja computational grid. Diurnal winds are added if the diurnal slope flow algorithm is enabled to produce the final initial wind field. Finally, the WindNinja solver is run on this initial wind field to produce a final flow solution that conserves mass.

Table 1. Weather model forecasts available for download in WindNinja

Model Name in WindNinja	Description	Horizontal Resolution	Forecast Duration	Temporal Resolution	Update Frequency
NCEP-NDFD-5km	National Digital Forecast Database	5 km	168 hours (7 days)	Every 6 hours	12 and 18 UTC
NCEP-NAM-12km-SURFACE	North American Mesoscale Model (lower 48 domain)	12 km	84 hours (3.5 days)	Every 3 hours	00, 06, 12, and 18 UTC
NCEP-NAM-Alaska-11km-SURFACE	North American Mesoscale Model (Alaska domain)	11 km	84 hours (3.5 days)	Every 3 hours	00, 06, 12, and 18 UTC
NCEP-RAP-13km-SURFACE	Rapid Refresh Model	13 km	18 hours (0.75 days)	Every 1 hour	hourly
NCEP-GFS-GLOBAL-0_5deg-SURFACE	Global Forecast System	0.5°	168 hours (7 days)	Every 3 hours	00, 06, 12, and 18 UTC

Non-neutral atmospheric stability

Atmospheric stability is a measure of the resistance of the atmosphere to vertical motion due to variations in air density with height above the ground. Under stable atmospheric conditions, vertical motion is inhibited and the flow will tend to flow around, rather than up and over terrain obstacles. Under unstable atmospheric conditions, vertical motion is favored and flow will tend to more easily move up and over terrain obstacles. Atmospheric stability is a dynamic phenomenon and it can vary spatially within a given domain.

The native WindNinja solver assumes a neutral atmosphere (vertical motions are neither suppressed nor favored). An optional atmospheric stability model has been incorporated into WindNinja for simulating non-neutral atmospheric conditions. The model estimates atmospheric stability from the surface heat flux calculated using methods from the diurnal slope flow model. Currently, a single stability value is assigned to the full vertical profile (from the ground surface to the top of the model domain) for each surface grid cell. Future improvements to the stability model will likely use additional information to more fully describe the state of the atmosphere. Because of this, the stability model is considered a beta test version at this time. Use of the stability model requires the following additional input parameters for calculation of the surface heat flux: cloud cover, date, and time. If the simulation is initialized with a weather model forecast, this information is obtained automatically from the weather model data, otherwise it must be supplied.

Elevation file grabber

An option to download a digital elevation model (DEM) has been added to WindNinja. This feature is referred to as the "elevation file grabber." The elevation file grabber uses a Google Maps interface which can be launched either from the graphical user interface or the command line interface (Figure 2). The elevation file grabber allows the user to swoop out an area of interest on the interactive map. After selection of the area, a transparent red box will be drawn on the map indicating the defined area (Figure 2). This box can be enlarged or shrunk by dragging the sides and corners of the box or it can be translocated by dragging the center icon. There are three data sources from which DEM data can be downloaded from: US SRTM, WORLD SRTM, and WORLD GMTED (Table 2). Once the area of interest has been defined and the DEM data source has been selected, the DEM can be downloaded by WindNinja from a United States Geological Survey (USGS) server.

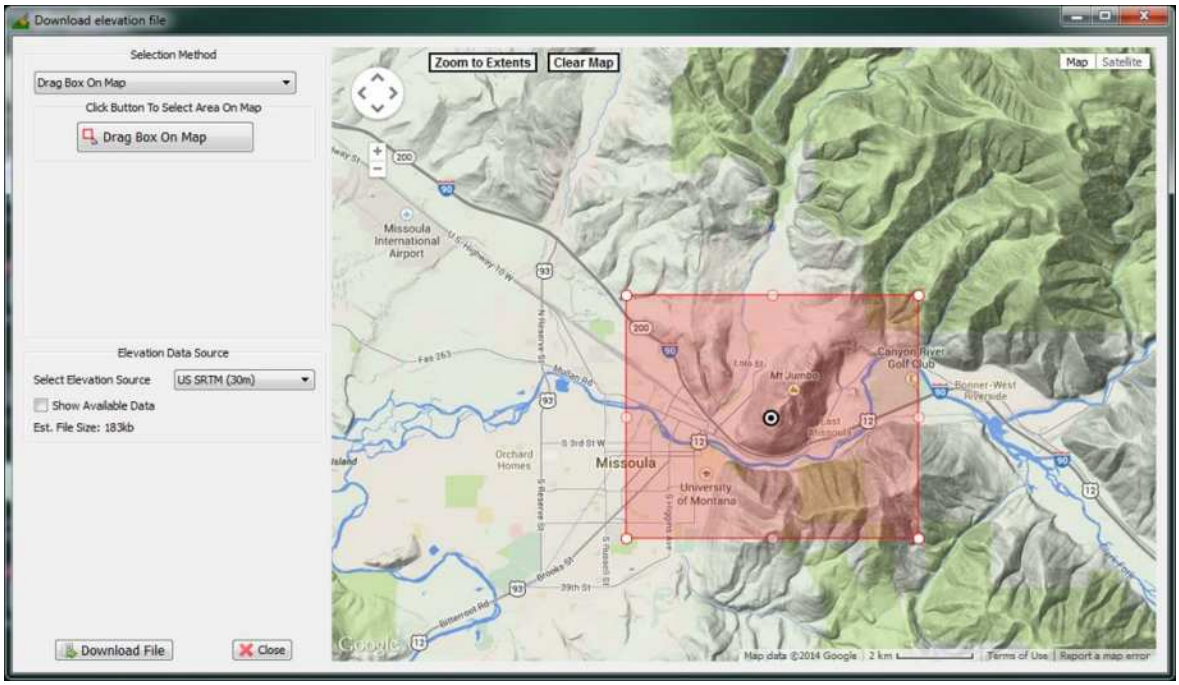

Figure 2. Elevation file grabber.

Table 2. Digital elevation model data sources

Data source	Resolution	Spatial extent	Description
US SRTM	30 m	Contiguous US, Hawaii, Puerto Rico, southern Alaksa	Data from the Shuttle Radar Tomography Mission (SRTM)
WORLD SRTM	90 m	-60° to +60°	Data from the Shuttle Radar Tomography Mission (SRTM)
WORL GMTED	250 m	-60° to +85	Global Multi-resolution Terrain Elevation Data 2010 (GMTED2010)

Model validation

There is little observational data available at appropriate spatial scales for evaluating high resolution wind models like WindNinja. To address this issue and facilitate validation of high-resolution wind models, we conducted a series of intensive field campaigns to collect high-resolution near-surface wind observations from four different field locations in complex terrain. Data from two of these field campaigns has been published (Butler *et al.* 2014) and used to evaluate use of WindNinja for downscaling numerical weather model forecast winds in complex terrain (Wagenbrenner, in preparation). Results from this work demonstrate that WindNinja can improve near-surface wind forecasts in many cases as long as the large-scale flow in the domain is adequately captured by the weather model. The biggest improvements in speed predictions occurred during periods of high winds and the biggest improvements in direction predictions occurred under periods of upslope and downslope flow. The largest errors in WindNinja-predicted wind speed and direction tend to occur on the lee side of terrain obstacles (Forthofer *et al.*, in press; Wagenbrenner *et al.*, in preparation). We found that the diurnal slope flow algorithm helped to correctly orient winds during periods of upslope

and downslope flows, but that the strength of the modeled slope flows tended to be weaker than the observed slope flows (Wagenbrenner *et al*. in preparation). This suggests that additional work could be done to improve parameterizations in the diurnal slope flow algorithm.

Ongoing work

Ongoing work includes incorporation of an optional momentum solver, design of an application for WindNinja simulations on mobile devices, and an additional GeoPDF output format option. Incorporation of the momentum solver should improve wind predictions on the lee side of terrain obstacles, in at least some cases. The new GeoPDF output format will all users to view gridded output surface winds on a map saved locally on their computer or mobile device. This will allow viewing of the output on a dynamic map without an internet connection or cell phone coverage and is expected to be useful to users in remote field locations. The mobile application will allow initiation of a WindNinja simulation from a mobile device. This should improve usability in field settings where use of computers or laptops may not be convenient.

Analysis of firebrand release on the spot fire mechanism

Miguel Almeida[a], Domingos Viegas[a], Jorge Raposo[a]

[a]*Centre for Forest Fire Research ADAI, Rua Pedro Hispano, 12, PT-3030-289 Coimbra, Portugal; miguellmd@yahoo.com, xavier.viegas@dem.uc.pt, jorge.raposo@dem.uc.pt.*

Abstract

Eucalyptus trees are among the most important sources of firebrands with potential to produce spot fires which are one of the most relevant manifestations of extreme fire behaviour. The mechanism of spot fires has several sequential phases starting in the release of a burning ember which is lofted and transported by the airflow, to land in a fuel bed causing a new ignition. In the present study, dedicated to the phase of firebrand release, an analysis of the firebrands released in a process of burning of eucalyptus trees is carried out.

Barks of eucalyptus trees have a great potential to produce firebrands during a forest fire. Sometimes these fuels are lay down on the ground or are attached to the trunk and to large branches of the canopy. In this study, the number and size distribution of firebrands released during the burning of these fuels for different scenarios are analysed. Three tests were made varying the location of the barks (suspended and lay down on a fuel bed) and the orientation of suspended barks (vertical and horizontal). An additional similar test was performed with a fuel bed composed of shrubs.

A particle image velocimetry system available in the Forest Fire Research Laboratory of ADAI was used to analyse the release of firebrands. Additionally, the convective up flow velocity and the temperature 2m above the tree, as well as the weight loss decay were measured. The final results among the several parameters controlled are compared.

Keywords*: forest fire, spot fire, spotting, firebrand, embers, eucalyptus, fire behaviour, extreme fire behaviour.*

Introduction and objectives

The importance of the spotting mechanism in the propagation of forest fires is widely recognized by both the scientific community and the operational elements of civil protection. Its importance is not only due to the effect on increasing the rate of fire spread but also due to the ability to overcome firefighting barriers and fuel breaks, as well as the capacity to surprise and trap people. Additionally, for larger firebrands and particular environment conditions, the long distance spotting mechanism may originate new independent fires which can stress the firefighting system.

For several years ADAI has been studying the spot fires mechanism splitting it in five main stages: (1) release of firebrands, (2) lofting of firebrands in the convection column, (3) downwind transport of the firebrand, (4) landing of the firebrand and possibility of ignition, and (5) interaction between the spot fire and original fire front. This study is focused on the release of firebrands resulting from the burning of eucalyptus trees, specifically the burning of the eucalyptus trees barks. The analysis was made using a particle image velocimetry (PIV) system.

There are several models related to forest fire however the major part is related to the aerodynamic lifting and downwind transport (e.g. Albini, 1979, 1981, 1983a, 1983b; Sardoy *et al.*, 2007) and some are related to the probability of ignition after the firebrand's landing (e.g. Viegas *et al.*, 2012). There are many models (e.g. Ellis, 2000) predicting the spotting mechanism for individual particles, or a set of particles with similar characteristics released in the same location. The major limitation of these models is the understanding of how and where the firebrands are released and what physical properties these firebrands have.

Release of firebrands is actually poorly understood. The use of PIV in this context may be of great useful however it is currently in a very early stage. Several authors have used the PIV technique in the context of fires specifically to determine the flame and the convective flow characteristics (e.g.

Morandini *et al.*, 2012; Horváth *et al.*, 2012) however those application were not in the context of spot fires. Hosseini *et al.* (2010) made a study reporting the characteristics of particle size distributions with focus on chaparral. Manzello *et al.* (2007) made a series of real-scale laboratory fire experiments to determine the size and mass distribution of firebrands generated from 2.6 to 5.2m high Douglas-fir (*Pseudotsuga menziesii*) trees using an array of pans filled with water to collect the firebrands generated from the burning trees.

Eucalyptus trees are among the main sources of firebrands with potential to cause a spot fire (McArthur, 1967). Barks of the eucalyptus trees (*Eucalyptus globulus* Labill.) were assumed in this study as being one of the most important components to produce firebrands. Normally the barks can be found lay down on the ground or may be attached to the trunk or to large branches of the tree. The barks attached to the trunk show an orientation predominantly vertical. The barks attached to the branches show an orientation with a greater horizontal component.

Several burning tests were carried out for three different scenarios: 1) barks lay down on a fuel bed, 2) barks suspended in a tree predominantly with vertical orientation, and 3) barks suspended in a tree mainly in the horizontal position. It is expected a faster and more intense combustion of the suspended barks and specifically the vertical barks (Almeida *et al.*, 2011). Higher intensity leads to a faster and more effective burning of the barks however it increases the up flow convective velocity intensifying the release of firebrands. On the other side, the horizontal orientation of the barks have a larger drag coefficient value (Almeida *et al.*, 2010) facilitating the uplift of the firebrands.

To sustain the combustion and to increase the fire intensity, a fuel bed of shrubs was used. To understand the effect of the shrubs in the release of firebrands, a fourth test with a single fuel bed of shrubs, without barks, was carried out.

The numerical and size distribution of the firebrands released during the burning was determined using a PIV system. In parallel other parameters like weight loss decay, temperature and vertical convective flow at 2m high were measured. A comparative analysis of the results was performed.

Experimental study

All the experiments following described were carried out in the Forest Fires Research Laboratory of ADAI (Association for the Development of Industrial Aerodynamics), in Lousã - Portugal.

Two different types of fuels were used in the experiments, namely eucalyptus barks (*Eucalyptus globulus* Labill.) and a mix of shrubs composed by heather (*Calunna Vulgaris*) and carquesia (*Pterospartium tridentatum*). The barks were detached randomly from the trunk and the large branches of the trees. The shrubs were cut using a brush cutter. All the fuels were collected in typical summer days and were stored inside the laboratory in controlled conditions of $T \approx 25$ºC and $RH \approx 40\%$.

As previously mentioned, four burning tests were carried out using shrubs (*T1*) or shrubs and barks (*T2, T3* and *T4*). Table 1 resumes the experimental conditions of each test. In *T1* the shrubs were lay down on the combustion table (Figure 1a).The fuel bed had the shape of a cone with a base of area of $0.81 m^2$ and 0.4m high. This "basic" fuel bed of shrubs was common to all tests. In *T2* the barks were lay down on the shrubs to cover the upper surface (Figure 1b). In *T3* (Figure 1c) and *T4* (Figure 1d) the barks were suspended in a tree skeleton only with thickest branches. It was assumed that tree skeletons used do not burn to loose significant weight nor to produce firebrands. In *T3* barks were suspended mainly with vertical orientation and in *T4* a predominant horizontal orientation of the barks was forced. The environmental laboratorial conditions (temperature *T* and relative humidity *RH*), the fuels moisture content (*FMC*), the initial fuel weight (m_0), the tree skeleton height (*H*) and diameter ($\varnothing$) and the distance (ΔH) from the surface fuels and the tree canopy were also measured before the burning. The fuels were roughly totally consumed during the test.

Table 1. Main data of the experimental conditions.

REFERENCE	INITIAL CONDITIONS	FUELS CHARACTERISTICS
T1	Fuel: shrubs Temperature (ºC): 29.8 Relative humidity (%): 48	FMC shrubs (% DB): 10.7 m_0 shrubs (kg): 2.7

(a) (b) (c) (d)

Figure 1. Images of the four burning tests carried out: a) T1, b) T2, c) T3 and d) T4.

The ignition was produced using a woollen yarn lying on the perimeter of the shrub fuel bed. The acquisition of weight, temperature and up flow velocity was initiated at the same time of the ignition. The PIV images started being captured when the total weight of the fuel bed was reduced to 88% of the initial value. By total weight of the fuel bed we understand the weight of all the elements over the table which, for example, in *T4* are the shrubs, the barks and the tree skeleton.

The fuel bed was set up on a balance (precision: 0.01kg) allowing the measurement of the weight loss decay during the burning. The temperature and the vertical flow velocity at 2m high in the central axis of the smoke plume were controlled throughout the experiment using a thermocouple and a *Pitot* tube, respectively.

The number and dimensions of the firebrands released were acquired from a PIV system. The PIV system is composed of a camera linked to a computer that store the images. The camera was placed in an elevated position in order to have a horizontal axis of image capture video. Figure 2 shows a representation of the experimental apparatus.

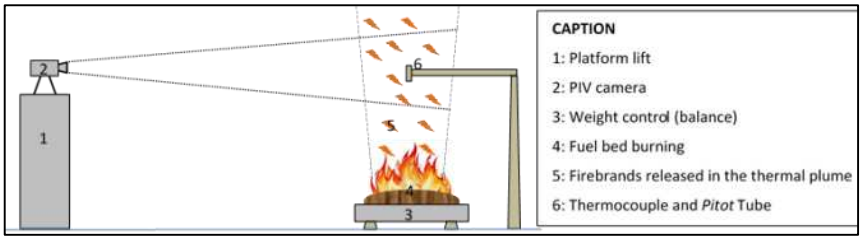

Figure 2. Experimental apparatus.

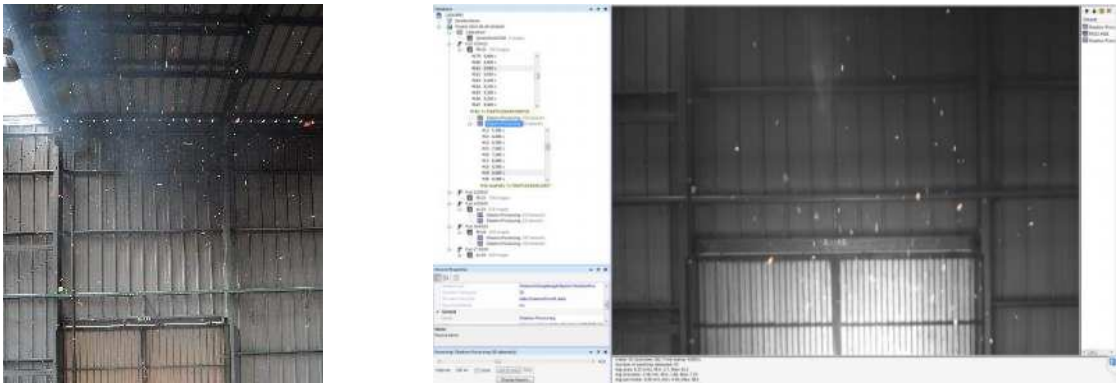
The images were captured for 25s. As previously mentioned, the image acquisition started when the total weight of the fuels was reduced to 88% of the initial value as it was observed to be the moment when the burning blows up to a higher intensity and more firebrands are released. The area covered by each PIV image is a rectangle of 2320mm width and 1728mm height with the centre 3.5m above the centre of the fuel bed. Particle were identified and characterized using the Dynamic Studio software of Dantec. After the preliminary identification of the particles of interest (Figure 3) only particles with equivalent diameter larger than 1.7mm were considered as interesting for this study. Besides the major part of the firebrands released has an equivalent diameter lower than 1.7mm, we considered that very small particles with lower calorific values do not represent an effective threat to cause a spot fire when lofted in the experimental conditions of burning.



(a) (b)

Figure 3. Images of the firebrand release (test T1): a) photographic image, and b) PIV image after the preliminary identification of the firebrands (red lines involving the particles).

Results and discussion

The weight loss decay was analysed taking into consideration that initial total weight was different among the four tests. Therefore a relative weight loss decay $\dot{m}$ was determined using Equation 1 where m_t is the mass of the fuel bed at any instant t and m_0 is the initial mass of the fuel bed. The weight of the tree skeleton was reduced as this element did not participated in the combustion. In Figure 4 the variation of $\dot{m}$ during the experiments is represented. Following Almeida (2011), the weight loss decay can be fitted with an exponential law as shown in Eqn. 2 where k is the weight loss coefficient represented in **Erro! A origem da referência não foi encontrada.**2. As can be seen the weight loss decay for *T3* and *T4* is quite similar and were the tests with faster decrease of fuel relative weight. On the other side, test *T2* burned slowly essentially due to the coverture of the shrubs fuel bed by the barks that muffled the flames delaying the burning. The values for Test *T1* were below those verified for T3 and T4 because the absence of barks that have a good combustibility rate.

The combustion rate during the range of time for what the PIV images were captures that is the period of interest for this study was very constant. The fitting of a linear equation of the values represented in Figure 4b drives to correlation coefficients r^2 larger than 0.98. Therefore the determination of average values for the other parameters (temperature, up flow velocity and number and area of firebrands) is reasonable.

The measured temperature *T* and the determined up flow velocity *V* values are represented in Figure 5. In Figure 5a, the values of *T* and *V* during the complete burning in test *T4* is given for exemplification. Figure 5b represents the values of *V* for tests *T1*, *T3* and *T4* during the time of the PIV images acquisition. The respective files of *T2* were corrupted and therefore the results for this test are not presented. Table 3 resumes the average values of T_{av} and V_{av} for each test. It is possible to observe that values of temperature and up flow velocity are lower for *T1* than for *T3* and *T4*, which are very similar. The lower intensity of *T1* verified and described during the analysis of *k* can explain these results. Additionally, the lower distance between the suspended barks and the *Pitot* tube, in *T3* and *T4*, when compared to the larger distance between the shrubs fuel bed and the *Pitot* tube in *T1*, can also explain that discrepancy of T_{av} and V_{av} among the tests.

V_{av} (m.s^{-1})	14.3	N/D	17.0	17.0

In Figure 6 the total number of particles released and captured by the PIV system for each test is shown. It is possible to see that in general terms the fuel bed composition producing more firebrands was that of test *T1* (shrubs) with an average value of 113 particles per image (Table 4) during the analysed range of time. Test *T2*, with barks and approximately the same load of shrubs than *T1*, produces an average value of 69 particles.image^{-1}. The barks work like a cover of the shrubs do not allowing the lofting of the firebrands. However, when this "cover" is passed through by the firebrands they can be lofted. The number of particles released during *T3* was even lower and N_{av} for *T4* was slightly above of *T2*. We could observe in laboratory that the tree skeleton with the barks suspended work as an obstacle for the lofting of the firebrands released from the shrub fuel bed. As consequence these firebrands were not lofted to the higher level were the PIV camera was pointed. When the barks start burning more intensively the number of firebrands increased assuming being counted 171 particles for *T4*. This was the larger value for all the tests. Surprisingly this increase of intensity was not traduced in an increase of the up flow velocity nor the weight loss decay. The superior number of particles verified in *T4* when compared with *T3* is due the higher drag coefficient of the horizontal barks facilitating the lofting of the particles and the breakage of the burning bark in small particles.

N_{av}	113	69	40	71

In Figure 7the distribution of the released particles by dimensional classes is represented for each test. The area of classes in mm^2 correspond to the projected area of the particles captured by the PIV system. Test *T1* only with shrubs as burning fuel has the larger number of firebrands, as it was mentioned before, however around 77% of the particles have a projected area below 100mm^2. Test *T2* was that one with less particles released however more than 41% of these particles have an area larger than 1000mm^2. The small particles released during the burning of shrubs were not lofted due to the barks cover however the burning of the barks produced firebrands with larger dimensions. Like for *T1* and

T2, particles below 100mm^2 were the most represented in *T3* and *T4*. While *T1* and *T2* roughly did not produced particles in the class [100; 500[mm^2, tests *T3* and *T4* with barks suspended, originate several particles in this range of area. On the other side these two tests produced less firebrands of larger dimensions. The more intensive burning verified in T3 and T4 can explain this achievement.

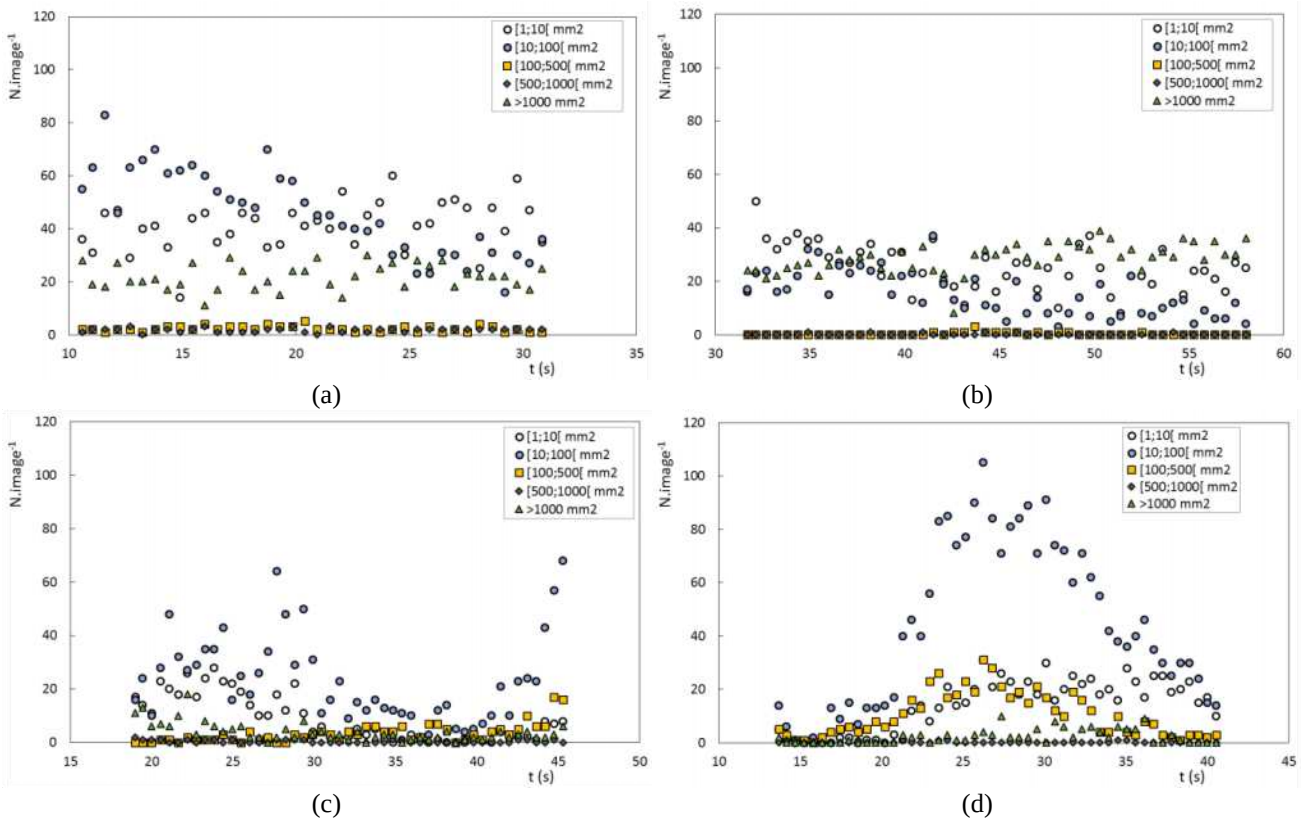

Figure 7. Numeric distribution of firebrands released during the burning captured by the PIV camera for T1 (a), T2 (b), T3 (c), and T4 (d).

The analysis of the projected areas was carried out as well as showed in **Erro! A origem da referência não foi encontrada.** and **Erro! A origem da referência não foi encontrada.**. If we consider that projected areas are proportionally related to the volume of the particles and consequently to the mass, it can be concluded that tests *T1* and *T2* produced a larger mass of firebrands. It can be seen in **Erro! origem da referência não foi encontrada.** that particles larger than 1000mm^2 contribute mainly for this result. The more intense tests *T3* and *T4* produced a lower mass of particles as a great amount of fuel is converted in smoke with particles below 1mm^2. Besides *T4* produced a larger number of particles than *T3*, the total area of the particles per image was similar due to the different distribution per area classes.

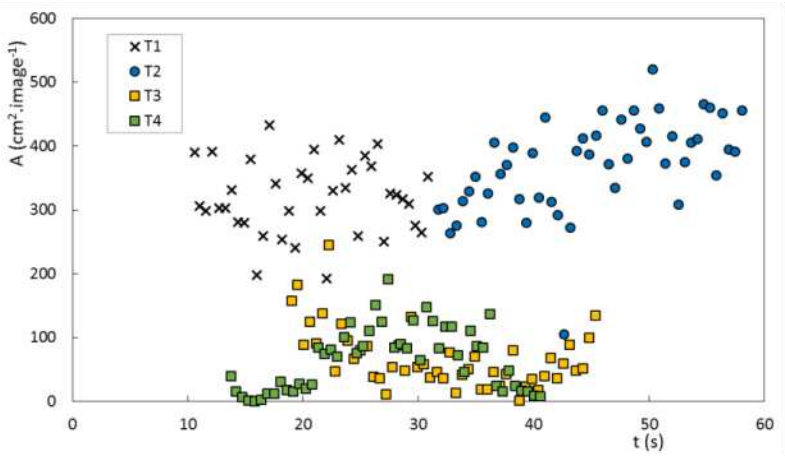

Figure 8. Total projected area of firebrands released during the burning captured by the PIV camera.

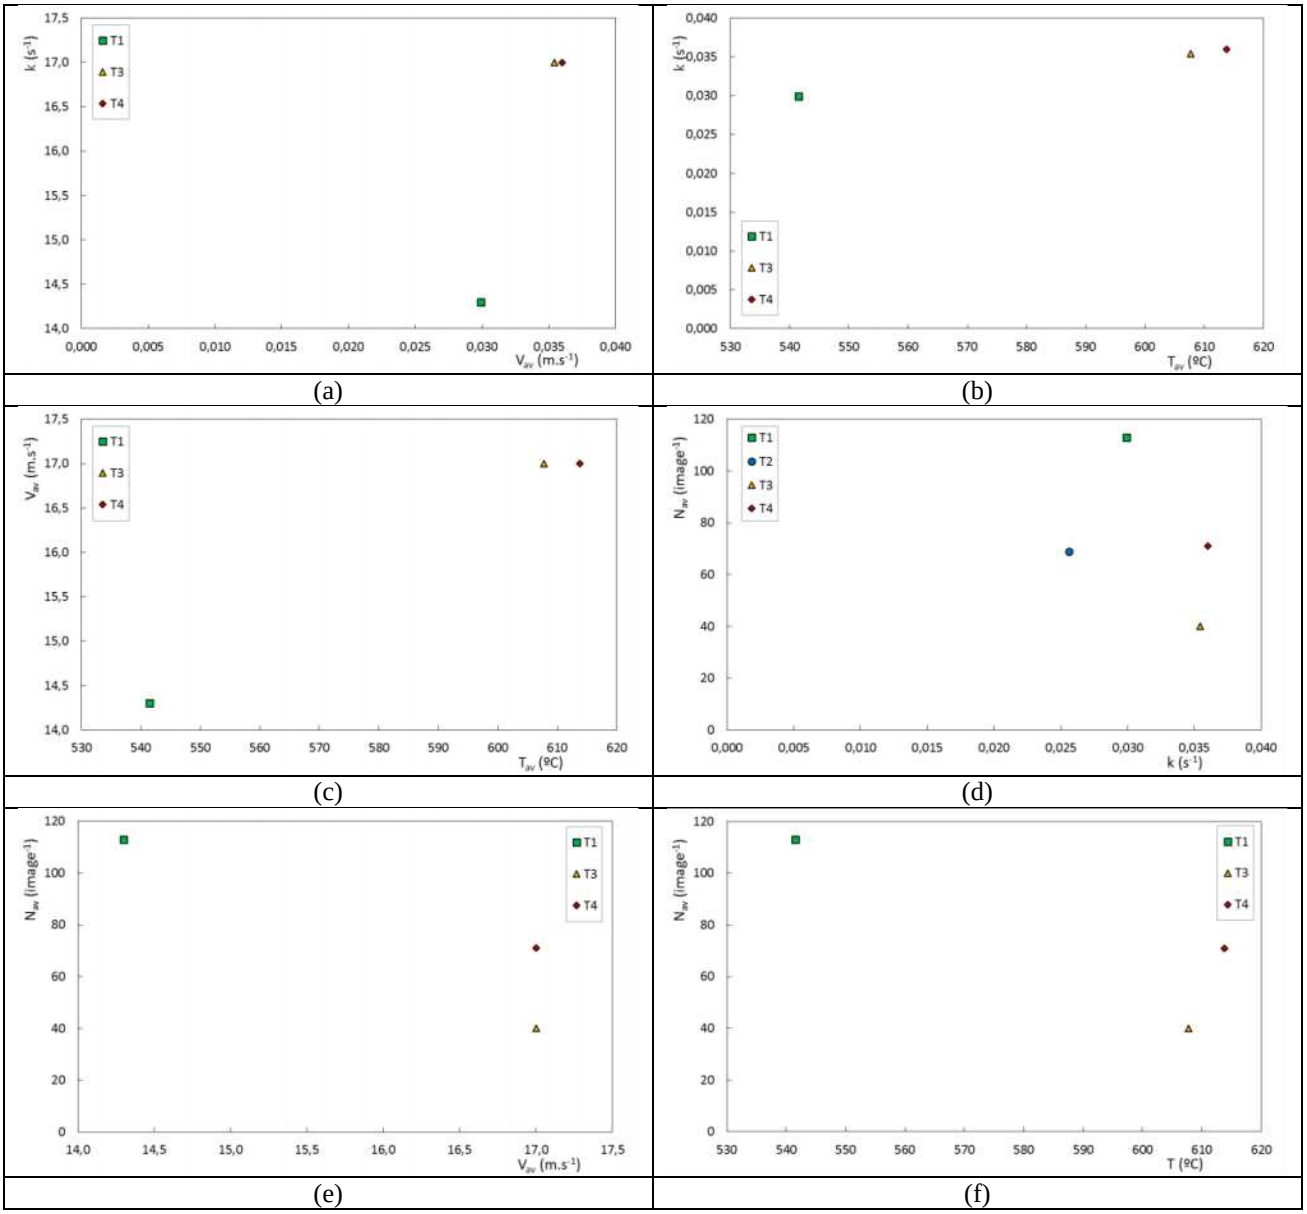
The four tests carried out are not sufficient to take ending conclusions on the relations among the parameters controlled. In addition the values of temperature and up flow velocity were not determined

for *T2*. Nevertheless in **Erro! A origem da referência não foi encontrada.** the relation among the arameters is presented. As it would be expected, *T*, *V* and *k* vary in the same direction (**Erro! A origem da referência não foi encontrada.**a, **Erro! A origem da referência não foi encontrada.**b and **Erro! A origem da referência não foi encontrada.**c). Parameters *T* and *V* are very related as *V* corresponds to the vertical convective flow that is induced by the heat of combustion. The number of particles released as function of the weight loss decay (**Erro! A origem da referência não foi encontrada.**d) is not well defined however it is possible to see a tendency showing a decrease of A_{av} with rising of *k* (**Erro! A origem da referência não foi encontrada.**h). This is due to the more intense and complete burning of the fuels for larger values of *k*. A negative effect of *T* and *V* to *N* and *A* is also verified in **Erro! A origem da referência não foi encontrada.**e, **Erro! A origem da referência não foi encontrada.**f, **Erro! A origem da referência não foi encontrada.**i and **Erro! A origem da referência não foi encontrada.**j. It would be expected that larger values of *V* would lead to an increase of *N* and *V* however, the larger values of *V* are related to more complete burnings (larger *k* and *T*) producing less particles. If to *V* was added an induced airflow (wind for example) maybe the number and area of the particles would increase in the same direction. The relation N_{av} *vs* A_{av} (**Erro! A origem a referência não foi encontrada.**g) is not well defined for the reasons previously explained.



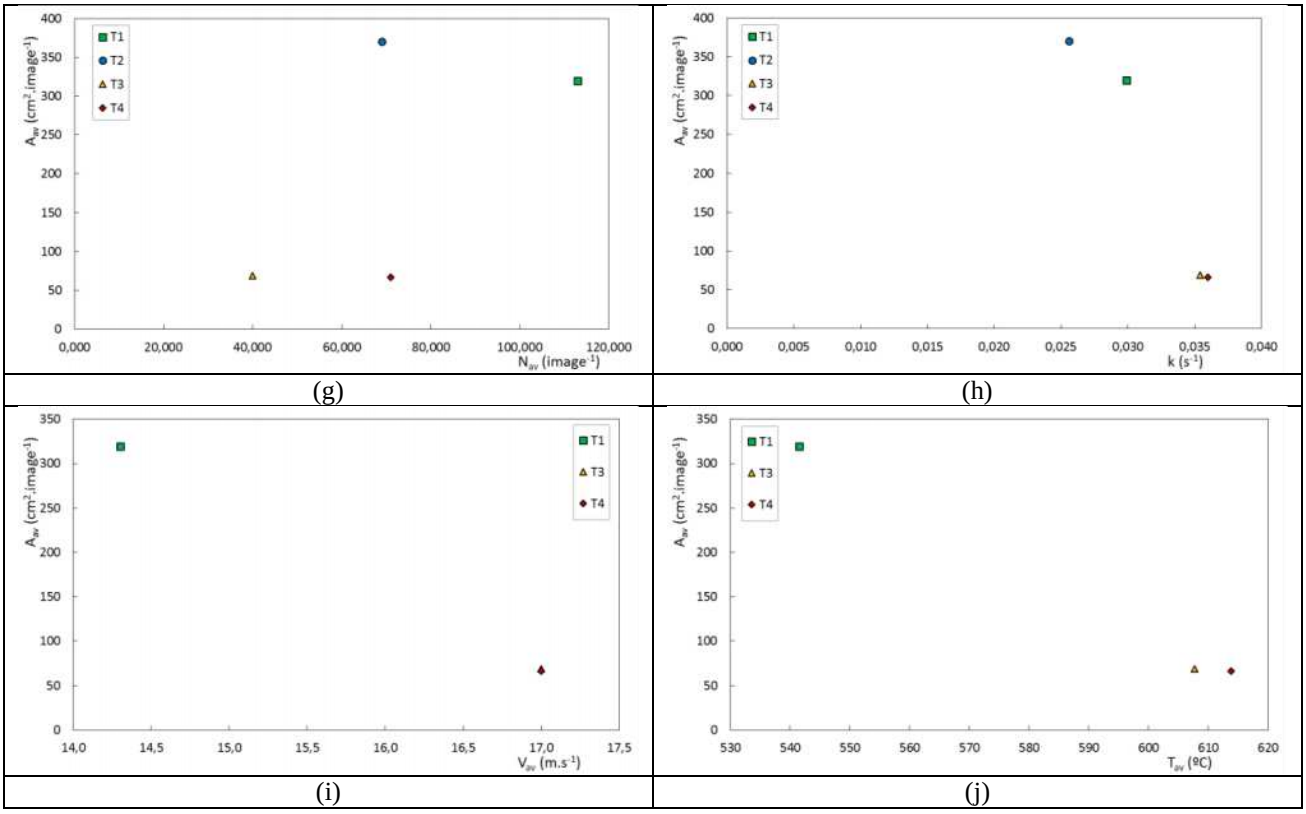


Figure 10. Relation between the parameters determined: (a) k vs V_{av}, b) k vs T_{av}, A_{av} vs k, (c) V_{av} vs T_{av}, (d) N_{av} vs k, (e) N_{av} vs V_{av}, (f) N_{av} vs T_{av}, g) A_{av} vs N_{av}, h) A_{av} vs k, (i) A_{av} vs V_{av}, and (j) A_{av} vs T_{av}.

Conclusions

Four burning tests were carried out in order to analyse the release of firebrands. Three of these tests burned shrubs and eucalyptus barks in different circumstances: 1) lay down of the shrubs fuel bed, 2) suspended in vertical position and 3) suspended in horizontal position. The fourth test consists of the burning of a singles fuel bed of shrubs.

The number and projected area of firebrands released, the weight loss decay, the temperature and the up flow velocity were determined. It was observed that burning shrubs with no barks (*T1*) working as obstacles produce many small particles below 100mm^2 (around 77%) and particles larger than 1000m^2 (around 19%). Test *T2* produced mainly particles larger than 1000m^2 (around 41%) as the less intense burning did not destroy the firebrands. Tests *T3* and *T4* produced mostly particles below 500mm^2 (89% and 97% respectively). Tests *T3* and *T4* were the tests with larger intensity and test *T2* was that with lower value of *k* due to the muffling that the layer of barks produce in the shrubs fuel bed. There was not a clear difference between the results of *T3* and *T4* with different orientation of the barks. The values of *T*, *V* and *k* for both tests were very similar as well as the total project area of the firebrands. The distribution of the particles released was slightly different with *T3* releasing more particles larger than 1000m^2 and *T4* producing more particles in the range [100; 500[mm^2. Maybe the more narrow net of the barks in the horizontal position is a more effective obstacle to the larger particles. However, the larger particle released during the four tests was observed in T4 with 2852mm^2. These particles have potential to produce spot fires at short distance. We believe that induced wind during the burning would lead to the release of larger firebrands with capacity to produce spot fires at superior distances. The number and area of the firebrands released was analysed using one single PIV camera. This limitation may sometimes lead to a number of firebrands released inferior to the real number as some particles may be hidden behind one another. We do not consider this error as very relevant as it is

would not be very frequent and eventual errors would be proportional to all the tests. The use of a second PIV camera capturing images in a perpendicular axis would avoid this fault and additionally would allow the determination of the velocity of firebrands which is much more accurate in a 3D analysis. The determination of the 3D shape of the firebrands would be possible with a second camera as well.

As future work we intend to extend the tests in number and carried out them for other scenarios with other fuels, introducing the induced wind as an additional parameter. The inclusion of a second PIV camera in order to avoid limitations and to analyse the velocity of firebrands is also foreseen.

List of acronyms

A [cm^2 or mm^2]	Projected area of the particles released captured by the PIV system
A_{av} [cm^2 or mm^2]	Average projected area of the particles released captured by the PIV system

Abstract
Laboratory scale investigation of a fire spreading on the windward face of a triangular section hill of variable shape with wind perpendicular to the ridgeline was performed. The work confirmed previous observations that the fire enlarges its lateral spread after reaching the ridgeline entering the leeward face with a much wider front. Reference fire spread velocities were measured and analyzed putting in evidence the importance of the dynamic effect due to flow velocity and its associated horizontal axis separation vortex strength without great dependence on hill geometry. A similar analysis performed to some real fires confirmed the same trend as was observed in the laboratory scale.

Keywords*: fire channeling; lateral fire spread; horizontal vortices*

Introduction

Predicting fire spread and behavior is one of the main challenges in forest fire research. It is widely recognized that wind, topography and fuels are the dominant factors affecting forest fire spread (Viegas 2004). The joint interactions among environmental factors and fire front influence fire propagation in various ways, particularly in areas with complex topography. In such conditions, many fatal accidents have been reported by a number of studies in different areas of the world. In fact, the interaction between wind, topography and fire front may lead to unusual patterns of fire spread that may surprise fire managers. An example of such a pattern occurs when a fire spreads across a two dimensional hill with wind blowing nearly perpendicular to the ridgeline. Pyrogenic vorticity, which manifests on the lee side of the ridge, produces a lateral enlargement of the fire that will then spread with a much wider front on that face of the hill and from then on (Simpson *et al*. 2013). This problem was first identified by McRae (2004) and it was analyzed by Sharples *et al*. (2011) and Sharples *et al*. (2012). A laboratory scale experimental research on this problem was carried out by the present authors for the case of a fire spreading upslope on the leeward face of the hill (Sharples *et al*. 2011). The interaction of the fire's plume with ambient horizontal vorticity near the top of this slope produced a lateral spread of the fire when it reached the ridgeline. This effect was confirmed in the numerical study presented by Simpson *et al.* (2013). In the above case the fire did not spread on the windward face and therefore this is possibly not the most interesting case to be analyzed.
In this paper the case of a fire spreading on the windward face of a two dimensional hill and its lateral spread at the ridgeline is analyzed. Laboratory scale experiments were performed in the large Combustion Tunnel of the University of Coimbra for various sets of hill configurations and flow velocities. Particular attention was given to the analysis of the lateral spread of the fire, and two models are proposed to estimate the relative growth rate of fire on both sides of the hill as a function of flow velocity and upslope non dimensional rate of spread. Our results put in evidence that the fire lateral growth is mainly due to the vortex flow dynamics, given its direct relationship with the dynamic

pressure of the flow. Moreover, we analyzed three case studies in which lateral fire growth in similar topographic and flow conditions were documented obtaining the same trend on the parameters variation as at laboratory scale.

Methods and Material

Physical problem

We consider a two dimensional hill with a low radius of curvature ridgeline subject to atmospheric flow with a reference velocity U that is assumed to be perpendicular to the ridgeline of the hill. We consider that the fuel bed is homogeneous and has uniform properties in the entire area of interest. In the present analysis we exclude crown fire spread and spot fire occurrence. The windward face (face *A* in Figure 1*a*) has an average inclination angle α_1 and the leeward face (face *B* in Figure 1*b*) has an average inclination angle α_2.

The wind flow will develop along face *A* as a turbulent boundary layer with increasing velocity from the bottom to its top. At the ridge of the hill, depending on the radius of curvature, the Reynolds number of the flow and its turbulence intensity, the flow may separate forming a horizontal axis vortex and reattaching downslope in face *B*. The shape and extension of this separation zone is very much dependent on the incident flow properties and on hill geometry. If the radius of curvature of the ridge is very small, we are in the presence of a sharp ridge like in the case of a bluff body. In this configuration flow separation will certainly occur, because theoretically the flow velocity at the edge of a convex dihedral is equal to infinity, regardless of the Reynolds number. In nature these situations are not uncommon, so we took into consideration this condition in order to avoid dependence on flow Reynolds number and consequently on scale effects.

The complex flow produced around two dimensional hills immersed in a turbulent boundary layer has been studied by Ferreira (1995), among others. Even in the relatively simple cases of sinusoidal or triangular cross sections, the flow topology in the absence of fire is not simple and there is not a uniquely defined reference velocity to characterize this flow. In numerical or experimental studies in which the imposed flow is either uniform or has a well-defined boundary layer profile it is relatively easy to define a characteristic flow or wind velocity, but this is not the case in full scale situations for which other parameters may be required to characterize the flow (cf. Viegas and Neto, 1991).

With reference to Figure 1*a*, we assume that there is a fire starting at a point O_1 in face *A* and spreading upslope along this face, with favorable wind until it reaches the ridgeline. In the limit this fire may have started before, but in that case it is assumed that it reaches this face with a relatively narrow fire front. It is observed that when the fire reaches the ridge and starts to descend face *B* it begins to spread laterally, with a rate that is much larger than the one it had on the windward face. This process has been observed in several real fires and is corroborated by numerical simulations and laboratory experiments like the present ones. Simpson *et al.* (2013) demonstrated that the lateral spread results from the interaction between the fire's plume and the horizontal vorticity due to flow separation near the top of the ridge. This interaction generates vertical vorticity on the fire's flanks, which in turn generates a lateral flow in the immediate lee face of the ridge. For this reason this phenomenon is appropriately designated by Simpson *et al.* (2013) as "Vorticity-driven Lateral Spread (VLS)".

The analysis of the enhanced lateral spread of the fire on both sides of the hill is the main purpose of this study.

Test configuration

In the present study we consider a two dimensional hill of triangular cross section, meaning that both faces *A* and *B* are plane surfaces. The inclination angles are α_1 and α_2 respectively for the windward face *A* and for the leeward face *B* (Figure 1*a*). The two faces intersect as a sharp ridge line. A reference Cartesian system is defined in the following way. The axis *OX* is parallel to the horizontal direction

and has its origin at the edge of the plane surface on which the hill is based; *OZ* axis is vertical and *OY* axis is also horizontal and parallel to the ridgeline of the hill.
Wind with a reference velocity *U* flows perpendicular to the ridgeline and in these conditions a vertical plane containing the *OX* axis is a plane of symmetry of the fire. The oncoming flow velocity may vary with *z* but not with *y*. We assume that a point source fire is ignited at point O_1 at a distance *a=50cm* from the base of the hill in the windward face. We define (cf. Figure 1*b*) the following distances travelled by the fire during its spread:
s_{1A} is the distance from the fire origin to the head of the fire along axis O_{S1} that is a symmetry line on face *A*;
s_{2A} is the distance from the fire origin O_1 to the back fire along the same axis but measured in the downslope direction (it is considered as a positive quantity);
s_{3AR} is the distance measured from the O_{S1} axis to the right flank of the fire on face *A*, measured along O_{S3A} axis that is an horizontal axis placed at a distance *b=20cm* from the ridgeline;
s_{3AL} is a similar distance measured to the left flank of the fire line;
s_{1B} is the distance from the ridgeline to the head of the fire along axis O_{S1A} that is a symmetry line on face *B* (with descending fire);
s_{3BR} is the distance measured from the O_{S1B} axis to the right flank of the fire on face *B*, measured along O_{S3A} axis that is an horizontal axis placed at a distance *c=10cm* from the ridgeline;
s_{3BL} is a similar distance measured to the left flank of the fire line;
We define the average value of the rate of spread along each one of the seven directions that were defined above as the slope of a linear fit of the function $s_i(t)$. This simplification is only acceptable if there are no consistent variations of the rate of spread (ROS) and it implies that the fire is spreading in a quasi-steady state, which may not be valid in all cases (cf. Viegas 2004).
Given the symmetry of the fire, we assume that $s_{3AR} = s_{3AL}$ and $s_{3BR} = s_{3BL}$. Therefore we only need to consider five relevant ROS to characterize the problem. The fire will spread upslope with a ROS R_{1A}, downslope with a ROS R_{2A} and laterally with a ROS R_{3A} (cf. figure 1b)). After reaching the ridgeline, the fire will spread downslope on face *B* with a ROS R_{1B}, and laterally with a ROS R_{3B}.
In order to minimize the effect of small variations of fuel bed properties, namely moisture content, following Viegas and Neto (1991) we use the non-dimensional ROS (NDROS) values given by:

$$R' = \frac{R}{R_o} \qquad [1]$$

In the present analysis we shall use the following five NDROS to characterize the spread of the fire along its main directions.

Upslope NDROS in face A: $$R'_{1A} = \frac{R_{1A}}{R_0} \qquad [2]$$

Downslope NDROS in face A: $$R'_{2A} = \frac{R_{2A}}{R_0} \qquad [3]$$

Lateral NDROS in face A: $$R'_{3A} = \frac{R_{3A}}{R_0} \qquad [4]$$

Downslope NDROS in face B: $$R'_{1B} = \frac{R_{1B}}{R_0} \qquad [5]$$

Lateral NDROS in face B: $$R'_{3B} = \frac{R_{3B}}{R_0} \qquad [6]$$

Given the importance of comparing the relative growth of lateral fire spread in faces *A* and *B* we shall use also the following non-dimensional parameter:

$$k_3 = \frac{R_{3B}}{R_{3A}} \qquad [7]$$

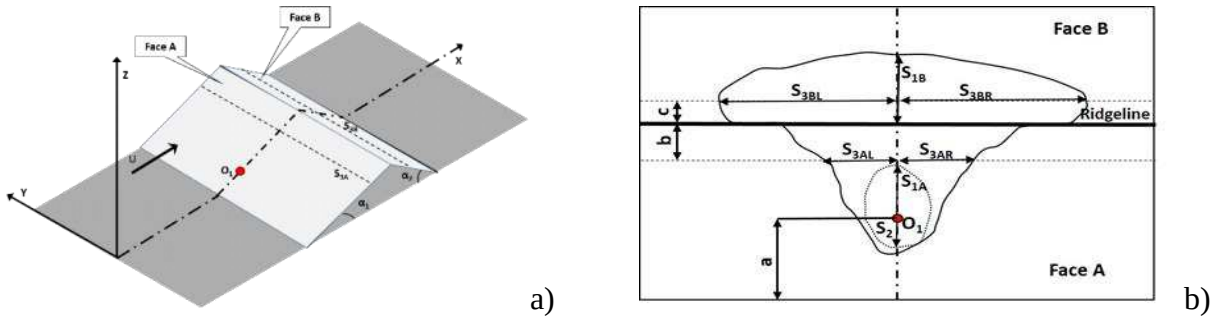

Figure 1. (a) Schematic representation of the fire; (b) Detail of the fire spread analysis.

Experimental Study

The experimental study was performed at the Combustion Tunnel TC 3 of the Fire Research Laboratory of the University of Coimbra in Lousã (Portugal). The Tunnel has a working section of $6\times8m^2$ and a maximum flow velocity of 7m s^{-1} (figure 2). A model of the two dimensional hill composed of two metallic plates hinged at the ridge line was used in the experiments. The width of the model is 4m, and the length of faces *A* and *B* are 1.5m and 1.0m respectively. The fuel bed for the experiments was composed by dry particles of straw with a constant load of 0.6kg m^{-2} (dry basis). Moisture content of the fuel was measured for each test or groups of tests with an A&D ML50 Moisture Analyzer. A reference test to measure the basic ROS R_o in no slope and no wind conditions was made in each test session. The corresponding values are given in Table 1.

The configuration of the model in each series of tests was adjusted fixing the value of α_1 of face *A*. Given the model construction, the slope α_2 of face *B* depended on α_1. Three values of α_1 were used in the present tests: 20º, 25º and 30º. The resulting values of α_2 were respectively close to: 30º, 40º and 50º. For each hill configuration five tests were performed with values of *U* equal to: 0, 1, 2, 3 and 4m s^{-1}. The values of α_1 and α_2 and flow velocity used in each test are reported in Table 1.

Figure 2. General view of the Combustion Wind Tunnel of the Forest Fire Research Laboratory of the University of Coimbra.

A point fire was ignited at point O_1 (Figure 1*a* and 1*b*), 0.5m above the base of face *A* (*a*=0.5m) and then the flow was turned on for the pre-adjusted velocity. Two video cameras, one IR camera and several digital photo cameras were used to record fire spread on each face of the hill. The images obtained were processed using a software developed by the ADAI team to analyze fire evolution and determine ROS values along relevant directions. Though in some cases the fire spread was not steady (cf. Viegas, 2006), we assumed that the ROS was constant along each spread direction (s_i) that was

considered, and therefore the corresponding average value of ROS was estimated as the slope of a straight line fitted to the plot of (s_i, t) using between four and ten data points. Lateral ROS R_{3A} was measured along a horizontal line 0.3m from the ridgeline, and R_{3B} was measured on face *B* along a horizontal line 0.1m from the ridgeline. Although the test configuration was nominally symmetrical, in order to assess this condition the lateral spread was measured separately for both sides (right and left) in each face: R_{3AR} and R_{3AL}, for face *A* and R_{3BR} and R_{3BL} for face *B*. As good symmetry conditions were found in the performed experiments the values of R_{3A} and R_{3B} given in Table 1 and that are used in subsequent analysis are the average of both left and right side estimates.

Case Studies

In order to assess the validity of present results obtained at laboratory scale we used data from some real fires in which lateral fire growth most probably due to channeling or horizontal axis formation on the lee side of a ridge have been observed. Some of them were already mentioned and described by Sharples *et al.* (2012).

4.1. Fire of Broken Cart

During the large fires that affected the city of Canberra (Australia) on 18th January 2003, various cases of VLS were observed (McRae 2004). Among these cases we selected the event of the Broken Cart Fire that is described by McRae (2004).

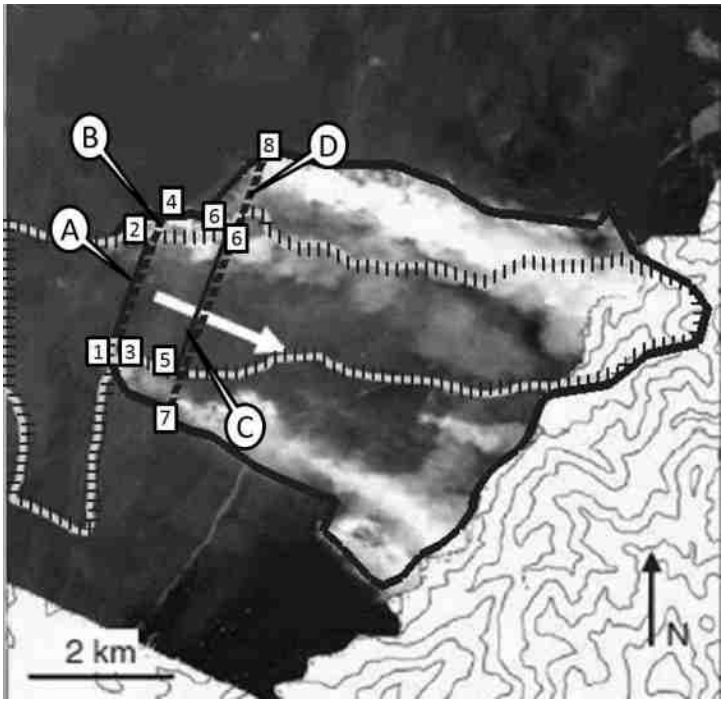

Figure 3. Schematic view of Broken Cart Fire (adapted from Sharples et al. (2012)).

In Figure 3 the white line with black dashes corresponds to 14:00 hours and the black bold line represents the fire at 15:09. The white bold arrow indicates the main spread direction due to the synoptic wind. Line A that is limited by points 1 and 2 represents the width of the main fire front before crossing the ridge at 14:00. Line B located between points 3 and 4, plotted with dashed bold line refers to the width perpendicular to the main spread direction before the ridge crossing at 15:09. The difference between the lengths of segments A and B divided by the time lapse gives the rate of enlargement of the fire front perpendicular to the main spread direction here designated as R_{3A}.
The measurements made after the fire crossed the ridge correspond to line C delimited by points 5 and 6 at 14:00 and line D between points 7 and 8 at 15:09. The rate of enlargement of the fire front after crossing the ridge that results from the analyses of these two lines corresponds to R_{3B}. The coefficient that gives the ratio of enlargement between side A (before the ridgeline) and side B (after crossing the ridgeline) is designated as k_3. The corresponding values are given in Table 2.

Table 2. Parameters of Case Studies analyzed in the present study

Case	R_o ($m\ s^{-1}$)	R_{1A} ($m\ s^{-1}$)	R_{3A} ($m\ s^{-1}$)	R_{3B} ($m\ s^{-1}$)	U ($m\ s^{-1}$)	R'_{1A} -	k_3 -
Broken Cart	0.06	0.69	0.12	0.42	9	11.60	3.59
Sa Costa	0.15	0.43	0.39	0.64	4	2.87	1.64
Golfo Aranci	0.06	0.54	0.18	0.68	10	9.69	5.70

4.2. Fire of Sa Costa

An interesting case study involving the fire spread process that is being analyzed occurred in Sardinia (Italy) on the 5th and 6th August 2010. This fire was reported in Cabiddu *et al.* 2010, and a brief description is presented here.
This fire is designated as Sa Costa and it occurred near the village of Jerzu, in the Province of Ogliastra, Eastern Sardinia.

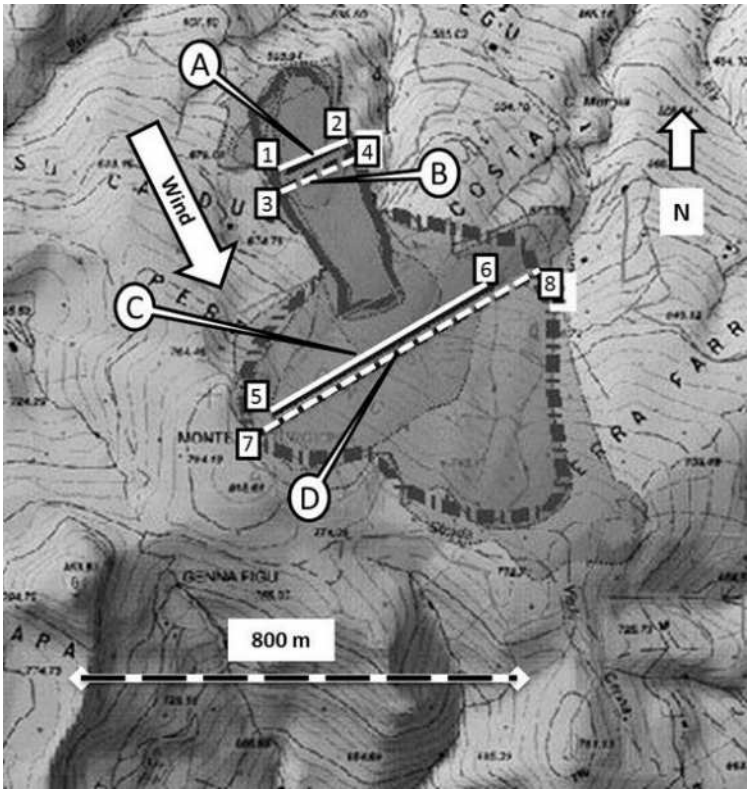

Figure 4. Spread of Sa Costa fire, in Eastern Sardinia, on the 5th of August of 2010.

In Figure 4 the analysis performed with the plots of the fire perimeter at different times are shown. The blue bold line corresponds to 17:05 and the dashed bold line represents the fire perimeter at 17:40. The wind direction was 320-330°.
The line A, plotted in bold white that is limited by points 1 and 2, represents the width of the main fire front before crossing the ridge at 17:05. Line B, located between points 3 and 4, refers to the width perpendicular to the main spread direction before the ridge crossing at 17:40. The difference between the lengths of the segments A and B divided by the lapse of time gives the rate of enlargement of the fire front perpendicular to the main spread direction here designated as R_{3A}.

4.3. Fire of Golfo Aranci

The fire of Golfo Aranci occurred in Northeast Sardinia (Italy) , near the town of Olbia, on the 24th June of 2013. The fire started at 14:43, the wind direction and intensity was practically constant and wind velocity decreased from 40 to 30 km h^{-1} over the duration of the fire.
When the fire reached a ridge with NNW-SSE direction, almost perpendicular to the wind direction, it spread laterally along the lee side of the ridge as it is shown in figure 5. Using the isochrones of fire spread that were provided by the *Sardinia Forest Service*, we estimated the relevant ROS values that are indicated in Table 2.

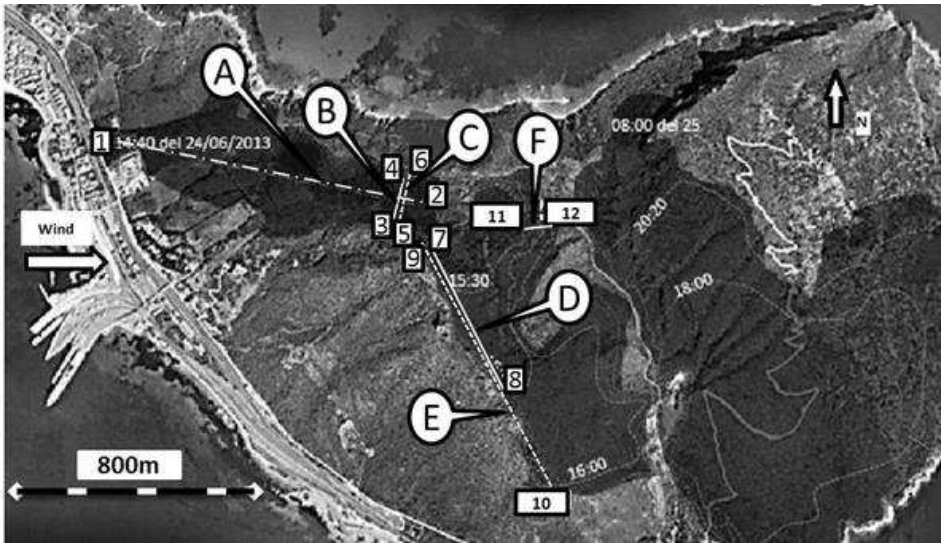

Figure 5. Spread of fire of Golfo Aranci in Sardinia, on the 24th June 2013.

By the analyses of the isochrones represented by the white lines and consequently of the fire perimeters defined at 14:40, 15:30 and 16:00 the rate of spread of the main fire front in side A, that is designated as R_{1A} was estimated. This calculation was based on the measurement of the length of line A located between points 1 and 2. The rate of enlargement of the fire front in side A, R_{3A}, corresponds to the difference of lengths of the segments B and C divided by the lapse of time. Line B is defined between the points 3 and 4, and line C is defined by points 5 and 6.
The rate of enlargement in side B, R_{3B} was estimated by the analysis of the relative growth of line E in relation to line D in the lapse of the time. Line D is limited by the boundary points 7 and 8 and line E is defined by points 9 and 10.
Finally line F, defined by points 11 and 12 and corresponding to a downslope fire spread, was used to estimate the basic rate of spread for this fuel bed in the absence of slope and wind.

Results and Discussion

5.1. Fire Contours

The analysis of the fire contours obtained in each laboratorial test and the respective shapes for the 15 tests performed are presented in figures 6, 7 and 8. In these figures face *A* is below and face *B* is above. The values in the axis correspond to the actual dimensions of the hill model in meter. The ridgeline corresponds to the dotted horizontal line at 1.5m from the bottom. The wind is blowing from the bottom to the up of the figure.

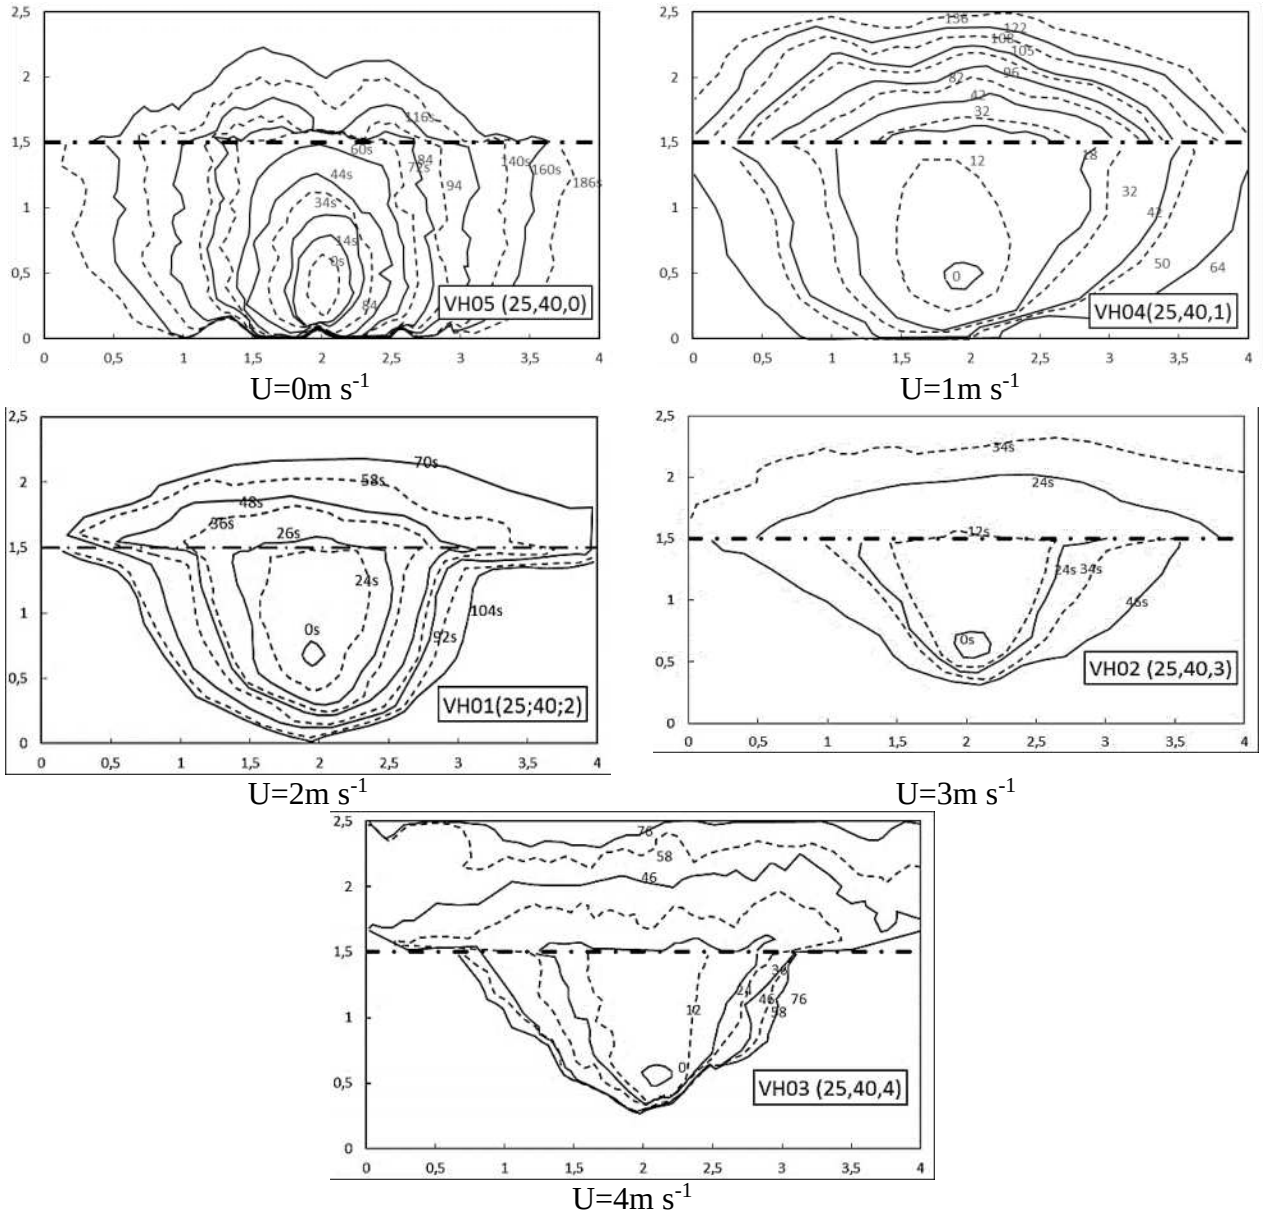

Figure 6. Fire line contours for tests with α_1=25º and α_2=40º for the indicated values of wind velocity.

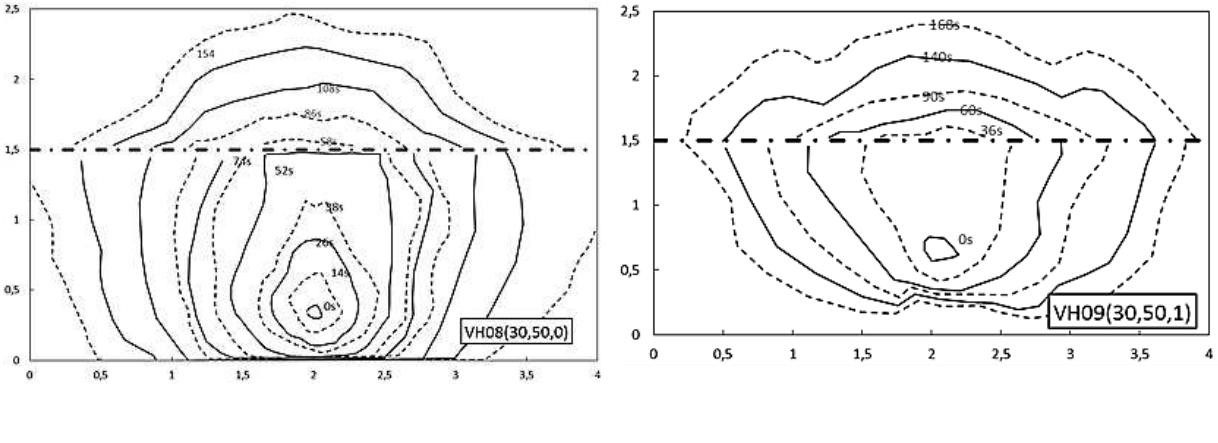

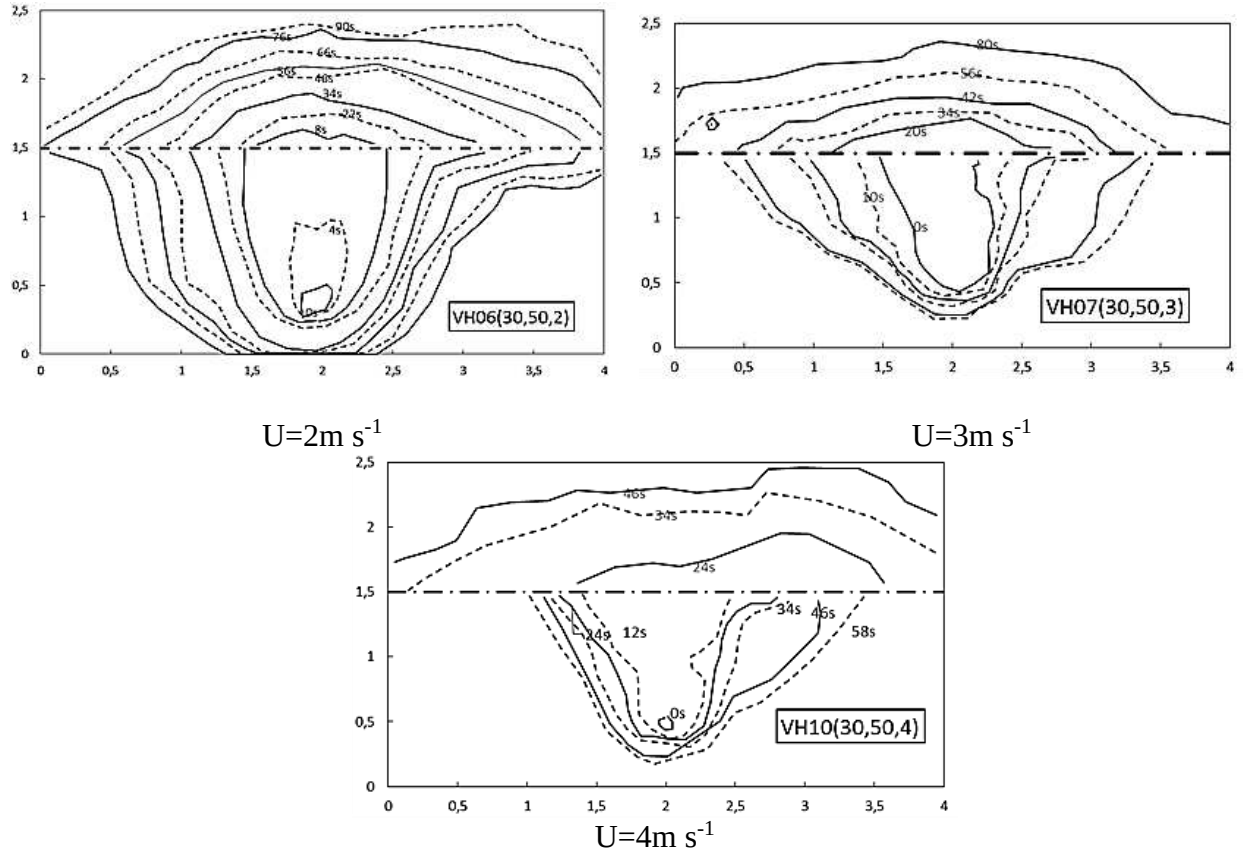

Figure 7. Fire line contour for tests with α_1=30° and α_2=50° for the indicated values of wind velocity

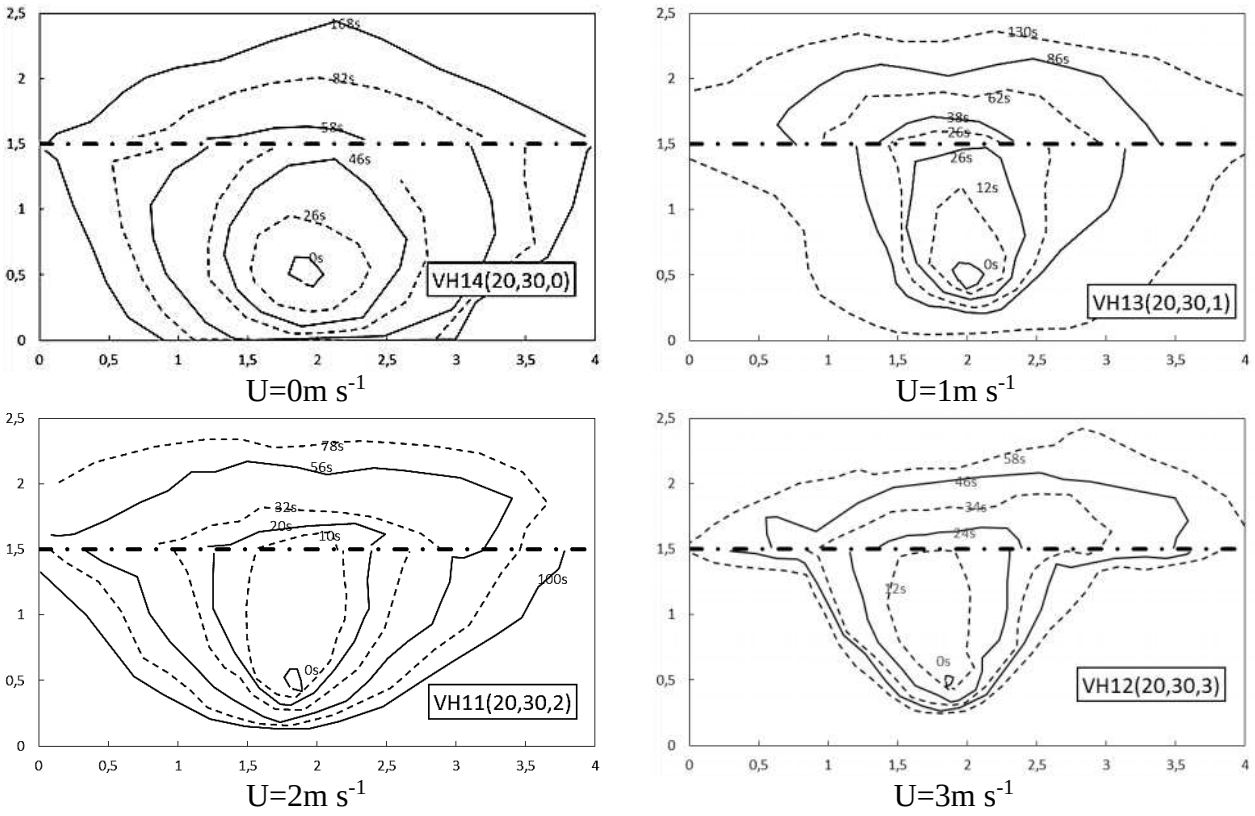

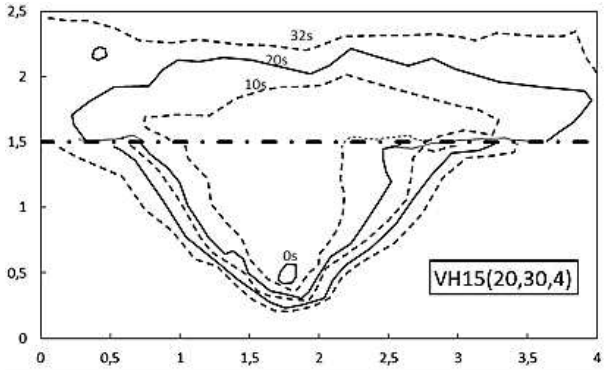

Figure 8. Fire line contour for tests with α_1=20º and α_2=30º for the indicated values of wind velocity

5.2. Rate of spread along wind direction

In Figure 9 the values of R'_{1A} show an increase approximately with the square of the reference flow velocity, but the dependence with slope angle α_1 is not clear. The data points corresponding to the real fires follow the same trend but with a different value of the reference wind velocity.

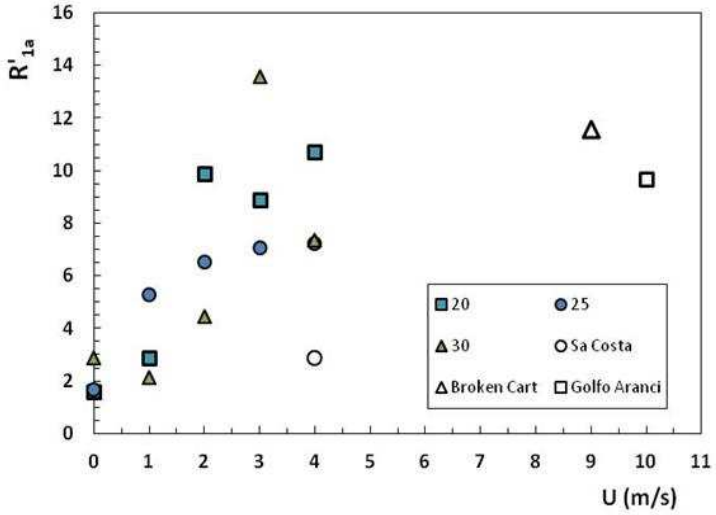

Figure 9. Evolution of **R'**$_{1A}$ *as a function of wind velocity for the three configurations tested and for Sa Costa, Broken Cart and Golfo Aranci Fires.*

As could be expected, the values of R'_2, shown in Figure 10, corresponding to the tail of the fire spreading downslope and with contrary wind, are quite low. These values are usually lower than 1.0 and tend to decrease with increasing wind velocity. In some cases it was observed that the fire would extinguish and fire spread ceased.

The values of R'_{1B}, corresponding to the average NDROS of the fire front descending the slope on face *B* with favorable wind, which are shown in Figure 11, show a practically linear increase with wind velocity with no marked dependence on the hill geometry.

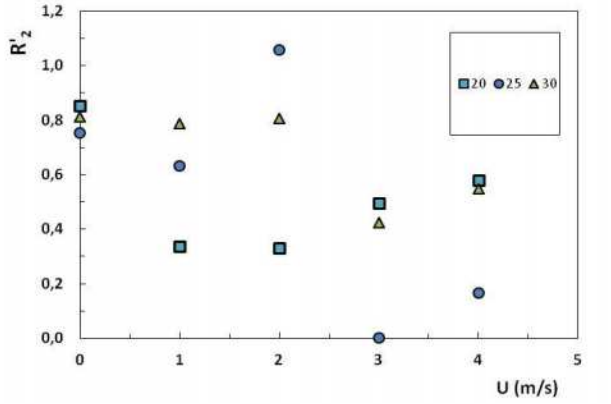

Figure 10. Evolution of **R'**$_2$ *as a function of wind velocity for the three configurations tested*

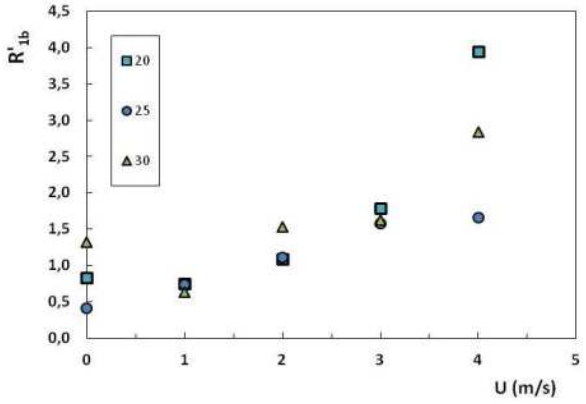

Figure 11. Evolution of **R'**$_{1B}$ *as a function of wind velocity for the three configurations tested*

5.3. Lateral Rate of spread

The analysis of lateral fire spread is of great interest in the context of the present work. In Figure 12 and 13 we show the results obtained for R'_{3A} and R'_{3B} respectively. As can be seen in Figure 10, the average rate of lateral growth of the fire on face *A* is relatively small and does not seem to depend very much either on the slope angle α_1 or on the flow velocity. The corresponding value of 2.6 for the Sa Costa Fire is within the range of our laboratory experiments.

The lateral growth of the fire in face *B* is performed with a NDROS R'_{3B} that is usually larger than R'_{3A} and shows a marked increase with flow velocity, with no clear dependency on hill geometry. The value of 4.26 for Sa Costa fire is slightly above our trend and seems to correspond to a slightly higher value of the reference wind velocity, possibly closer to 2.5ms^{-1}.

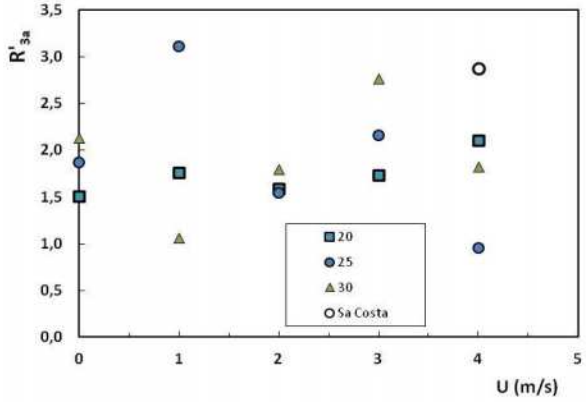

Figure 12. Evolution of **R'**$_{3A}$ *as a function of wind velocity for the three configurations tested. The point corresponding to Sa Costa fire is shown in the figure.*

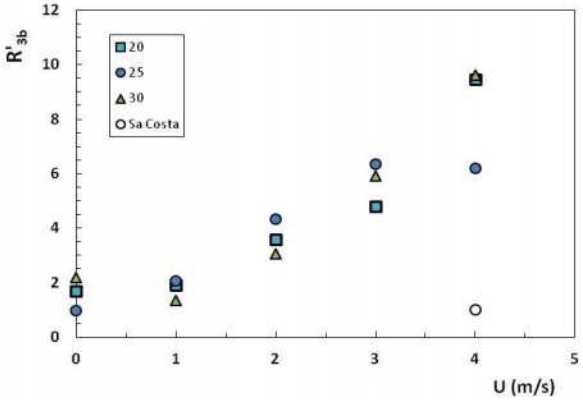

Figure 13. Evolution of **R'**$_{3B}$ *as a function of wind velocity for the three configurations tested. The point corresponding to Sa Costa fire is shown in the figure.*

5.4. Evolution of lateral fire growth ratio k$_3$

Parameter k_3, introduced in equation [7] provides a comparison between the rates of lateral growth of the fire in the windward and leeward faces of the hill (faces *A* and *B* respectively).

The evolution of k_3 as a function of wind velocity is shown in Figure 14. As can be seen, k_3 values increase with the square of *U* and exhibit only a small dependence on the hill geometry in the present set of test conditions. The values of k_3 obtained for the real fires are shown in Figure 14 as well. A good model to estimate k_3 as a function of *U* is obtained with the following equation:

$$k_3 = 1 + a_3.U^2 \qquad [8]$$

The values of coefficient a_3 and of the corresponding r^2 fitness parameter for each configuration and for the entire set of laboratory data, excluding two cases for which $k_3<1$, are given in Table 3. The value of a_3=0.041 obtained for the field cases is much lower than the average value obtained for laboratory experiments (a_3=0.256). This difference can be explained by the already mentioned difficulty in defining a reference velocity for tests in combustion tunnels and for field cases. The ratio between the values of a_3 for laboratory and field cases indicates that the field reference velocity is approximately 2.5 times larger than the combustion tunnel velocity. Assuming that the velocity profile near the ground is logarithmic, this is equivalent to considering that the wind tunnel velocity is measured at the height of 1.5m while the field reference wind velocity is measured at 10m height.

Table 3. Parameters of Model to estimate k_3 as a function of flow velocity

Case	a_3	r^2
α_1=20º; α_2=30º	0.217	0.972
α_1=25º; α_2=40º	0.321	0.850
α_1=30º; α_2=50º	0.230	0.894
All Laboratory Tests	0.256	0.859
Field cases	0.041	0.892

In our opinion, the result expressed by this model is quite relevant as it indicates that the relative rate of growth of lateral fire depends on the dynamic pressure that is proportional to the kinetic energy of the incident flow. This fact puts in evidence that the lateral growth of the fire is a consequence of the flow on the lee side of the ridge which is comprised of horizontal axis vorticity caused by flow separation at the ridge. Without disregarding the effects of the combustion energy added to the flow, this result shows clearly that the lateral growth of the fire is mainly a result of the vortex flow dynamics.

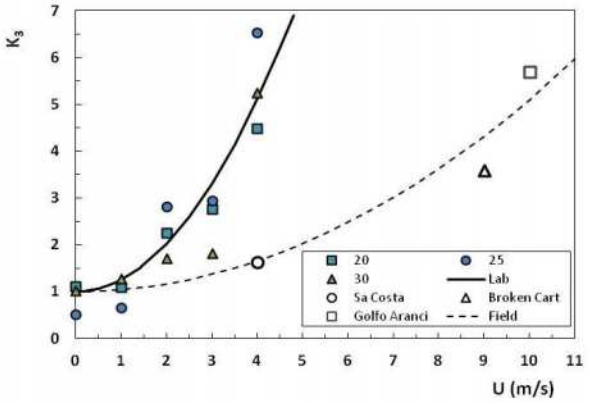

Figure 14. Evolution of k_3 as a function flow velocity for laboratory tests and for the real fires. The two lines correspond to the present model for laboratory and field cases.

Conclusion

The experiments discussed above demonstrate that the interaction of a fire with wind flowing in complex terrain can give rise to dynamic mechanisms that can enlarge a fire front near the top of a crest. In addition, the main direction of fire propagation is different to the expected direction of fire spread.

The authors intend to extend this experimental program considering other hill configurations and the influence of fuelbed composition on the lateral spread parameters. The influence of wind direction in relation to the ridgeline will be analyzed as well.

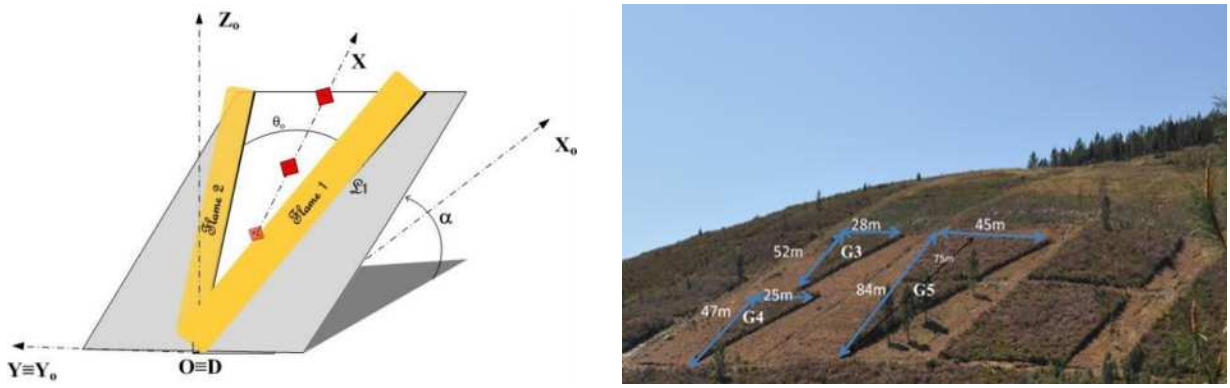
Abstract
The merging of two linear fire fronts intersecting at a small angle creates an accelerating fire that is designated as "jump fire", given the very high value of the rate of spread that it can reach in a relatively short time. In this work an analysis of the jump fire process based on laboratory scale, field scale experiments and large fire scale observation was performed. This confirmed that independently from the scale of analysis the fire in this condition follows the same behaviour pattern that is due to the fire geometry and to the associated heat transfer mechanisms that induce the phenomenon of a quick acceleration followed by a deceleration phase. S type pitot tubes were used to study the flow pattern inside or near the fire front to better understand the mechanisms of fire induced convection given its very important role in these fires.

Keywords*: Forest fire behaviour; Jump fire; Merging fire; Dynamic effect; Extreme Fire*

Introduction
The concept of "jump fire" behaviour associated to the merging of two linear fire fronts that intersect at a point making a small angle between them as was introduced in Viegas *et al.*, (2012, 2013) with a conceptual model of energy release by the fire front, mainly by radiation was proposed to justify the very rapid decrease of a reference rate of spread (ROS) that was observed in laboratory scale tests performed with horizontal fuel beds. In the present study the previous work is extended to consider the effect of slope, various types of fuels, and different fire dimensions. A comparison of the results obtained at laboratory scale with the tests performed at field tests in the Lousã Mountain and also with the case of a very large forest-fire that occurred in Canberra in 2003 was made.

Experimental Study

Physical problem
We consider two linear fire fronts that intersect at point *D* and making an angle θ_o between them spreading on a uniform fuel bed making an angle α with the horizontal. The axis *OX* is assumed to be a symmetry line of the fire (figure 1a)). Particular attention is given in this study to the displacement of the intersection point *D* of the two fire lines that has a velocity or rate of spread *R*. In order to generalize our results we use the reference basic ROS R_o of a linear fire front in the same fuel bed in the absence of slope or wind, to define the non-dimensional ROS $R'=R/R_o$.



a) *b)*

Figure 1. a) Schematic representation of the problem. b) View of the plots burned at the field tests of jump-fire in Gestosa.

The configuration of the fuelbed is shown in figure 1 schematically for the laboratory and for the field tests respectively. In all tests the fuelbed had a triangular shape with an angle θ_o=30º and the fire front was initiated along the two large sides of the triangle (indicated as Flame 1 and Flame 2 in figure 1a). A large set of tests on the scope of jump fires was performed both at laboratory and at field scale. From these tests some were selected for the present work including a case study of the Canberra 2003 fire. The main parameters of the cases that are considered in this paper are given in Table 1.

Laboratory Experiments

Laboratory experiments were carried out at the Forest Fire Research Laboratory of the University of Coimbra using the table DE4 that has a useful area of 6x8 m^2 with a slope (α) that can be varied in the range of 0º to 40º.

The methodology used is similar to the one described in Viegas *et al*. (2013) with the addition of flow velocity measurements using S type pitot tubes placed along OX axis at 1, 3 and 6m from point *D* as indicated in figure 1a). The measured properties were temperature, pressure and heat flux. The measurement of the temperature was made with a multi-point system of 25 K type thermocouples, connected to a NI cDAQ-9174 that allows a synchronous data-logging. This 25 thermocouples (TC) were placed in a beam coincident with the OX axis. The position of each thermocouple is known and the gap between thermocouples is constant of 20cm the rate of acquisition was of 1Hz. For a spatial

distribution of the temperature along the fuel-bed infrared images from each experiment were recorded, using an infra-red camera FLIR ThermaCam SC640 The acquisition rate was also 1Hz. In both methods the presence of the fire front was considered for values of temperature above 350ºC that was considered as sign of the existence of flame in the place or time of measurement. Using IR methodology the position of the fire perimeter at given time frames was assessed and from these images the ROS at various positions of the fire perimeter namely at point D were measured. Using the thermocouples and knowing time interval required for the fire to travel from one position to the next the ROS of the fire along OX axis was measured as well. Besides this all the tests were recorded by a Sony high definition video camera and temporized shots were also taken with a Cannon photographic high performance digital camera.

The flow velocity was measured at three different points along OX axis at 1m, 3m and 6m from the origin, with pitot tubes designated respectively P1, P2 and P3. The pitot tubes used were type S specially designed for the purpose as they are indicate to perform measurements inside dirty and high temperature flows. The pitot were placed along the centre line at the high of 15cm from the ground so that the pitot was always above the fuel bed but inside the flame zone. Each pitot was connect by pipes to a differential pressure transducer Gems 5266-50L Very Low Range Differential Pressure Transmitter. These transducers were connect to a multifunctional NI 6009-DAQ that made the data-logging of the signal also with a frequency of 1Hz. With the data collected by this method using the values of synchronous temperature measurements by the application of a calibration it was possible to estimate the flow velocity induced by the fire phenomena.

2.3. Field Experiments

The field tests were performed in Gestosa, Lousã, with *V* shaped plots with dimensions indicated in figure 1 b). The plots were prepared cutting shrub vegetation with height varying between 0.5 and 1.2m using mechanical tools in order to give the plots the desired shape. The average slope of these plots is 30º and the initial angle between the fire fronts was 30º. In order to assure a simultaneous ignition of the two fire lines along their entire length pyrotechnics devices were used. Due to the presence of lateral wind during the experiments full symmetrical conditions were not obtained. During these tests infrared and visible range images were recorded to allow fire spread analysis. Thermocouples were disposed along the central axis of the plots to measure the temperature evolution and consequently the rate of spread in the centre line as in the laboratory experiments. The real case occurred during the merging if two large fires in the vicinity of Canberra in January 2003, that are documented in Doogan (2006), creating a very intense jump-fire phenomenon. In mid-afternoon of the 18th January 2003 the flanks of Bendora and McIntyres large fires merged on undulating ground covered by grass, shrubs and groups of tress under a strong wind of the order of 25m/s. The merging of these fires developed very rapidly towards Canberra and even produced a tornado near one of its flanks. More details on this fire can be found in Sharples *et al.,* (2012).

Results and Discussion

3.1. Effect of fuel bed slope

In Figure 2 the dimensional rate of spread ROS for three different slope angles 0º, 20º, 30º and 40º with fuel bed of dead pine needles of Pinus pinaster is plotted as function of time t. As it is typical for the jump fire phenomena these tests show a pattern of behaviour that involves a sharp acceleration in its initial phase until the peak velocity is reached and afterwards it decreases reaching relatively low values.

The analysis will be mainly focused in speeding up phase of the fires. The deceleration phase was already considered in Viegas *et al*. (2012) but needs to be more investigated. Although some observations and comments on this phase are made here its more detailed analysis will be the scope of future work.

As can be seen in figure 2 for α=0º the acceleration phase lasts less than two seconds and therefore it is not captured with the experimental methodology that was used. Forα=20º this phase lasts about 12 seconds and therefore can be clearly picked up in our laboratory experiments. The same happens for α=30º and 40º for which the acceleration phase takes about 22.5 and 15.1 seconds respectively. The peak ROS value also increases with slope angle. In these tests the following maximum ROS values were observed: 7.7cm/s, 15.4cm/s, 22.5cm/s and 39.4 cm/s for α=0º, 20º, 30º and 40º respectively. It is interesting to notice that on the contrary the deceleration phase duration decreases with slope angle except for the case of α=40º here no deceleration phase was recorded. In these experiments the following values were registered for the duration of the deceleration phase: 300s, 60s and 5s for α=0º, 20º or 30º respectively.

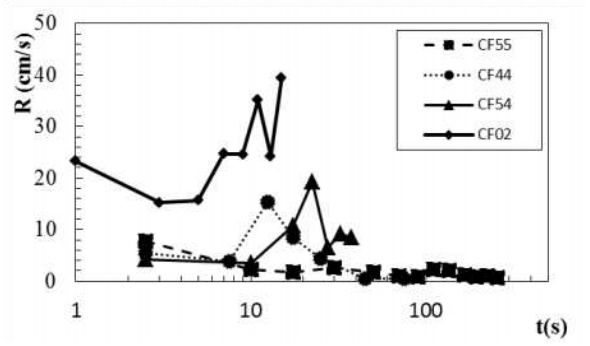

Figure 2. Plot of the Dimensional rate of spread R as function of time t for three different slope angles 0º; 20º 30ºand 40º with fuels

The change of jump fire behaviour from an accelerating ROS to a deceleration indicates that this phenomenon is based on the shifting of the main physic heat transfer processes of convection and radiation. Convective flows generated by the interaction of the fire fronts that are developed during the fire front evolution play a major role in the acceleration phase but there seems to be an opposing effect due both to convection and radiation (associated to the change of flame geometry) that stops the acceleration phase and produces the deceleration phase that seems to be mostly related to this change of flame geometry.

Analysis of the fire acceleration phase

The phase of sharp acceleration can be interpreted at the light of the concept of dynamic fire behaviour due to the feedback between the fire and its surrounding flow proposed in the model to predict eruptive fires presented in Viegas (2006). According to this model the time involved in the acceleration of a pint source fire front in a slope or canyon is associated to a characteristic time of each fuel bed. This time is related to the residence time of the combustion in the fuel bed and therefore it is large for heavier fuels. The special configuration of the jump fire create similar effects due to the heat transfer processes associated to the phenomena particularly to the role of convection in this phase. In spite of this similarity it was realised that contrary to eruptive fires in jump fires the increasing phase has a limit of growth.

In order to better interpret the problem the use non-dimensional parameters based on selected reference parameters is adopted. This method is also required to overcome the problem of scale and allows the application of results of laboratory scale tests to full size experiments or even to real fires with much larger dimensions.

To describe the evolution of ROS in the course of time the non-dimensional parameters *R'* and *t'* were used to present the results of both laboratory and field scale tests in figure 3. The non-dimensional value of $t'=t/t_o$ was evaluated following Viegas (2006) the residence time t_o that was measured in our tests were used. These values are given in Table 2.

Table2: Characteristic Residence time for the different fuels

Fuel	Residence time t_o(s)
Straw	42,81
Pine needles	54,21
Shrubs (lab.)	65,63
Shrubs (field)	286,00

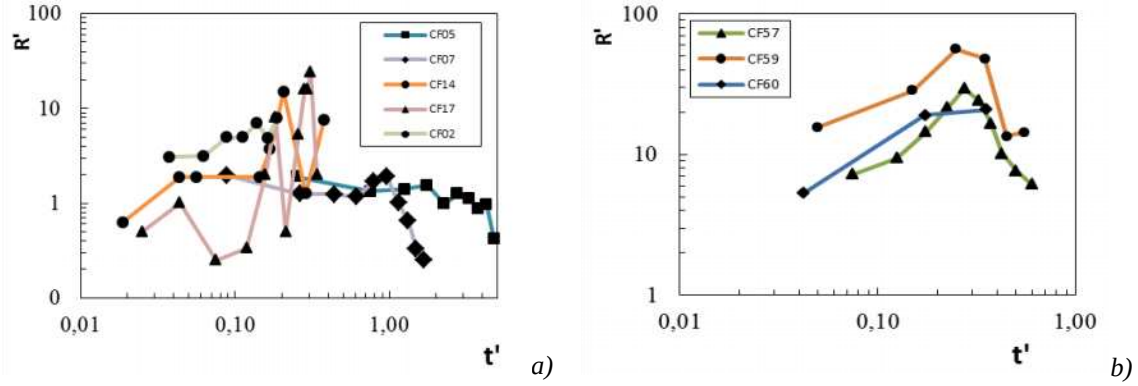

Figure 3. Evolution of non-dimensional rate of spread R' as function of the reference time t', for laboratorial tests a), field tests and the case of Canberra, Australia b).

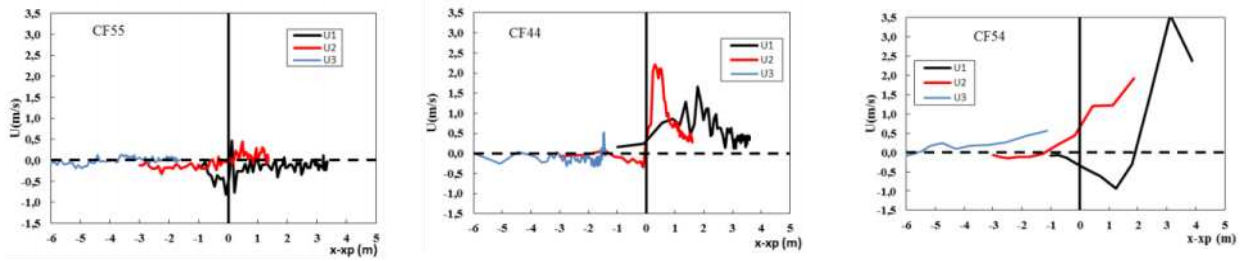
In figure 3 a) the values of *R*' for a set of laboratory experiments with *Pinus pinaster* needles were plotted as a function of *t'* for slope angle values of 0º, 10º, 20º, 30º and 40º, although this is not the same set of tests of figure 2 they are in agreement with the previous set. The peak values of *R'* are in the range between 3 and 25. The accelerating phase can be clearly observed in these tests for values of t'<0.3. The same trend that was referred above can be observed here: while for the case of α=0º the accelerating phase was not observed in the case of α=40º the deceleration phase is non-existent.
In figure 3 b) the corresponding results for two field tests and for the Canberra fire are shown. The similarity between figures 3 a) and 3b) is quite apparent in spite of the scales of the tests. The similarity can be observed both in the general form of the curves but also in the order of magnitude of the reference parameters like for example the peak values of R' and of the corresponding values of t'.

3.3. Flow analysis

In order to better assess and understand the role of convection induced by the fire during the speeding up process, results of sample flow velocity measurements are presented.
In figure 4 the horizontal flow velocity *U* (m/s) close to the fuel bed measured at each station is plotted as a function of the distance x-x_p of the fire front to the corresponding sensor for three values of slope angle. These figures put in evidence the complexity of the flow associated to fire evolution and of the rapidly changing character of the induced flow near the fire front. We observe periods of negative flow velocity (flow in the negative direction of OX axis), followed by periods of positive velocity. The negative flow velocity acts as a counter flow in relation to flame spread and it may explain the fact that the acceleration phase is limited. The positive or inflow flow velocity is observed mainly after the passage of the fire front and it is an indication of fire acceleration. This is more clearly observed in figure a c) for α=30º. In this case it is interesting to see that at pitot P1 placed 1m above the origin of OX axis the flow is negative after the passage of the fire and then reaches a very high positive peak, corresponding to the acceleration of the fire along the slope while at pitot P2 (x=3m) the flow is positive even before the fire reaches the pitot station.

The peak of the inflow velocity increases with α in correspondence to the increase of the maximum value of ROS.



a) b) c)

Figure 4. Flow speed U measured at three differents points along the center line placed at 1m (U1), 3m (U2) and 6m (U3) from point D, for three different slope angles a) 0º; b) 20º and c) 30º .

Conclusion

Analysis of the jump fire process based on laboratory scale, field scale experiments and large fire scale observation shows that in all cases the fire follows the same behaviour pattern that is due to the fire geometry characteristics of two convergent fire lines and to the associated heat transfer mechanisms that induce the phenomenon that is designated as jump-fire.
Taking into account the data presented it is possible to realize that the patterns of behaviour of the jump fires are very much dependent on the convective flows generated by this special way of burn. The complex geometry of jump fires give origin to unstable boundary conditions that will dynamically affect the fire spread both by convective flows and by radiative heat transfer processes that are greatly affected by morphisms in the fire fronts that occur in this phenomena in the course of time.
The S type pitot tubes appeared as important tools to analyse the flow pattern inside or near the fire front contributing to a better understanding of the mechanisms of this phenomenon given the very important role played by induced convection in these fires.
More research is necessary to be able to model the complex heat and mass transfer processes during a jump fire for arbitrary fuel and boundary conditions. The authors will develop an effort towards producing such a model to explain and predict the two phases of jump-fires.

Symbology

Symbol	Units	Description
α	-	Inclination angle
θ	-	Angle between the fire fronts
O	-	Origin of reference Cartesian system
D	-	Intersection point D of the two fire lines

X	-	Coordinate along reference OX axis
Xo	-	coordinate along reference horizontal axis OXo
Y	-	coordinate along reference OY axis
Yo	-	coordinate along reference horizontal axis OYo
Zo	-	coordinate along reference horizontal axis OZo
$\mathcal{L}_1$	-	Fire line 1
$\mathcal{L}_2$	-	Fire line 2
R	$cm.s^{-1}$	Rate of spread (ROS)
R_o	$cm.s^{-1}$	Basic rate of spread of linear fire in the absence of slope and wind
R'	-	Non-dimensional rate of spread (NDROS)
U_1	$m.s^{-1}$	Flow velocity measured by Pitot 1
U_2	$m.s^{-1}$	Flow velocity measured by Pitot 2
U_3	$m.s^{-1}$	Flow velocity measured by Pitot 3
t_o	s	Residence time
t'	-	Reference time
P1	-	Pitot station 1
P2	-	Pitot station 2
P3	-	Pitot station 3
PP	-	Fuelbed of Pinus pinaster dead needles
SH	-	Fuelbed of dead shrubs
IR	-	Infrared image
TC	-	Thermocouple

Abstract
In this work will be studied the application of the Mean Radiant Temperature method in the evaluation of radiative heat exchanges between a fire front and a group of firemen. The development and the application of the Mean Radiant Temperature method will be presented in this work.
The obtained results are used to analyse the protection made by firemen bodies in the others firemen in front a fire front. The obtained protection can be used in order to reduce the fire front radiative flux value that the firemen are subjected.
In this study will be used a numerical model, that evaluates the human and clothing thermal response, in steady-state and transient conditions. The software calculates not only the temperature field in the human body tissue, arterial and venous blood and clothing, but also the blood and tissue mass field in the human body and the water mass field in body skin surface and clothing.
This model considers the human body divided in 25 cylindrical and spherical elements, being each one sub-divided in 12 layers, which could be protected from the external environment through some clothing layers. The computational model of the human body and clothing thermal system is based on the energy balance integral equations for the human body tissue, blood and clothing as well as mass balance integral equations for the blood and transpired water in the skin surface and in the clothing. A thermoregulatory system model was adapted to control the human body tissue temperature.
The radiative heat exchange numerical model between a fire front and the firemen is based in the Mean Radiant Temperature method. This numerical model considers the view factors determination between the firemen bodies and the surrounding surfaces (fire front and environment) and between the occupants' section. In this calculus the grid generation around the firemen and in the fire front is used to evaluate the view factors.
In the numerical simulation, presented in this study, is considered a fire front, the floor, the environment and a group of firemen. The numerical model calculates the Mean Radiant Temperature, that a group of 9 firemen are subjected.

Keywords*: Fire Behaviour and Modelling, Human and Clothing Thermal Response, Mean Radiant Temperature Method, Numerical Simulation.*

Introduction

This study is a continuation of Conceição (2002), Conceição *et al*. (2006B) and Conceição and Viegas (2010). In the previous work the view factors between a firemen and the fire front was made, while in this work the numerical model considers the view factors determination between the firemen bodies and the surrounding surfaces (fire front, floor and environment) and between the occupants' section.
In Conceição (2002) the numerical model was used to study the fireman thermal sensation nearby a fire front. In the three analyzed situations, the radiant temperature, body skin and clothing temperatures and transpired sweat rate field were calculated. The more uncomfortable situation was verified when the fireman is localized in front to the fire central area and distanced 5 m from the flames, being the allowable exposure time, for a non-acclimatized subject with the warning criteria, of around 4.5 hours. During the fire extinction was suggested that the distance between the fireman and the fire front should be the highest possible. It was also suggested that the fireman should avoid being located in front to the flames central area.

In Conceição *et al*. (2006B) the numerical model, that simulates the human and clothing thermal responses, in steady-state and transient conditions, were used to study the fireman thermal sensation nearby a fire front. This numerical model was used to evaluate the thermal sensation that a fireman, equipped with special protective clothing, is subjected nearby vertical flames, with a height of 2 m and a length of 10 m. In this theoretical study the fireman was placed 5 m distanced from the flames and localized in front to the flames central area. The body and clothing temperatures, the radiant temperature, the heat and mass fluxes field and the comfort levels were calculated. The influence of the clothing thickness and the special protective clothing emissivity coefficient reduces, in the fireman thermal comfort sensation were analyzed. The theory used to evaluate the fireman thermal comfort was based in the extension of the PMV model. This extension, used in warm environments, combines the "static" PMV model and the adaptive model. The idea was to use the traditional PMV model, that considers the human body thermal balance, and the expectations verified in the adaptive model. It was verified that the Predicted Percentage of Dissatisfied people increases lightly when the clothing thickness increases and decreases when the special protective clothing emissivity coefficient reduces. In Conceição and Viegas (2010) the radiative heat exchanges between the fire front and two firemen was evaluated. In the radiative heat exchanges the Mean Radiant Temperature method, with correction, was applied. The Mean Radiant Temperature, the skin and clothing temperature and the Predicted Percentage of Dissatisfied people were evaluated. The fireman located behind was protected to the fire front by the fireman located in front. In accordance with the obtained results the radiant protection, promoted by the fireman located in from, with a Predicted Percentage of Dissatisfied people of 25.0 %, reduced the Predicted Percentage of Dissatisfied people, that the fireman located behind is subjected, for 18.1 %.

Physical Model

In the numerical program the human body is divided in 25 cylindrical or spherical elements: the head, the neck, the trunk divided in three, the arms divided in four, the hands, the legs divided in four and the feet. Each element is sub-divided in 12 cylindrical or spherical layers (1 in the core, 2 in the muscle, 2 in the fat and 7 in the skin) and could be still protected of the external environment through several clothing slices. The main arteries and veins and the capillary blood system is also considered in this work.
In the methodologies used in view factors determination each human body element or surrounding surfaces, with inclinations, dimensions and temperatures equal to the respective body or surrounding section, are divided in infinitesimal areas.
In the radiation by long wave phenomena calculus are also considered the shading effects that the body elements surfaces promote in each element.

3. Mathematical Model

The human body thermal system is based on the energy and mass balance integral equations:

- The energy balance integral equations are developed for each tissue slice and for the arterial and venous blood, of each human body element;
- The mass balance integral equations are developed, in each element, for the blood and for the transpired water in the skin surface.

To simulate the clothing thermal system are also developed energy and mass balance integral equations:

- The energy balance integral equations are developed for each clothing layers, in each element;

- The mass balance integral equations are developed for the clothing layers and for the adsorbed/desorbed water vapour in the clothing fibber layers.

The thermoregulatory system, used in the control of the human body temperature, is constituted by (see Stolwijk, 1970):

- heat transport from internal to external tissue;
- heat loss by evaporation;
- additional heat through shivering.

More details about the numerical model are presented in Conceição (2002), Conceição *et al*. (2006A), Conceição *et al*. (2006B), Conceição and Lúcio (2010) and Conceição *et al*. (2010).

Mean Radiant Temperature

The radiant heat exchanges by long wave phenomena are calculated, in this work, using the Mean Radiant Temperature method (Fanger, 1970), with correction (see Conceição and Lúcio (2010). The Mean Radiant Temperature model, presented in Fanger (1970), considers, only, the heat exchanges by radiation between the human bodies sections and the surrounding surfaces. The Mean Radiant Temperature used the view factors calculated between the human body sections and the surrounding surfaces and the surrounding surfaces temperature.
The Mean Radiant Temperature method, developed in this work, considers:

- the heat exchanges between the human body sections and the surrounding surfaces, namely the fire front, the floor and the environment;
- heat exchanges between the human bodies sections of each occupant;
- heat exchanges between the human bodies sections of different occupants.

The Mean Radiant Temperature method, that also considers the view factors correction, calculates, step by step, the Mean Radiant Temperature, using the human body and surrounding surfaces temperatures, calculated in each iteration, and the pre-calculated view factors.

Results and Discussion

In this work the radiant heat exchanges that 9 firemen are subjected nearby vertical flames, with a height of 4 m and a length of 10 m, is evaluate. In this theoretical study the firemen, placed in front to the fire front, are distanced 4, 5 and 6 m front to the flames central area. In this study the Mean Radiant Temperature, the body and clothing temperature field, that 9 protected fireman are subjected, are evaluated.
The obtained results are used to analyse the protection made by firemen bodies in the others firemen in front a fire front. The obtained protection can be used in order to reduce the fire front radiative value that the firemen are subjected.
In figure 1 the grid generation in the 9 firemen, in the ground, in the environment and in the fire front is presented, while the figure 2 the detailed grid generation in the 9 firemen is presented. The location of the fireman and the flame is also presented in the same figure.
In the grid generation is considered that the surroundings surfaces are divides in 100 elementary surfaces and that each human body sections surface is divided in 68 elementary surfaces. The increase of the elementary surfaces number the computational time increase substantially, while the reduction of the elementary surfaces number the approximation of the view factors is bad.
In the view factors determination, used to evaluate the Mean Radiant Temperature, are considered 9 occupants divided in 25 cylindrical or spherical human bodies sections, namely the head, the neck, the trunk divided in three, the arms divided in four, the hands, the legs divided in four and the feet.

In each human body section are calculated:

- 6 view factor for each surrounding surface (1350 view factor);
- 25 view factors between each human bodies sections of each occupant (5625 view factor);
- 25 view factors between each human bodies sections of different occupant (50625 view factor);

Thus, in general, the total view factors calculated is 57600. However, in each view factors determined between one human body and one plan 6800 calculations is made, while in each view factors determined between two elements 4624 calculations is made.
The Mean Radiant Temperature is presented in figures 3. In the Mean Radiant Temperature evaluation is used the surface temperature field and the view factor between the human body sections and the surrounding surfaces.
The surrounding and firemen temperature is evaluated:

- In the surrounding temperature field the fire front, floor and environment temperature are introduced in the numerical model;
- In the firemen temperature field the human body sections temperature is calculated in the numerical model.

The view factor between the human body sections and the surrounding surfaces is evaluated:

- the view factor between the human body sections and the surrounding surfaces, namely the fire front, the floor and the environment;
- the view factor between the human bodies sections of each occupant;
- the view factor between the human bodies sections of different occupants.

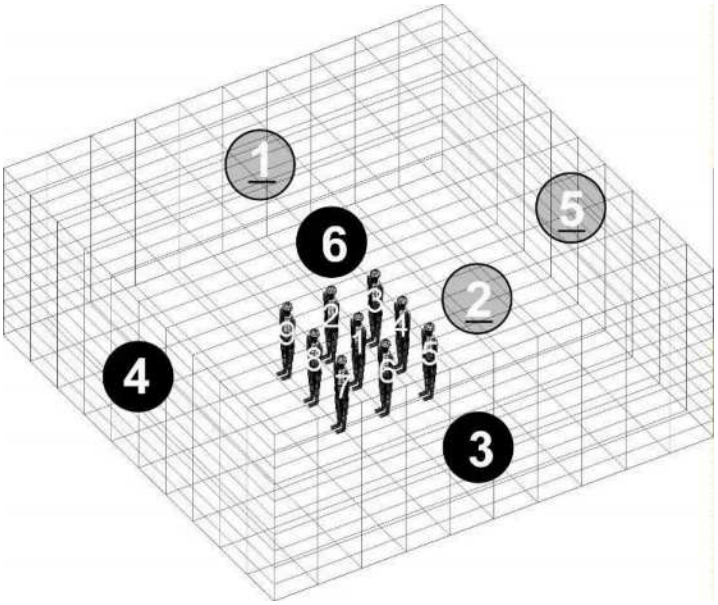

Figure 1. Grid generation in the 9 firemen, in the ground, in the environment in the fire front. Surface 4 are associated with the fire front, surface 2 are associated with the floor and the others surfaces are associated with the environment.

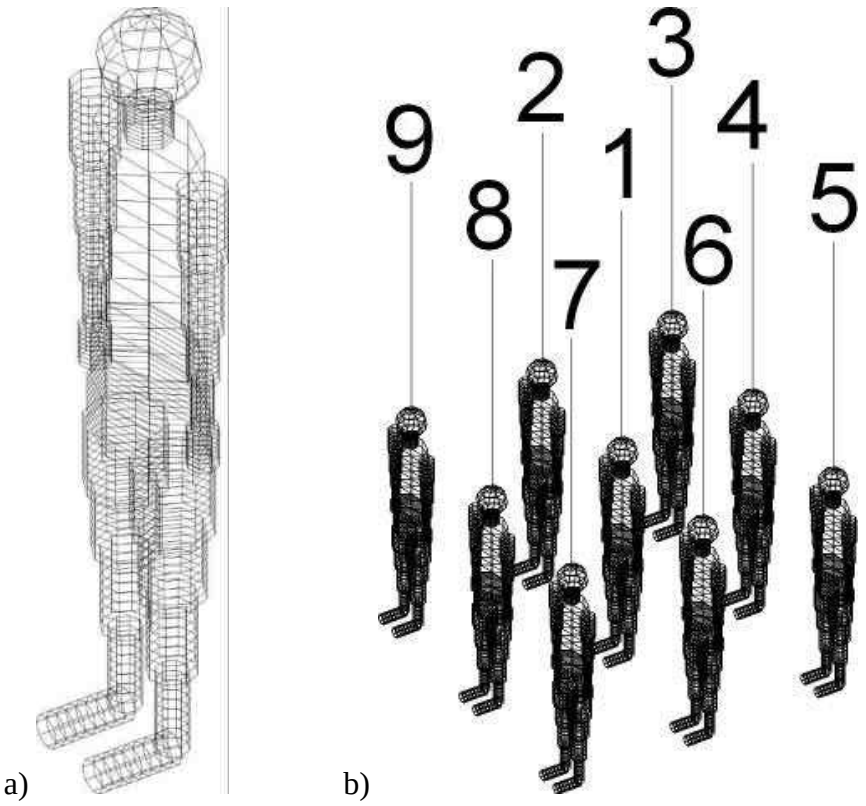

Figure 2. Grid generation around a fireman a) and around a group of firemen b).

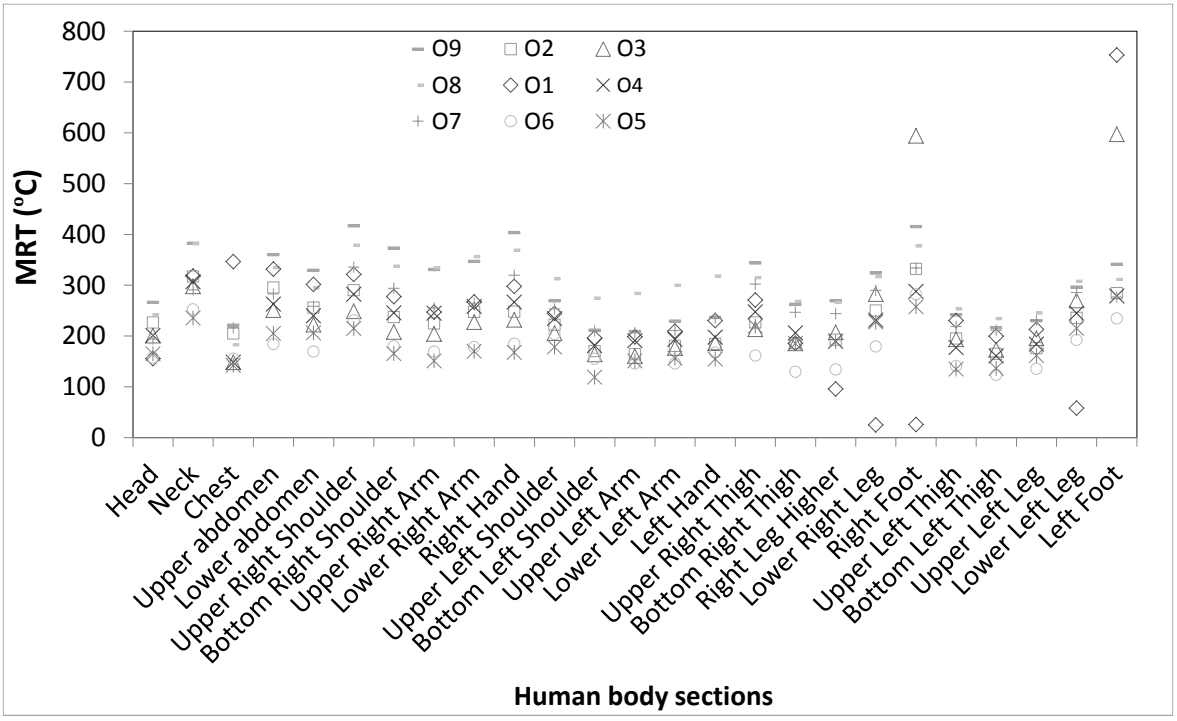

Figure 3. Mean Radiant Temperature.

In accord to the obtained results, is verifying that:

- In general, the highest Mean Radiant Temperature is verified in firemen located in the front of the group and the lowest Mean Radiant Temperature is verified in firemen located in the

behind of the group. This fact is associated with the protection that the fireman located in front promote in the fireman located behind and due the distance between the fire front and the fireman is highest for the fireman located behind;
- However, in some firemen sections, as example in the foot, the previous conclusions are not verified;
- In general, the protection made by the firemen posture, located in front, is higher than 150 ºC (Mean Radiant temperature).

Conclusions

In this work is studied the application of the Mean Radiant Temperature method in the evaluation of radiative heat exchanges between a fire front and a group of 9 firemen placed in front of the fire front. The obtained results are used to analyse the protection made by firemen bodies in the others firemen in front a fire front. The obtained protection can be used in order to reduce the fire front radiative value that the firemen are subjected.

The Mean Radiant Temperature evaluation, used to evaluate radiative heat exchange between the firemen and the surrounding surfaces, is evaluated fiction to the view factors between the firemen body section and the surrounding surfaces and the surrounding surfaces temperature. In accordance with the obtained results, in the view factor determination, the increase of the elementary surfaces number the computational time increase substantially, while the reduction of the elementary surfaces number the approximation of the view factors is bad.

In general, the highest Mean Radiant Temperature is verified in firemen located in the front group and the lowest Mean Radiant Temperature is verified in firemen located in the behind group. In general, the protection made by the firemen posture, located in front of the fire front, is higher than 150 ºC (Mean Radiant Temperature)

Abstract
A new method to customize Fire Behaviour Fuel Models was developed by linking Genetic Algorithms (GA) to the Rothermel's equation implemented in the Rothermel package for R. GA randomly generates solutions of fuel model parameters to form an initial population. Each solution is validated against observations of fire rate of spread (ROS) via a goodness-of-fit metric (i.e., RMSE). The population is then selected for its best members, crossed over, and mutated within a range of fuel model parameters space, until fitness is maximized. We tested the performance of GA-optimization against custom fuel models calibrated in two previous studies in grass and shrub fuels. GA was constrained using fuel parameters ranges reported in the selected studies, and was fit against the published ROS measurements. We compared goodness-of-fit (RMSE; R2adj) of fuel models calibrated by GA against that of the original studies. GA improved the fit of Rothermel's model for both studies: RMSE decreased from 5.5 to 4.6 m/min and from 6.9 to 5.4 m/min, respectively for grass and shrub fuel models. R2-adj increased from 0.83 to 0.84, and from 0.73 to 0.83, respectively. We then ran GA-optimization to calibrate a Calluna heaths fuel model against ROS and environmental data measured under experimental conditions. We obtained ranges of fuel model parameters (fuel load; fuel structure) by a field survey in both experimental plots and other Calluna sites of North-West Italy. Ranges of fuel flammability parameters were derived from the literature. We divided fire experiments into a calibration and a validation dataset (20 ROS each) and ran GA-optimization on the calibration dataset to customize the Calluna fuel model. We predicted ROS in the validation dataset by running the Rothermel modelon each of the following fuel models: i) GA-optimized fuel model; ii) the Standard Fuel Model which minimized RMSE against observations; iii) custom fuel models for Calluna heaths, parameterized using modal values from the overall fuel inventory, or inventoried at each experimental plot. Predictions of the Rothermel model reformulation implemented in FCCS, using as input modal values at the vegetation complex or at plot scale, were also evaluated. ROS predictions obtained by GA-optimized fuel model against the calibration dataset had a RMSE of 1.66 m/min and R2-adj of 0.96. When tested against the validation dataset, GA-optimized fuel model produced the lowest prediction error of all the alternative fuel models (RMSE = 1.74 m/min R2-adj = 0.90). FCCS predictions produced RMSE= 3.76 and 2.24 m/min, respectively using modal values from the fuel complex or at the plot scale, and R2-adj= 0.86 in both cases. GA-optimization provided an objective and accurate calibration of custom fuel models. It can be implemented in several fire prediction systems based on the Rothermel model, including the Rothermel package for R. Increasing the range of fuel model parameters beyond the measured values (e.g., +25%, +50%) can further improve GA model performance. However, this raises the question on how far apart from the field truth a fire behaviour fuel model should be stylized.

Keywords*: custom fuel model, optimization, fire rate of spread, prescribed burning, wildfire*

Introduction

Rothermel's model (Rothermel 1972) is the primary surface fire spread model of many fire prediction systems (Sullivan 2009; Finney *et al*. 2011; Andrews 2013). In the Rothermel model the forward rate of spread of a surface fire (ROS) is predicted as a function of topography, fire weather and a "fire behaviour fuel model" (hereafter: fuel model) that consists of a number of fuel parameters for a given fuel complex (Albini 1976; Burgan and Rothermel 1984). Standardized fuel models have been developed to facilitate the prediction of ROS (Anderson 1982; Scott and Burgan 2005). However, using standard fuel models can result in poor predictions and this has prompted the need to develop custom fuel models (Cruz and Alexander 2013). Customizing a fuel model is an iterative process of

comparing predictions to observed fire rate of spread, and subjectively adjusting the fuel model parameters until a satisfactory result is achieved (Burgan 1987). However, due to complex relationships in Rothermel's model, it is not always easy to guess how changes in fuel parameters will affect the fire behaviour prediction (Burgan and Rothermel 1984).
Optimization methods, which explore many possible combinations of fuel model parameters, showed the best solution for calibrating custom fuel models in previous studies (Cruz and Fernandes 2008). However, there are no standard methods or published codes for running an automated optimization of a custom fuel model against observed/expected fire rate of spread.
Genetic Algorithms (GA) (Holland 1975) have been used to calibrate models in several fields (e.g., Wang 1991), including fire science (Finney 2004; Lautenberger *et al*. 2006; Wendt *et al*. 2013). However, an optimization of fuel model parameters using GA has not been attempted yet. GA is a search heuristic which generates numeric solutions to an optimization problem using techniques inspired by natural evolution (e.g., mutation). During GA, many solutions are randomly generated to form an initial population. Each solution is validated against the observations via a user-defined metric of goodness-of-fit. The population is then selected for its best members, crossed over, and randomly mutated within a range of parameter space, until fitness is maximized.
The study objectives are: i) to test a fuel model calibration method based on GA; ii) to implement the GA-optimization method to calibrate a fuel model for *Calluna* heath vegetation.

Methods

GA-optimization testing

To predict the forward rate of spread at the head of a surface fire (ROS), we used Rothermel's equation implemented in the *ros ( )* function of the Rothermel package for R[1] (Vacchiano and Ascoli 2014). To test GA-optimization, we searched for studies with the following characteristics: i) a published dataset of observed ROS, including fuel moisture, wind speed and slope steepness associated to each observation; ii) custom fuel model parameters calibrated using the ROS dataset; iii) inventory and laboratory fuel data from which to infer ranges of fuel model parameters to force the GA-optimization (Table 1, columns A-B); iv) ROS predictions using the same equation implemented in the Rothermel package for R (corrections to original the equation as implemented in BehavePlus). Following these criteria, we found suitable data for both grass (Sneeuwjagt and Frandsen 1977) and shrub fuels (Van Wilgen *et al*. 1985).
GA-optimization was carried out using the *GA* package for R (Scrucca 2014). GA were run with 9999 maximum iterations, a mutation probability of 0.1, and elitism of 0.05 (i.e., the 5 best solutions are retained at each simulation). As a fitness metric, we chose the root mean square error (RMSE) of observed vs. predicted ROS. Then, we compared goodness-of-fit (RMSE; R^2adj) of GA-optimized fuel models against the calibration methods used in selected studies, while keeping constant the fire environment (i.e., fuel moisture; wind speed; slope).

Heathland fuel model calibration

We implemented the GA-optimization to calibrate a custom fuel model for *Calluna* dry heathlands against ROS and fire weather data recorded under experimental conditions (Ascoli *et al*. 2013; Vacchiano *et al*. 2014). We measured ROS in nine wind-driven field fire experiments using a microplot approach (Simard *et al*. 1984; Fernandes *et al*. 2001). We discarded data recorded during the acceleration, backfire and flank fire phases, retaining a total of 40 ROS observations ranging between 0.9 and 26.3 m/min. Environmental variables (min-max) were as follows: ignition line length = 25-50 m; fire plot size = 1250-4000 m^2; 1h fuels moisture = 10-27%; live woody fuel moisture = 50-70%; wind speed = 0.4-7.9 km/h; slope = 0%.

We obtained ranges of fuel model parameters (Table 1, column C) related to fuel load (1-h, 10-h, 100-h, Live Herb, Live Woody) and structure (Fuel Bed Depth) by a field survey in both fire experiment plots and additional *Calluna* stands in North-West Italy (twelve stands x 6 obs.). Ranges of fuel flammability parameters (SA/V, Moisture of extinction, Heat content) were derived from published datasets and laboratory studies. The fuel model was conceived as Dynamic.

We divided fire experiments into a calibration (four experiments, 20 ROS obs.) and a validation dataset (five experiments, 20 ROS obs.). We ran GA-optimization using the same setting as for the test analysis. Then, we predicted ROS in the validation dataset by using the *ros ( )* function of the Rothermel package for R, and compared goodness-of-fit (RMSE; R^2adj) of predictions obtained by the following fuel models: i) GA-optimized fuel model; ii) the Standard Fuel Model which minimized RMSE against observations, as determined by the *bestFM ( )* function of the Rothermel package (Vacchiano and Ascoli 2014); iii) a custom fuel model for *Calluna* heaths, parameterized with modal values from the overall fuel inventory (72 obs.); iv) a custom fuel model parameterized with modal values from fuels inventoried in each fire experiment plot (6 obs. per plot). Predictions of the Rothermel's model reformulation implemented in the Fuel Characteristics Classification System (FCCS) (Sandberg *et al*. 2007), using modal values at the vegetation complex or at plot scale, were also evaluated.

Results and discussion

GA-optimized fuel models improved the fit of Rothermel's model for both grass and shrub tests, relative to the published fuel models. RMSE decreased from 5.35 to 4.32 m/min and from 7.18 to 5.45 m/min, respectively. R^2-adj increased from 0.83 to 0.84, and from 0.73 to 0.83, respectively.
In heath fire experiments, ROS predictions obtained by GA-optimized fuel model against the calibration dataset had a RMSE of 1.66 m/min and R^2-adj of 0.96. When tested against the validation dataset, GA-optimized fuel model produced the lowest prediction error in comparison to all the alternative fuel models (Figure 1).

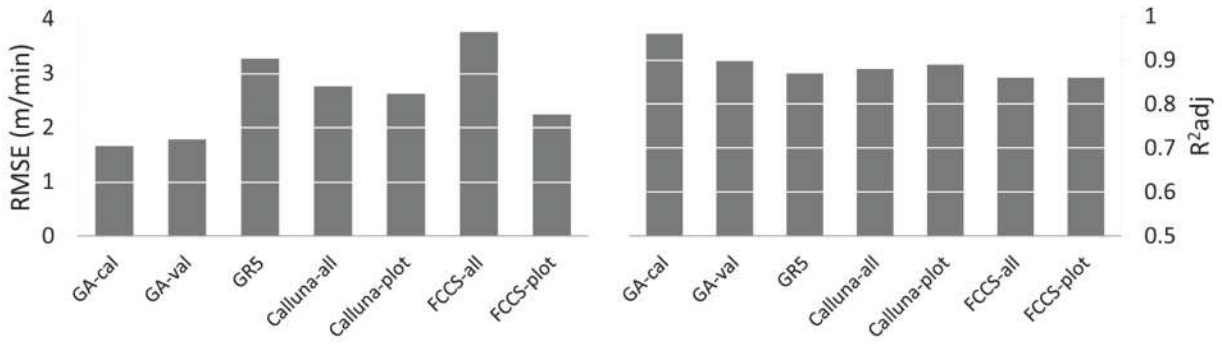

Figure 1. RMSE (left) and R^2adj (right) values for alternative fuel models predictions against the validation dataset

In accordance with previous studies, our results confirms the usefulness of calibrating a custom fuel model to improve Rothermel's model prediction, rather than limit its use to the set of Standard Fuel Models (Cruz and Fernandes 2008). Given the relative homogeneity of fuel conditions in heath vegetation at the study site, our results show that site-specific fuel parameters assessed at the plot scale did not improve predictions of Rothermel's model. However, when using variables measured at the plot scale, FCCS performance was second only to GA. This supports the potential of Rothermel's model reformulation embedded in FCCS, which aims to improve ROS predictions by using modal values of measured plots, bypassing the need to calibrate a stylized custom fuel model (Sandberg *et al*. 2007).
GA-optimization provided an objective and accurate calibration of custom fuel models. It can be implemented in several fire behaviour prediction systems based on Rothermel's model, including the Rothermel package for R. Increasing the range of fuel model parameters beyond the measured values (e.g., +25%, +50%) can further improve GA model performance (analysis not showed). However, this raises the question on how far apart from the field truth a fire behaviour fuel model should be stylized.

Abstract
The process of radiative ignition from wild land flames is studied using a simple heat transfer model. For vertical flames (no wind and no slope effects), it is found that the fuel ignition time increases exponentially with distance, which reveals the existence of a characteristic length above which no ignition occurs. The influence of flame size and fuel moisture content on this length is examined. For distances from the flame much smaller than the characteristic length, the ignition time is found to be independent of the moisture content. The existence of such a characteristic length is of major concern for studying percolation-like spread/non spread transition.

Keywords*: Wild land flame radiation, characteristic length, ignition.*

Introduction

Propagation/non-propagation transition threshold is possible only for finite mean free paths [1]. A finite path length is induced by an exponentially decreasing connection probability with the distance between sites. In the frame of propagation of epidemics and forest fires, small world networks seem to be good candidates. They exhibit long-range connections [2] with an exponentially decreasing connectivity distribution. In computer networks (scale free networks), there is no percolation threshold because the connectivity distribution is power-law decreasing (the characteristic length is infinite) [2]. As stated by Albini [3] the dominant mechanism for fire spread is often radiation for the simple reason that the movement of air is toward the burning zone rather than away from it, at least in the near vicinity of the fire edge where rapid heating of unignited fuel is taking place. This situation is obtained even for wind-aided fire spread whenever the flame structure stands erect from the fuel surface rather than being blown through it. Following Billaud *et al*. [4] and Mudan [5], radiation flux is asymptotically power-law decreasing with distance. However, when studying radiative ignition of wildland fuels, a characteristic length can emerge. This is the aim of the present work. The influence of flame properties and fuel moisture content is also examined.

Ignition process

A simple physical model, derived from that of Koo *et al*. [6, 7], is used for steady-state contiguous fire spread in a thermally-thin uniform porous fuel bed (see Fig.1). In this model, the fuel bed is horizontal or inclined with a slope $\boldsymbol{\phi_s}$. It has a length L_{fb} and is assumed to be a thin homogenous, porous fuel layer (its thickness e is small compared to the fuel bed and flame sizes). The fuel medium is preheated to ignition by radiative heat transfer from the flaming zone and losses radiation to the ambient. The solid model of a single flame is used where the visible flame is regarded as a uniformly-radiating solid body with a cylindrical shape, of length L_f and radius r, and with thermal radiation emitted from its surface. Combustion and chemical reactions are thus assumed to be infinitely fast. The reference system is attached to the flame sheet so that the flame is fixed at $y = 0$. The ignition of a fuel bed

control volume located at a constant distance *y* is examined., and the tilt angle of the flame $\boldsymbol{\theta}$ is caused by the wind speed $\boldsymbol{U_w}$ and the gravitational constant $\boldsymbol{g}$. It is approximated as [6]

$$\theta = \tan^{-1}\left[\frac{1.4\ U_W}{\sqrt{g\ L_f}}\right] \quad (1)$$

The heat supplied by the flame radiations leads to the fuel thermal degradation and to rise the temperature until it reaches the ignition temperature $\boldsymbol{T_{ign}}$. The temperature of the combustible layer is thus time and distance dependent ($\boldsymbol{T_y(t)}$). It is at room temperature $\boldsymbol{T_{rt}}$ for $\boldsymbol{y = \infty}$, and at the flame temperature $\boldsymbol{T_f}$ for $\boldsymbol{y = 0}$.

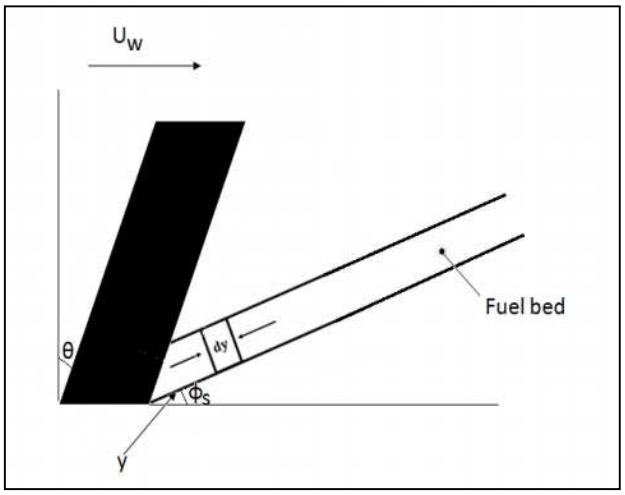

Figure 1. Planar projection of a flame spread schematic.

Consider a volume element $dy \times e \times l$ (l being the width of the fuel bed) of the combustible layer heated by a flame radiation at a distance y. Neglecting the convection flux, the total flux q_T received by this element is

$$q_T = q_{sr} + q_{rl} \quad (2)$$

The radiation flux q_{sr} received from the flame is defined as:

$$q_{sr} = \frac{a_{fb} \times \sigma \times \varepsilon_f \times T_f^4}{e} F \quad (3)$$

Where a_{fb} denotes the absorption coefficient of the combustible element layer, ε_f is the emissivity and σ the Stephan Boltzmann constant. The view factor (F) is determined by Monte-Carlo simulations for a cylindrical flame shape [4, 5]. The Monte-Carlo method used reduces to a stochastic ray-tracing method where discrete energy bundles are sent through the computational domain with the ray direction is sampled.
The radiation loss of the surface element q_{rl} is given by

$$q_{rl} = -\frac{\sigma \times \varepsilon_c \times (T_y^4 - T_{rt}^4)}{e} \quad (4)$$

Where ε_c denotes the emissivity of the combustible element layer. Convective heat transfer is defined as heat transfer between the fuel bed and the ambient air due to bulk fluid motion. The fuel bed may

be heated or cooled by exchanging heat energy with the air by convection both on the surface and in the bulk.
The total heat flux (overhead flame radiation minus radiative losses) increases the temperature of the fuel control volume until it reaches the ignition temperature so that

$$q_T = \begin{cases} \rho_c \times C_p \times \Phi \times \frac{dT}{dt} \,, for\ T \neq 373^0 K \\ -\rho_c \times h_{vap\times} \Phi \times \frac{dW}{dt} \,, for\ T = 373^0 K \end{cases} \quad (5)$$

Here ρ_c is the fuel density, C_p its specific heat, Φ the volume fraction of the solid phase (fine fuel particles), W is the fuel moisture content (FMC), and h_{vap} the latent heat of water evaporation. The boundary conditions associated to Eq. (5) are

$$\begin{aligned} &T(y=0) = T_{ign}, T(y=\infty) = T_\infty \\ &W(y=0) = 0, W(y=\infty) = W_0 \end{aligned} \quad (6)$$

Here W_0 is the initial FMC, T_{ign} and T_∞ are respectively the ignition and ambient temperature. Three different heating processes appear before ignition; wet fuel preheating, drying and pyrolysis. A plateau appears at 373°K due to the phase change as shown in Fig.2.

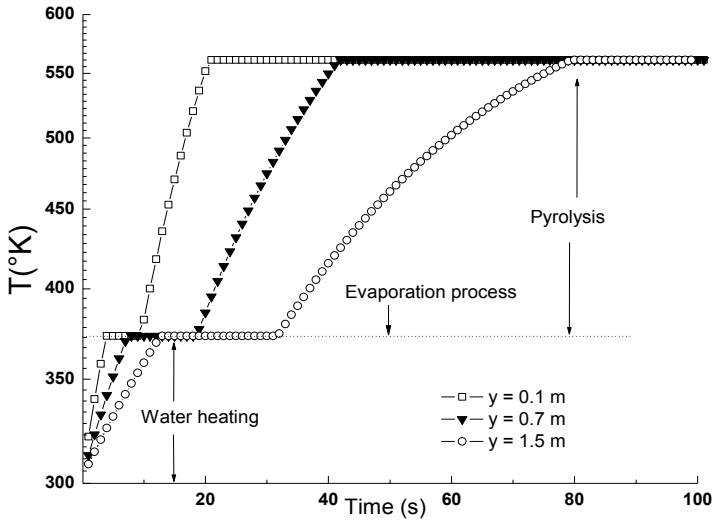

Figure 2. Time evolution of the fuel temperature for various distances y. Ignition temperature is 560°K.The water heating, evaporation and pyrolysis are shown.

Results

In the reference case, the flame is vertical with $L_f = 4\,m$ and $r = 1\,m$, and the FMC is 0.2. The ignition temperature is 560°K and the emissive power of the flame is $120 kW/m^2$. As shown in Fig.3, above $y = 0.5m$, the ignition time exhibits an exponential increase with the distance y from the flame. It behaves as $t_{ign} \propto e^{y/l_c}$ where l_c ($l_c = 2.77 \pm 0.01m$ in Fig.3) is the characteristic ignition length. For $y > l_c$, the ignition time increases faster than the exponential increase.
The existence of a characteristic length of radiative ignition allows reducing the computational time of fire spread simulations, only a small deterministic area of radius l_c (the so-called interaction domain)

being involved in the fire propagation process. This length was empirically introduced in previous studies of forest fire spread and percolation [8].

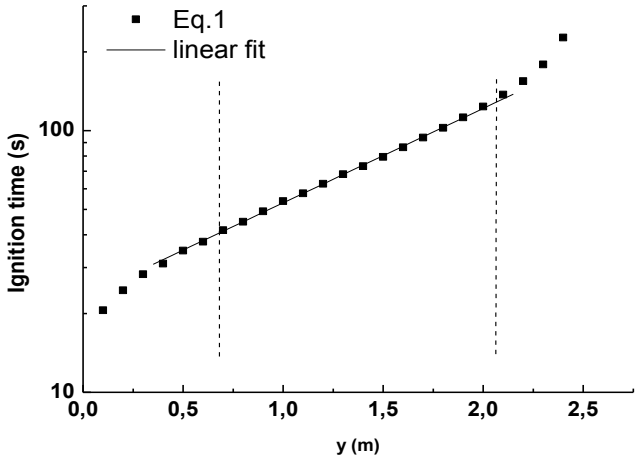

Figure 3. Ignition time vs. y.

The influence of flame height and radius on the ignition characteristic length l_c is shown in Fig.4. The characteristic length l_c increases as a power-law with the flame height. Saturation occurs for L_f around $10m$ (Fig.4a), due to the decreasing contribution of the upper part of the flame. For $L_f = 10m$, the characteristic ignition length increases logarithmically with the flame radius (Fig.4b). This logarithmic behavior indicates a slight dependence on the flame radius.

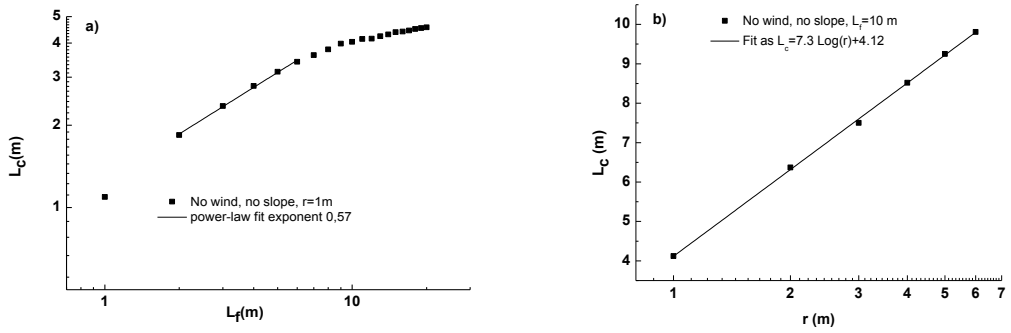

Figure 4. Characteristic length (l_c) vs. a) flame length (logarithmic plot) and b) flame radius (semi-logarithmic plot).

Ignition time increases linearly with FMC, whatever the distance from the flame (Fig.5), according as: $t_{ign} \propto FMC \times e^{y/l_c}$. This indicates that the characteristic length l_c does not depend on FMC, which only delays the ignition time. This result does not agree with the trends obtained experimentally by Trabaud [9], indicating a critical moisture content FMC_{max} above which ignition cannot occur

$$t_{ign} \propto \frac{1}{FMC_{max} - FMC} \quad (7)$$

One of the reasons of this discrepancy is the high flux and small distance y to the flame. Furthermore, flammable gas emission may occur during water heating before evaporation so that, at ignition temperature the remaining gases become insufficient for igniting the fuel. This effect is being included in the present model.

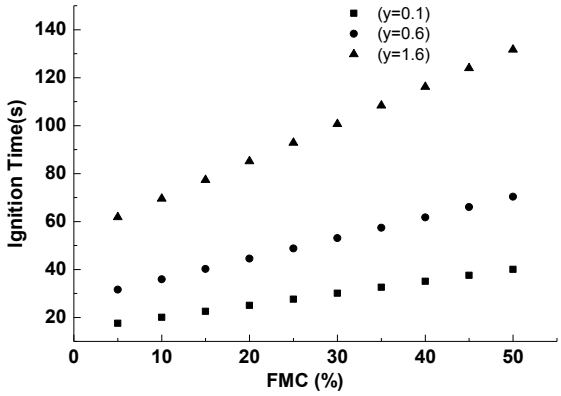

Figure 5. Ignition time dependence on the fuel moisture content for various distances from the flame.

Conclusions

Using a simple thermal model, the existence of a characteristic length of radiative ignition was demonstrated. The dependence of this length on the flame height and radius was investigated. It is also found that this characteristic length was independent of the fuel moisture content. Wind and slope effects on the characteristic length are currently studying.

Abstract
Prescribed fires are an important fuel management tool in Mediterranean fire-prone landscapes, but there is a lack of custom fuel models developed for Mediterranean-type ecosystems and, in particular, for describing ecosystems, which have been treated with a prescribed fire. Such custom fuel models would allow using fire modeling-based approaches for assessing the efficiency of real prescribed fires in relation to fire control at the landscape scale, but also for exploring the efficiency of alternative prescribed fire scenarios under climate change. Pre-burn field-collected vegetation data for shrublands under a *Pinus halepensis* canopy in a semi-arid Mediterranean study area located in southern Catalonia (Northeastern Spain) are presented and compared to values of vegetation parameters published in previous works and commonly used for fuel models characterization. The differences found at the species- and community-levels support the need of developing custom fuel models for improving future fire projections.

Keywords*: prescribed fire, custom fuel models, fire modeling, Mediterranean ecosystems, Aleppo pine*

Introduction

Wildfires are a major cause of environmental degradation in northern Mediterranean countries. The magnitude of the problem will likely be enhanced by climatic change, making necessary the implementation of landscape-level designed fire management strategies (Duguy *et al.* 2013).
Landscape-level fire prevention planning requires a better understanding of how ecosystems, and vegetation in particular, may respond to specific management actions. In recent years, prescribed fires have gained attention as an interesting fuel management alternative to mechanical or chemical tools and livestock grazing, both from economical and ecological points of view (Fernandes 2002, Fernandes and Botelho 2003, Goldammer and Bruce 2004, Rigolot 2005, Cassagne *et al.* 2011). However, while wildfire effects on Mediterranean ecosystems have been comprehensively treated in the literature (Trabaud *et al.* 1985a, 1985b, Pausas *et al.* 1999; Delitti *et al.* 2005; Baeza and Vallejo 2008; Duguy and Vallejo 2008), prescribed fire effects are not so well documented and require further attention before this tool may be extensively applied (Montiel and Kraus 2013).
Short and medium-term effects of prescribed fire are currently being evaluated for shrublands under *Pinus halepensis* canopy within the framework of the ForBurn-Land project funded by the Spanish Ministry of Science and Innovation (AGL2012-40098-C03-02). The focus is on the understory of Aleppo pine stands because almost 367,000 ha of such forests were planted or seeded in Spain between 1940 and 1980, increasing the existing extension of almost 674,000 ha of naturally regenerated *Pinus*

halepensis forests. An additional surface of 786,000 ha, resulting from the secondary succession on abandoned crops, had to be added after 1980.
In general, Aleppo pine forests contribute to the high fire-proneness of Mediterranean landscapes and fire usually plays a major role in the regeneration and dynamics of this pioneer plant community (EEA 2006). The crown structure and the morphology of the pine needles allow ample radiation to reach the soil, so a dense and flammable evergreen sclerophyllous shrub layer (with garrigue to maquis-like physiognomies; EEA 2006), which may cause extreme fire intensities (Martins-Fernandes 2001), is often well developed. Moreover, in the past two decades, the lack of the required preventive silvicultural treatments has resulted in very hazardous stand structures unfavorable for management (Vega-Garcia and Chuvieco 2006). Consequently, we study here the effects of prescribed understory fires under *Pinus halepensis*. Prescribed crown fires are not considered, as they are not allowed in current fuel management planning in Spain (Decreto 312/2006, de 25 de julio in Catalonia and RCARA, de 11 de enero de 2013 in Asturias).
Spatially-explicit fire models, such as FARSITE (Finney 1998), have shown to correctly project fire growth and behavior of hypothetical fires through Mediterranean landscapes (Arca *et al.* 2007, Duguy *et al.* 2007). The reliability of their predictions strongly depends, however, on the accuracy of the fuel-related inputs (Arca *et al.* 2007). Seeking to improve fire simulation options, some scientific precedents in Mediterranean environments have tried to develop new fuel model types (i.e. Prometheus), but few have been based on extensive field measurements; e.g. the UCO40 system developed in Andalucia by Rodriguez y Silva and Molina-Martínez (2012), and most have been limited by scale and budget (Arroyo *et al.* 2008).
The purpose generally stated in previous works is the improvement of fire behavior modeling (Papió and Trabaud 1991; Pereira *et al.* 1995; Bochet *et al.* 2000; Dimitrakopoulos 2001; Viegas *et al.* 2001; Cohen *et al.* 2003; Baeza *et al.* 2006; Pellizzaro *et al.* 2007a; Cassagne *et al.* 2011; Santana *et al.* 2011)., but the evaluation of fuel management alternatives is not explicitly commented.
In that sense, there is still a lack of custom fuel models (CFM, hereafter) developed for Mediterranean ecosystems and, in particular, for describing ecosystems which have been treated with a prescribed fire. Such CFMs would allow using fire modeling-based approaches for assessing the efficiency of real prescribed fires in relation to fire control at the landscape scale, but also for exploring the efficiency of alternative prescribed fire scenarios under climate change.
Consequently, we intend to customize fuel models for pre- and a post-prescribed fire situations in shrublands under a *Pinus halepensis* canopy in a representative study area located in southern Catalonia (Northeastern Spain). The characterization and use of such CFMs are expected to provide more reliable fire modeling projections and, thus, foster the use of fire models as supportive tools for optimizing the landscape-scale planning of prescribed burnings in relation to wildfire prevention. Given that this project is still ongoing, only the pre-fire situation will be presented at this time.

Methods

2.1. Study area

The study area (Figure 1) is located in El Perelló (Southern Catalonia, Spain; UTM Zone 31N; x: 304762, y: 4530927; 250 m a.s.l.). The area is characterized by a semi-arid Mediterranean climate with mild winters and dry and warm summers in which water deficit may reach 300-400 mm. The mean annual precipitation is around 550 mm and mean annual temperature around 17 ºC (POUM Perelló, 2010). Stony Lithic Xerorthents and Lithic Haploxerolls developed over limestones and dolomites (Soil Survey Staff 1999) sustain a forest of *Pinus halepensis Miller* (Vigo *et al.*, 2006) with a canopy cover around 80%. The dominant shrub species in the understory are *Pistacia lentiscus*, *Quercus coccifera*, *Ulex parviflorus*, *Rosmarinus officinalis*, and *Erica multiflora. Rhamnus alaternus*, *Olea europaea* and *Chamaerops humilis* are other common woody species.

The pine stands were planted in 1970 on old crops (cereal, almond and olive groves) that were abandoned in the 1950s. A mechanical treatment was applied in 1998 to reduce the biomass of the understory.

Methods

Three plots (10x10 m) were installed in the study area. The vegetation samplings were carried out in February 2013 and March 2014, before and after, respectively, a prescribed burning for fuel hazard reduction that was conducted over 2.1 ha in May 2013 and that only affected the understory. The three plots were divided in a hundred $1m^2$ quadrats for inventory of specific composition (list of species) and vegetation structure. The minimum and maximum height (of shrub layer and highest individuals among dominant shrubs), the minimum and maximum crown diameters, and the cover percentages (shrub and herbaceous layers) were measured.

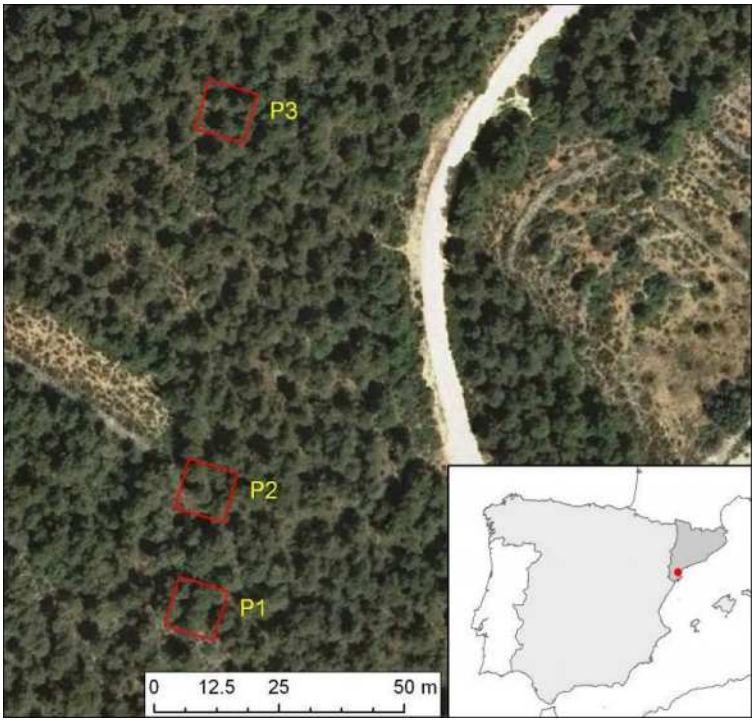

Figure 1. Location of study area and of the three sampling plots. Source: ***PNOA*** *ordered by © Instituto Geográfico Nacional de España*

Outside the plots, 20 individuals of each of the five dominant shrub species (*Rosmarinus officinalis*, *Pistacia lentiscus*, *Quercus coccifera*, *Ulex parviflorus* and *Erica multiflora*) were selected taking into account the dimensional range of each species in the site. Individuals were measured (minimum and maximum crown height and crown diameter), cut, weighted in the field, and reweighted after removing the fine live fraction (diameter < 6 mm) in order to develop allometric relations between the estimated volume and aerial phytomass. The data were processed in order to obtain fuel loads for the description of a CFM. The values of those parameters were then compared to the ranges found in the literature for the same species and similar Mediterranean plant communities. Additionally, those values were also compared to those of analogous fuel model types in the classifications by Scott and Burgan (2005), Anderson (1982) and the UCO40 system by Rodriguez y Silva and Molina-Martínez (2012).
Also, fine live (woody, herbaceous) and dead (fine, coarse) fuel moisture contents were sampled four times along the fire season in 2013 (June, July, August and September). Ten samples were taken by

fuel category and species, sealed, weighted (fresh weight), oven dried (80ºC) during 48h and reweighted afterwards (dry weight). Moisture content was estimated as a dry weight percentage.

Results

The values collected in the field for a set of fuel-related relevant characteristics and for the five sampled shrub species are presented in Table 1 along with the values found in the literature. Under the label "Proxy fuel load variables", the variables used for establishing allometric relationships are presented in the first six rows for our target species. They are followed by four woody fuel load fractions estimated based on those allometries. Below, available direct measurements of fuel load fractions obtained by destructive field sampling are recorded (Live Woody Fuel Load only), followed by total values (added fractions) obtained by any of these procedures (Aerial Phytomass).
Under the label "Custom fuel model input set" are listed some variables that are usually considered for fire modeling under semi-physical models based on Rothermel's (1972) equations, such as FARSITE (Finney 1998). Finally, moisture content data are presented, and the references are provided. In order to facilitate comparisons with fuels described in other studies, data compiled in the table are not restricted only to fuel loads.

Table 1. Fuel-related variables at the species level. The data presented in brackets correspond to FORBURN field data and the rest is bibliographic data. RO: Rosmarinus officinalis; PL: Pistacia lentiscus; QC: Quercus coccifera; UP: Ulex parviflorus; EM: Erica multiflora; (-): not available; H: height; D: diameter.

For most variables, values are not available for all the species dominating the plant communities of our study area (Table 1). Those species are among the most common species that can be found in shrubland ecosystems of Western Mediterranean basin, though. This lack of data highlights the fact that many fuel-related parameters have not been sufficiently studied in previous work and shows the need of further field-based research on those variables.

The values of fuel-related relevant characteristics for some Mediterranean plant communities similar to the shrublands that have been sampled in the study area are presented in Table 2, as well as the data obtained in our site.

First rows describe the composition and cover variables of the plant communities, followed by fuel fractions estimated through destructive sampling in the field. Total values (added fractions) obtained by any of these procedures are below (Total Shrub Load).

Variables usually considered for fire modeling under semi-physical models based on Rothermel's (1972) equations are listed afterwards and shadowed in grey. Last rows provide fuel moisture data and bibliographic sources of values. Again, in order to facilitate comparisons with communities in other studies, data compiled in the table are not restricted only to fuel loads, but other variables are included.

SOURCE		FORBURN	Santana *et al.* 2012	Santana *et al.* 2012	Saglam *et al.* 2008	Bilgili and Saglam 2003	Duguy *et al.* 2007	De Luis *et al.* 2004; Baeza and Vallejo 2008	Kalabokidis *et al.* 2013	Kalabokidis *et al.* 2013

Once more, the compilation of available data presented in the table shows the need of further research for implementing better structural descriptions of some very common Mediterranean plant communities. This lack of reliable data for most fuel-related relevant vegetation parameters makes very difficult an appropriate structural characterization of the corresponding plant communities and, thus, a good description of the derived custom fuel models.

As for our FORBURN data, we found that before the prescribed burning, the total herbaceous cover in the three sampled plots was 50, 61 and 51%, respectively, while the total shrub cover was 58, 41 and 40%, respectively. Among shrubs, *Pistacia lentiscus* was the species with the largest covers (36.6 - 69%) and estimated phytovolumes (in % of total phytovolume of shrub understorey in the community, 33.3 - 73.5%), followed by *Rosmarinus officinalis* (6.5 – 35%, for cover, and 6.1 - 41.7% respectively), *Quercus coccifera* (4.9 - 37.1% cover and 2.3 - 26%), *Erica multiflora* (2.3 - 17.3% cover and 1.5 - 17.8%) and *Ulex parviflorus* (2.2 - 6.4% cover and 1.7 - 4.3% total phytovolume of shrub understorey).

Other species present (*Rhamnus lycioides, Rhamnus alaternus, Chamaerops humilis, Thymus vulgaris* and *Genista sp.*) had very low cover values (always less than 1.8%) and were not considered for our fuel model description purposes. Given the generally rather low percentage covers reached by *Ulex parviflorus* in the studied shrubland, the standing dead woody fuel loads of that species were not considered either.

Over the three plots, shrubs height did not exceed 150 cm. Species averaged heights were weighted by cover (Martins-Fernandes 2001) to provide an integrated site value of 0.68 m. The mean total shrub biomass in the pre-burn situation reached on average 15.25 tn.ha-1. This aerial weight of shrubs or live woody fuel load (LWFL) was lower than those found in Saglam *et al*. (2008) and Bilgili and Saglam (2003), within the range in Duguy *et al*. (2007), De Luis *et al*. (2004) and Baeza and Vallejo (2008), and higher than in Kalabokidis *et al*. (2013). This value is also higher than the total fuel load values provided by Anderson (1982) for shrub-type models 6 and 7 (14.8 and 12.1 t.ha-1, respectively), by Scott and Burgan (2005) for shrub-type model SH2 (12.9 t.ha-1), and by Rodriguez y Silva and Molina-Martínez (2012) for M5, HPM4 and HPM5 models (10.55, 11.13 and 10.74 t.ha-1, respectively). It is smaller than the total fuel load value provided by Anderson (1982) for shrub-type model 4 (32.1 t ha-1), although this fuel load amount includes a large value of dead fuel load (12.4 t ha-1). Our plant community value is also smaller than the fuel load value provided by Scott and Burgan (2005) for shrub-type model SH5 (16.09 t ha-1). This latter fuel model appears, nevertheless, as the

most appropriate standard fuel model that might be attributed to the studied community. SH5 is described as a shrubland with a heavy shrub load, in which the shrub layer height may range from 120 to 180 cm (Scott and Burgan 2005).
Those results are indicative of the wide margin for error that may exist when using for fire modeling fuel models that have not been developed in a customized way, i.e. based on local vegetation structural data collected on the field. They also confirm the need of new CFMs.
An aspect that sometimes makes difficult the appropriate understanding or selection of both standard and custom fuel models, as well as the comparisons between them, is the use of different units by the authors. We have presented all the variables shown in our tables using international system units in order to make those tables more useful for future evaluations and decision processes.

Discussion and management implications.

When considering individual species, Aleppo pine stands in our study site appear to be characterized by a shrub understory with smaller total fuel loads than those found in other Mediterranean ecosystems analyzed in the literature. The dimensional values found for the main shrubs present in our site are similar to those appearing in published works, but their aerial phytomasses and phytovolumes per unit area appear to be smaller. In our site, the understory is dominated in cover, volume and biomass by *Pistacia lentiscus*, although with smaller biomass values (10.72 t.ha-1) than those found by other authors, ranging from 14.19 to 158.20 t.ha-1 (Papió and Trabaud 1991; Dimitrakopoulos 2001; Dimitrakopoulos and Panov 2001; Dimitrakopoulos and Papaioannou 2001; Cohen *et al*. 2003; Pellizzaro *et al*. 2007a; Pellizzaro *et al*. 2007b). The differences may be explained by different conditions in these studies in terms of climatic variables, but also species composition and tree cover. The study by Papió and Trabaud (1991) was placed in a location with a mixed garrigue of *Quercus coccifera* with 919 mm of annual precipitation and no tree cover, while Pellizzaro *et al*. (2007a) and Pellizzaro *et al*. (2007b) worked in maquis and garrigue in a site with about 600 mm and without tree cover. Data in Dimitrakopoulos (2001), Dimitrakopoulos and Panov (2001) and Dimitrakopoulos and Papaioannou (2001) comes from general phrygana and maquis formations, but no climatic data is provided. For Cohen *et al*. (2003) only general locations are referred. Comparability among results is complicated by the lack of descriptions in these cases, but clearly studies in locations with a tree cover are lacking, which justifies our work.
For comparisons at the community level, a lower total shrub biomass in the pre-burn situation was in agreement with the fact that the mean annual rainfall in our study area is lower (300 - 400 mm, with a quite significant water deficit spanning 3-5 months with semiarid conditions, POUM Perello, 2010) than in other studies in which mean annual precipitation ranges between 450 and 700 mm (Lesvos, Greece, Kalabokidis *et al*. 2013), 466 and 700 mm (Valencia Region, Spain, De Luis *et al*. 2004; Duguy *et al*. 2007; Baeza and Vallejo 2008; Santana *et al*. 2012), or even 805 mm and 1200 mm (Turkey, Bilgili and Saglam 2003; Saglam *et al*. 2003). A lower biomass value resulting from more adverse ecological site conditions may be the major causative factor.
However, differences in the procedures followed by different authors for estimating the apparent phytovolumes and other proxy or intermediate variables may certainly have had also an impact on biomass estimations.
Both species and community FORBURN fuel load data estimates highlight the difficulty of carrying out comparative studies considering Mediterranean-type shrublands that may cover a wide range of ecological and land use history situations, and also the crucial need of standardizing the experimental protocols for the characterization of such plant communities in relation to the description of a larger number of custom fuel models. This also applies to other important variables, such as the fuel moisture, which is currently estimated with drying protocols varying from 24 h at 105 ºC (Viegas *et al*. 2001; Saglam *et al*. 2008) to 48 h at 60 ºC (Rodríguez y Silva and Molina-Martinez 2012), for instance.

The fact that in our pine stands the understory is dominated in cover, volume and biomass by *Pistacia lentiscus* raises questions regarding past silvicultural treatments implemented in those stands, but also about future stand treatments. The mechanical fuel reduction treatment applied in 1998 may have favored this species and controlled, on the contrary, the presence of some seeder shrubs (Baeza *et al.* 2003).
Unless excessively tall and thus producing ladder fuels in the pine stands that would increase the risk of crown fires, *Pistacia lentiscus* is a resprouter species, which is usually considered for ecological restoration purposes in Mediterranean fire-prone ecosystems, since its presence gives resilience to those systems (CEAM 2009).
On the contrary, *Ulex parviflorus (gorse)* and *Rosmarinus officinalis* are obligate seeders, which tend to accumulate large amounts of fine dead fuels and need to be controlled (Duguy and Baeza 2009). In gorse communities, in particular, the standing necromass incrases strongly with age, promoting conditions conducive to high intensity fires (Baeza *et al.* 2006). It has been recommended, therefore, to apply a combination of treatments, such as mechanical fuel reduction actions combined with repeated prescribed burnings in order to decrease fuel loads in such communities (Baeza and Duguy 2009).
A single prescribed fire conducted in 2010 in a similar pine stand adjacent to our site seems to have generated this reduction effect over *Ulex parviflorus* cover (M. Castellnou, personal communication, October 2012).
In any case, fuel reduction treatments must be designed taking into account the characteristics and ecological requirements of the species within the target ecosystems (Baeza 2004) and, particularly, the reproductive biology of the key species (Baeza and Duguy 2009). Within a climate change context, treatments strategies should also consider the need of an increased resilience of ecosystems to fire, conservation and promotion of biodiversity, carbon budgets and desertification issues (Hurteau *et al*. 2008).
As this project is still ongoing, post-fire data are not presented at this time, but if those data show that the structural characteristics of the plant community have not been significantly modified by the prescribed fire, the description of a different custom fuel model for the post-fire situation will not be justified. This would, of course, mean that the executed burning has not been an efficient tool in relation to fuel control and, therefore, fire prevention. Prescribed burning may have modified, however, the species composition of the *Pinus halepensis* forest understory. Such changes would require a further analysis, if they happen.
The comparison of total fuel load values (total shrub aerial biomass) of the studied community with those given for existing fuel model types under different classification systems, which are often used in Mediterranean ecosystems, leads to consider that significant errors can be made when using those latter fuel models for fire modeling in our region. It clearly shows the need of describing local custom fuel models for shrublands developed under an Aleppo pine canopy in semi-arid Mediterranean conditions.

Abstract

Since the year 2000 Bulgaria is facing progressive increase of wildland fire occurrence. That is caused mainly because of human mistakes in having fire camps or agricultural land processing after crop harvesting. At the moment Bulgaria has no working mechanism to spot such fires before they become a threat, however the team from Bulgarian Academy of Sciences is working on fire behaviour modelling issues since 2007 and in this work will be presented the first attempts for Bulgarian forestry data classification according to the existing 53 FBFMs, and estimations where custom fuels has to be prepared for better representation of the potential fire spread. Calibrations with FARSITE runs have been performed for the area of Zlatograd Forestry Department (Bulgaria) data set (Dobrinkova et. all 2014). The results are compared with Harmanli (Bulgaria) WRF-Fire/S-Fire simulations (Jordanov et. all 2012) in order to see how the different fire behaviour fuel models estimations reflect in the final simulated burned area. Conclusions for fire behaviour fuel modelling based on both simulation approaches in Zlatograd and Harmanli areas gives future application of the presented work for Bulgarian test cases.

Keywords*: Bulgaria, Forestry data, fire behaviour fuel model data preparation, fuel modelling*

Introduction

FARSITE runs with the standard or custom Fire Behaviour Fuel Models in Bulgaria has never been done until our first attempts for this on the test cases selected randomly for the period 2011-2012 on the territory of Zlatograd Forestry Department. In the previous works on Bulgarian test case nearby the area of Harmanli town has been used CORINE categories (Jordanov et. all 2012; Dobrinkova et. All 2011). The approach in Harmanli test case gives CORINE species division adapted only to the thirteen classes of Anderson (Anderson 1982). However this approach has some weaknesses, because fuel load parameters description with satellite images only is hard to be provided.
The current work present chronologically how the available forestry data from the Zlatograd Forestry department is prepared for the FARSITE runs from turning the list of biological species into FBFMs according to the FARSITE input instructions. Most of the collected data has been provided as paper maps which processing into digital GIS (Geographic Information System's) layers had to meet the requirements of FARSITE. The standard FBFMs (Anderson 1982) and (Scott and Burgan 2005) has been taken into consideration with their parameters for fuel load (1-hr, 10-hr, 100-hr, live herbaceous and live woody), compared to the test cases according to the best collected data.
This work is giving both Harmanli and Zlatograd FBFMs methodologies and how they have been implemented in the WRF-Fire/S-Fire and FARSITE runs. The conclusions give comparison on the achieved results with some plans for future refinements.

Harmanli test case data preparation and FBFMs summary

In the Harmanli test case has been used WRF-Fire/S-Fire computer based tool, which is a combination between the mesoscale atmospheric code WRF-ARW (Skamarock 2008) with a fire spread module, based on the Rothermel model (Rothermel 1972) implemented by the level set method. A simulation

with WRF-Fire/S-Fire requires input data from a variety of sources from meteorological initial and boundary conditions to static surface properties.

For the meteorological inputs the U.S. National Center for Environmental Protection (NCEP) gives a 1 degree resolution grid covering the entire globe with 6 hour reanalysis cycle. The data is freely available and can be downloaded automatically over HTTP by using a simple script. Creating simulation also requires a number of static data fields describing the surface properties of the area. All such data is available as part of a standard global dataset for WRF. The fields in this dataset are available at various resolutions ranging from about 1 km to 10 km, which is sufficient for most mesoscale weather modeling purposes. Each field is stored in a unique format consisting of a series of simple binary files described by a text file. A geogrid utility in the WRF preprocessor (WPS) interpolates the data in these files onto the model grid and produces an intermediate NetCDF file used in further preprocessing steps. While the standard geogrid dataset is sufficient for most weather forecasting applications, it lacks two high resolutions fields. These fields are surface topography and fuel information. Both are essential for modeling fire behavior because they directly affect the rate of spread of the fire front inside the model.

Topography at a resolution of about 90 m for the area of Harmanli is used from the Shuttle Radar Topography Mission (SRTM) at http://eros.usgs.gov. The data received from the server is a GIS raster format (DTED), which is processed and converted to geogrid binary data format.

The final piece of surface data needed for input into geogrid is a categorical field describing the properties of the fuels. In the U.S., this data is readily available from the USGS, however, no such data exists for the Harmanli or any other Bulgarian region region. Instead for this field is used data from the Corine Landcover Project (financed by the European Environment Agency and the member states) see Table 1. This project provides landcover data for Bulgaria with 100 m resolution with a 25 ha minimum mapping unit http://www.eea.europa.eu/data-and-maps/data/corine-land-cover-2006-raster.

Table 1. Fuel categories from satellite imagery and CORINE code (in parentheses)

Category	Description
1	Artificial, non-agricultural vegetated areas (141,142)
2	Sport Complex,Irrigated Cropland and Pasture,Bare Ground Tundra, Arable land (211,212,213), Open spaces with little or no vegetation (331,332,333,334,335)
3	Cemeteries, Dryland Cropland and Pasture, Grassland, Permanent crops(221,222,223), Pastures (231), Heterogeneous agricultural areas(241,242,243,244), Scrub and/or herbaceous vegetation associations (321,322,323,324)
4	Herbaceous Tundra, Parks
5	Wooded Wetland
6	Wooded Tundra, Orchard
7	Mixed Forest
8	Deciduous Needleleaf Forest, Forests (311,312,313)
9-13	N/A
14	Urban fabric (111,112), Industrial, commercial, and transport units (121,122,123,124), Mine, dump and construction sites (131,132,133), Wetlands(411,412,421,422,423), Water bodies (511,512,521,522,523)

The downloaded satellite data along with orthophoto data from the geoportal of the Ministry of Regional Development (MRD) of Bulgaria can be used to estimate the fuel types of the domain like conifer or deciduous woods. All rivers, lakes, villages and forest areas can be vectorized using the orthophoto images combined with CORINE2006 into a GIS vector shape file. The vectorized file provides very high accuracy of representation for non burning areas like rivers and lakes. For the areas

with woods is used Table1, where a description of the fuel categories for the Harmanli simulation corresponds to the Anderson thirteen classes with additional one class for the non burning areas. This fuel level data combined with the vectorized landcover areas gives us a final shape file with attributes for each polygon fuel level. The resulting input files contain all the standard WRF fields along with several additional variables generated from the high resolution topography and fuel categories.
However no fuel load description about 1-hr, 10-hr, 100-hr, live herbaceous and live woody parameters can be estimated with such approach. The problem here is that the satellite images from CORINE project can not provide high resolution with all species information on the land cover. The ortophotoes can provide the canopy cover, but not the fuel load description and in these cases the best solution is to find forestry department plan for any wild land area in Bulgaria. The Bulgarian Forestry department plans contain information which can be used for the fuel load estimations and refinements in the Table 1 categories. Such approach is described in the Zlatograd test case area.

Harmanli test case analysis

The Harmanli test case simulation result is presented on the Figure 1B. The simulated area has significant similarity in the fire spread shape, but it does not fully comply with the real burnt area Figure 1A. The total simulated burnt area also does not correspond with the real one.

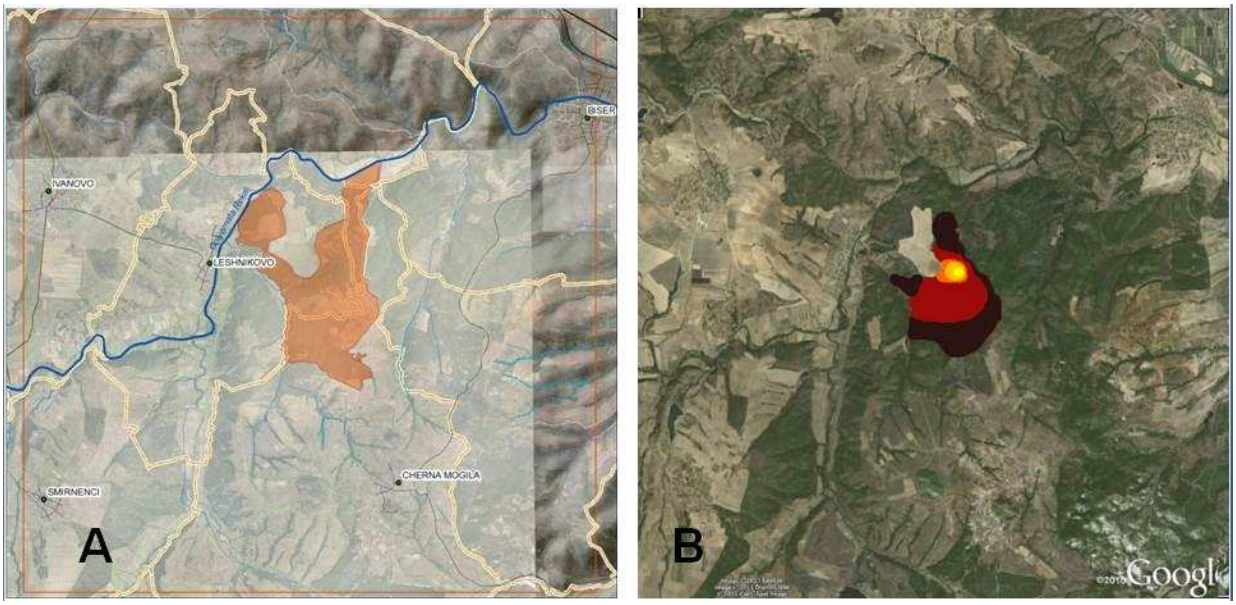

Figure 1. A. Real burned areaof the fire Harmanli(Bulgaria) test case, B. Simulated burned area on the Harmanli(Bulgaria) test case

The difference can be caused mainly from two components the fuel type definitions and weather inputs in the fire zone described in the simulation methodology of Harmanli fire simulation. Further analysis need to be performed and more information on the real fire spread has to be collected in order to be finally defined which components has to be additionally refined. The result however is important, because with this simulation is given the opportunity to operational teams of the responsible authorities in Bulgaria to achieve results on fire spread even with weather inputs and estimations on fuels and topography.

Zlatograd test case data preparation and FBFMs summary

The forestry department of Zlatograd area covers 33,532 ha, of which 31,856 ha are state owned forests. It consist of the municipalities Zlatograd, Madan and Nedelino. In the period 2011-2012 fifteen different size and location wildland fires had occurred in Zlatograd forestsry department (Table 2). These wildfires burned in a variety of vegetation types and were more than likely started by humans to clear agricultural debris or prepare fields, based on the villages nearby. Paper maps from the forestry department identified the ignition location and final fire shape; this data was digitized in a GIS, which allowed each ignition point to be viewed with background orthophotos and the spatial Zlatograd vegetation classification showing pre-fire vegetation (Figure 2).

Table 2. Fire information provided by the Zlatograd Forestry. Department for the period 2011-2012

Fire No.	Vegetation type	Burned area in decares	Date of occurrence	Hour of start	Hour of end
1	Durmast	3.0	25 March 2012	1330	1530
2	Beechwood	5.0	29 March 2012	1400	1800
3	Scotch pine	1.0	16 June 2012	1500	1700
4	Scotch pine	7.0	6Aug. 2012	1640	1950
5	Scotch pine	5.0	6 Aug. 2012	1710	2130
6	European black pine	4.0	27Aug. 2012	1200	1600
7	Scotch pine	3.0	5 Sept. 2012	1400	2030
8	Scotch pine	6.0	6 Sept. 2012	1400	1930
9	Scotch pine	2.0	6 Oct. 2012	1600	2320
10	Scotch pine	1.0	16 March 2011	1310	1400
11	Scotch pine	1.0	5 April 2011	1715	1900

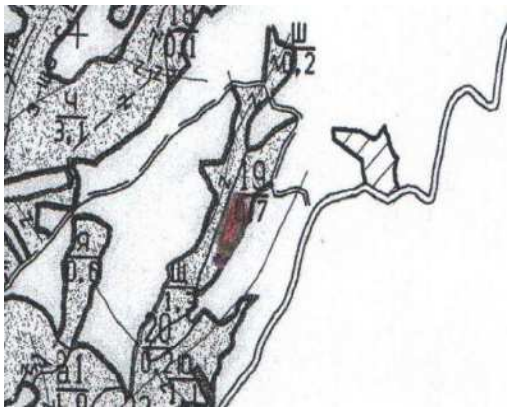

Figure 2b: Paper map sample

Zlatograd test case data preparation and analysis

The first step in preparing data to run spatial fire behaviour analyses was to determine suitable fuel models for fire locations in the Zlatograd test area. This was done by using BehavePlus (Andrews 2007). BehavePlus is a point fire behaviour prediction system that can be used to analyze fire growth and behaviour for homogeneous vegetation with static weather data. Using a number of standard fuel models developed for the United States (Anderson 1982; Scott and Burgan 2005), was evaluated which fuel models were best able to produce estimates of fire behaviour and growth in BehavePlus similar to those observed on each of the fifteen fires.

In addition to fuel model, BehavePlus requires inputs for weather, fuel moisture, slope, and duration of the burning period. Weather data was obtained for each fire from TV Met, a private company in Bulgaria, which provided calculated fine dead fuel moisture values (Rothermel 1983). The weather stations in the area of interest are quite sparse and that let to estimations for some of the zones of fires. Estimations on live herbaceous and live woody fuel moisture values were based on the expected phenological stage for the time of year that the fire occurred. To estimate slope, was used 30 m resolution digital elevation model (DEM) from the National Institute of Geophysics, Geodesy, and Geography in Bulgaria, then subsequently calculated the average slope for each fire using standard geospatial processing in ArcGIS (ESRI 2010). Burn period length for each fire was obtained from the Zlatograd forestry department data (Table 2).

Based on initial BehavePlus results using standard fuel models, custom fuel models were developed for some vegetation types not well represented by the US fuel models. Custom fuel models were developed for native durmast oak and grass as well as one of the Scotch pine sites by modifying fuel loading parameters to better match local vegetation and reflect the lack of woody debris in the understory, as it is collected as firewood by the local population. The custom fuel model developed for grass has a much lower rate of spread and flame length than any of the standard grass fuel models.

Following evaluation of fuel models with BehavePlus, were then performed analyses in FARSITE, a spatial fire growth system that integrates fire spread models with a suite of spatial data and tabular weather, wind and fuel moisture data to project fire growth and behavior across a landscape. It was defined test landscapes using a 500 m buffer zone around each of the fifteen Zlatograd fires (Figure 3); this footprint comprised the extent of the spatial analysis for each individual wildfire.

Input for FARSITE consists of spatial topographic, vegetation, and fuels parameters compiled into a multi-layered "landscape file" format. Topographic data required to run FARSITE include elevation, slope, and aspect. Using the aforementioned 30 m DEM, was calculated an aspect layer, and then clipped elevation, aspect, and slope rasters to the extent of the fifteen test landscapes. Required vegetation data include fuel model and canopy cover. Fuel models within the 500 m buffered analysis area for each individual fire were assigned based on the BehavePlus analyses; fuel model assignments were tied to the dominant vegetation for each polygon based on the Zlatograd forestry department's vegetation data. Canopy cover values were visually estimated from orthophoto images and verified with stand data from the Zlatograd forestry department. Additional canopy variables (canopy base height, canopy bulk density, and canopy height) that may be included in the landscape file were omitted, as these variables are most important for calculating crown fire spread or the potential for a surface fire to transition to a crown fire. None of the fifteen fires analyzed experienced crown fire.

Tabular weather and wind files for FARSITE were compiled using the weather and wind data from TV Met, Bulgarian meteorological company that included hourly records. Tabular fuel moisture files were created using the fine dead fuel moisture values calculated for the BehavePlus analyses for 1-hr timelag fuels. The 10-hr fuel moisture value was estimated by adding 1% to the 1-hr fuel moisture and the 100-hr fuel moisture was generally calculated by adding 3% to the 1-hr fuel moisture. The live fuel moisture values previously estimated for BehavePlus analyses were used to populate live herbaceous and live woody moisture values.

All simulations performed in FARSITE used metric data for inputs and outputs. An adjustment value was not used to alter rate of spread for standard fuel models, rather custom fuel models were created. Crown fire, embers from torching trees, and growth from spot fires were not enabled.

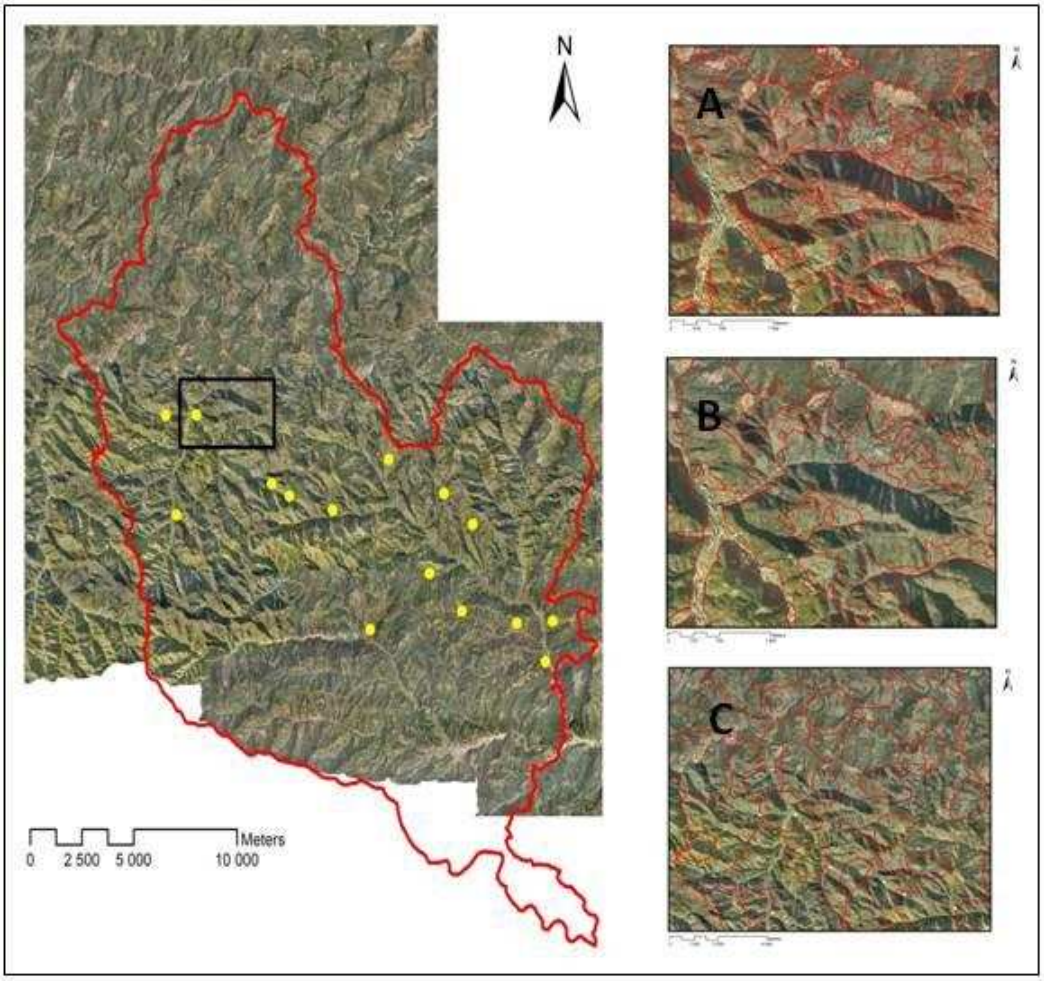

Figure 3. Location of the 15 fires (yellow dots) in the Zlatograd area that occurred in 2011-2012 that were used to develop fire behavior analysis methodology. The outline of the municipality of Zlatograd is shown in red, with the orthophoto imagery used to identify canopy cover underneath. The black box indicates the location of the three inset maps on the right. Inset maps are: A) Zlatograd forestry polygons; B) Corine land cover polygons; and C) Bondev vegetation map polygons.

From the performed analysis and achieved results with the prepared data FARSITE runs gave quite reasonable estimations of burnt areas close to the real burnt one. The results were mainly calculated with custom fuel models and standard ones based on the forty FBFMs (Scott and Burgan 2005).

Conclusions

Based on the work performed with Harmanli and Zlatograd forestry department's test areas summary of the most suitable approximation of classes corresponding to the vegetation types is provided in Table 3.

Table 3. Estimations from 40 standard US Fuel Models to Bulgarian Vegetation/Fuel Models

Vegetation Type	Possible Fuel Models	Logic/Assumptions
Scots pine (Pinus sylvestris)	188 (often used for ponderosa pine) 183 – modified	Ponderosa pine (*Pinus ponderosa*) may be a suitable western US proxy. Otherwise, probably a modified 183 (TL3) to increase rate of spread and flame lengths.
Black pine/Acacia (Pinus nigra/Acacia)	161 183 – probably modified	FBFM 161 works best when the understory is dominated by an herbaceous understory including forbs and grasses (it is dynamic). Creating a custom fuel model starting from FBFM 183 is another solution, to increase the rate of spread and flame lengths. Using FBFM 165 would assume ladder fuels to be present and will probably overpredict rate of spread and flame lengths.
Beechwood (Fagus sylvatica)	182/186 (dormant season fire) 161 (growing season fire)	FBFM 182 or 186 (or a custom FBFM) may be used when a fire is mostly burning through hardwood (round leaf) litter. FBFM 186 tends to have much higher rate of spread and flame lengths than 182. FBFM 161 is dynamic and may be used during the growing season when a fire would be expected to burn through the understory vegetation.
Durmast (Quercus dalechampii)	182/186 (dormant season fire) 161 (growing season fire)	FBFM 182 or 186 (or a custom FBFM) may be used when a fire is mostly burning through hardwood (round leaf) litter. FBFM 186 tends to have much higher rate of spread and flame lengths than 182. FBFM 161 is dynamic and may be used during the growing season when a fire would be expected to burn through the understory vegetation.
Grasslands	101 (may be best for grazed pasture) 102 (ungrazed pasture) Custom FBFM (lower ROS and FL than FBFM 101)	Assumes no irrigation. Rate of spread and flame length drastically change depending on chosen FBFM.

In this table are provided just first estimations on classification which for Bulgarian vegetation types can be further expand and calibrated in further test cases. The fire behaviour fuel modelling work requires future expansion and more tests with different species from all regions of Bulgaria. However the estimated first steps are good basis for development and expansion of what is achieved so far.

Abstract
The combustion of forest fuels at laboratory scale is studied by using a Large Eddy Simulation (LES) fire simulator named ForestFireFOAM (FFF), based on the FireFoam package with the addition of a multiphase formulation adapted for highly porous fuel, such as pine needles. Experiments conducted with the FM-Global Fire Propagation Apparatus (FPA) were reproduced with FFF. Arrhenius-type laws were used to model the evaporation and pyrolysis rates. As these laws are temperature-dependent, the mass loss rate and the temperature distribution inside the fuel sample were selected as comparison criteria to better understand the porous fuel heating process using appropriate convective and radiative models and to better describe the burning dynamics of the fuel.

Keywords*: Pyrolysis, wildland fuel, FireFOAM*

Introduction

This study is dedicated to the modelling of the ignition and burning dynamics of pine needle litters. How these moist and highly porous fuels burn represents a fundamental research gap that leads to bigger gaps when it comes to studying their flammability and wildfire spread. This gap hampers the further development of risk indexes and CFD fire spread models. The main goal of this study is to apply a multiphase approach [1–3] that is often used to describe fire propagation [4–6] to the study of piloted ignition of wildland fuels. The multiphase model is based on the resolution of the set of conservation equations governing the time evolution of the coupled system formed by a porous vegetation and its surrounding gas medium, different sub models such as radiation, convection, turbulence, and combustion are included to close the model (Grishin & Albini, 1997). Some of these sub models are not directly relevant for piloted forest fuel ignition modelling at laboratory scale. Such as in (W Mell, Jenkins, Gould, & Cheney, 2007) where a large scale fire spread is started using an ignition line or in (Margerit & Sero-Guillaume, 2002) where an ignition temperature is used. Indeed, the heat and mass transfer processes involved are the same, but the *in situ* conditions lead to a different modelling of these processes due to the underlying assumptions. These assumptions are valid for propagation modelling but not in ignition modelling, since the flow could be laminar during the ignition phase, particularly under no-wind conditions before changing to a turbulent regime. An attempt to correct these models in order to simulate forest fuel ignition has been realised in (Consalvi, Nmira, Fuentes, Mindykowski, & Porterie, 2011). However, ignition procedure was not described thoroughly: The only given assumption was "the criterion for ignition is the thermal runaway in the gas phase: $\frac{\partial^2 T_{g,max}}{\partial t^2} = 0$, where $T_{g,max}$ is the maximum gas temperature at the vicinity of the pilot flame" (Consalvi *et al*., 2011).

The multiphase formulation was implemented in FireFOAM, a Large Eddy Simulation (LES) solver for fire application, in the C++ object-oriented toolbox of OpenFOAM. The modified solver is called ForestFireFOAM. In addition to presenting the theoretical approach, several strengths and weaknesses

of the current sub-models are identified by comparing simulations to results of fire experiments conducted in the FM-Global Fire Propagation Apparatus (FPA), by burning small samples of dry pine needles exposed to a radiative heat flux. Pine needle beds are used as a reference fuel because they are well characterised in literature and they allow obtaining repeatable fuel bed properties under laboratory settings. Simple modelling of the fuel degradation during the burning of the fuel sample is applied to understand flaming and smouldering. However, in this work the focus is only on heat transfer modelling before and until ignition in order to understand the heating process using appropriate convective and radiative models. It is important to understand this aspect since mass loss rates are highly dependent on the pyrolysis rate, which is usually modelled using an Arrhenius law that is a function of the fuel temperature.

Mathematical formulation

Solid fuel modelling

The solid fuel constituting a forest fuel layer and its interactions with the gas phase are represented by adopting a multiphase formulation [1]. This approach consists in solving the conservation equations (mass, momentum and energy) averaged in a control volume at an adequate scale that contains a gas phase flowing through N solid phases and considering the strong coupling between phases [2]. Here, only one solid phase is considered, and consists of particles of the same geometrical and thermophysical properties, providing the same behaviour. Physico-chemical processes such as pyrolysis, chemical reactions, char oxidation occurring in the solid and gas phases have to be taken into account as well as other phenomena including combustion, radiative and convective heat transfer. The required formulation is made of a set of coupled nonlinear equations, which are presented in (Morvan *et al*., 2009). The fuel bed is considered as a homogeneous distribution of solid particles whose dimensions and physical properties are evaluated from experimental data. Vegetation state must be characterized using the following set of physical variables: Fuel volume fraction (α_s), fuel density (ρ_s), surface area to volume ratio (σ_s), moisture content (Y_{H2O}), fuel temperature (T_s), and fuel composition.

Adjustments were made in order to better estimate the drag force ($\overline{F_i}$) resulting from the interaction between the gas flow and vegetation, in the momentum equation presented in (Morvan *et al*., 2009).

$$\overline{F_i} = \rho C_d \frac{\alpha_s \sigma_s}{2} \left\| \tilde{U} \right\| \tilde{u}_i \qquad (1)$$

The drag force coefficient C_d was averaged and considered constant (C_d =0.15) (Morvan *et al*., 2009). In this study, it is modelled depending on the mesoscopic Reynolds number, defined as:

$$Re_M = \frac{U}{\nu \sigma_s} \qquad (2)$$

where ν represents the air kinematic viscosity. This Reynolds number is compared to a transitional Reynolds number $Re_{M,lim}$ that takes into account the transition from Stokes to inertial flow (Lesieur, 2008). Since an intermediate flow is expected between these two regimes, it is hard to clearly define such a Reynolds number. However, vortices generated by the vortex shedding in the wake of vegetation elements exhibit dislocations responsible for a turbulent break-up (Williamson, 1992). The turbulent flow is then responsible for a constant drag coefficient (Nepf, Sullivan, & Zavitoski, 1997). That is why the Reynolds number accounting for the vortex shedding transition is retained, providing the upper limit for the transition from Darcian to Forchheimer flow. Since the surface area to volume ratio for cylinders of diameter (d) can be define as: $\sigma_s = 4/d$, the transitional Reynolds number for the vortex shedding is evaluated at $Re_{M,lim} \sim 50$ for litters, regarding their typical porosity [10, 11].

For 5% porosity litters:

$$C_d = \begin{cases} \frac{10}{Re_M} \text{ if } Re_M < Re_{M,lim}; \\ C_d = 0.2 \text{ else} \end{cases} \quad (3)$$

For 10% porosity litters:

$$C_d = \begin{cases} \frac{7.5}{Re_M} \text{ if } Re_M < Re_{M,lim}; \\ C_d = 0.15 \text{ else} \end{cases} \quad (4)$$

Turbulence and combustion

The turbulence model is based on the LES approach developed in the solver OpenFOAM ("OpenFOAM User Guide, OpenFOAM The Open Source CFD Toolbox ," 2010). The turbulent sub-grid scale stress is modelled by the eddy viscosity concept through a one-equation model for the turbulent kinetic energy K (Fureby, Tabor, Weller, & Gosman, 1997), with an additional sink term due to dissipation of sub-grid-scale energy in the canopy (Shaw & Patton, 2003):

$$\frac{D\bar{\rho}K}{Dt} = \frac{\partial}{\partial x_j}\left(\mu_t \frac{\partial K}{\partial x_j}\right) - \bar{\rho} C_d \alpha_s \sigma_s |U| K - C_\varepsilon \frac{\bar{\rho} K^{3/2}}{\Delta} - \rho \widetilde{u_i'' u_j''} \frac{\partial \tilde{u}_i}{\partial x_j} + W \quad (5)$$

$$W = -\frac{\mu_t}{Pr_t \bar{\rho}^2} \frac{\partial \bar{\rho}}{\partial x_j} \frac{\partial \tilde{p}_H}{\partial x_j} \quad (6)$$

$\Delta = (\Delta_x \Delta_y \Delta_z)^{1/3}$ represent the sub-grid filter size, Pr_t represents the turbulent Prandtl number and P_H the hydrodynamic pressure. Most combustion models [5, 12] use Eddy Dissipation Concept (EDC) models for the rate of combustion, which was developed for fully developed turbulent flow.

An extension of the EDC model was proposed (Ren, Wang, & Trouvé, 2013) where the characteristic time scale of fuel-air mixing is different under turbulent and laminar flow conditions. The fuel mass reaction is expressed as:

$$\overline{\dot{\omega}_F'''} = \frac{\bar{\rho}}{\min\left(\frac{k_{sgs}}{C_{EDC}\varepsilon_{sgs}}, \frac{\Delta^2}{C_{diff}\alpha}\right)} \min\left(\tilde{Y}_F, \frac{\tilde{Y}_{O_2}}{s}\right) \quad (7)$$

where $\tilde{Y}_F$ and $\tilde{Y}_{O_2}$ are the fuel and oxygen mass fraction, α is the thermal diffusicuity, C_{EDC} = 4 and C_{diff} = 10 [19]. The ratio $\frac{k_{sgs}}{\varepsilon_{sgs}}$ is the turbulent time scale and the ratio $\frac{\Delta^2}{\alpha}$ is the molecular diffusion time scale.

Convective heat transfer

The term representing the contribution due to convective heat transfer Q_{conv} between hot gases, the flame and the unburned solid fuel is written as follows in the energy balance equation (Morvan *et al.*, 2009):

$$Q_{conv} = \chi(T - T_s) \quad (8)$$

With T and T_s the gas and solid phase temperatures, respectively. The heat transfer coefficient χ is estimated for low Reynolds numbers, for which independent particle behaviour is observed (Raupach & Thom, 1981), hence the use Hilpert correlation (Incropera, DeWitt, Bergman, & Lavine, 2007) with the Nusselt number:

$$Nu = \frac{\chi D}{K} = C Re^m Pr^{1/3} \quad (9)$$

Providing the value of χ:

$$\chi = \frac{K}{D} C Re^m Pr^{1/3} \quad (10)$$

K is the air thermal conductivity and D is the effective diameter equivalent to $4/\sigma_s$. Hence, $Re = 4Re_M$. C and m are coefficients (Incropera *et al*., 2007) evaluated for a circular cylinder in cross flow. On the basis of the results on momentum absorption found in (Raupach & Thom, 1981), the same relationship and coefficients at low Reynolds are kept, where interactions between solid particles are negligible. At higher Reynolds, results from (Lamorlette & Collin, 2012) are used to take into account these interactions.

Re < 4	C=0.989	m=0.330
4 < Re < 40	C=0.911	m=0.385
40 < Re < 1560	C=0.683	m=0.466
1560 < Re	C=3.030	m=0.266

2.4. Radiative heat transfer

The term coming from the radiative heat transfer Q_{RAD} can be written as follows:

$$Q_{RAD} = \frac{\alpha_s \sigma_s}{4}[J - 4\sigma T_s^4] \quad (11)$$

$\frac{\alpha_s \sigma_s}{4}$ represents the solid fuel extinction coefficient for spherical particles [17–19]. The total irradiance J is:

$$J = \int_0^{4\pi} I d\Omega \quad (12)$$

Including the contribution of the flames (soot particles) and the embers, the Radiation Transfer Equation (RTE) can be written as follows:

$$\frac{d\alpha_g I}{ds} = \frac{\alpha_s \sigma_s}{4}\left[\frac{\sigma T_s^4}{\pi} - I\right] + \alpha_g \sigma_g \left[\frac{\sigma T^4}{\pi} - I\right] \quad (13)$$

Even if the soot particles in a flame can agglomerate adopting very complex forms, they are assumed spherical (Φ = 1μm). The soot field is calculated solving a transport equation for the soot volume fraction, assuming that the production rate of soot particles in the flaming zone is 5% (in mass) of the solid fuel pyrolysis rate. The contribution of soot oxidation is neglected in the flame. Considering that this soot production rate represents the maximum value reached in the under-oxygenated region of the flame, this source term is multiplied by the ratio $(Y_{O2}^* - Y_{O2})/ Y_{O2}^*$, representing the deviation from the oxygen concentration at atmospheric conditions. Then, the RTE is solved using a finite volume Discrete Ordinate Method (fvDOM), consisting of the decomposition of the radiation intensity I in a finite number of directions. The irradiance J is calculated by integrating this set of discrete contributions with a numerical Gaussian quadrature (Siegel & Howell, 1992).

Simulations, experiments and discussion

3.1. Experimental configuration

Experiments were performed with the FM Global Fire Propagation Apparatus (FPA), which provides controlled and repeatable conditions. Mass loss rate was measured and the exhaust gases were analysed for composition, heat release rate was deduced by calorimetry [21, 22] and vertical temperature was measured in the sample. Experiments were carried for dry *Pinus resinosa* (Red pine) for two different heat fluxes, 20 and 40 kW/m^2 with closed baskets and no flow injected in the FPA chamber where the sample holder is located. More details are provided in (Thomas, Everett, Simeoni, Skowronski, & Torero, 2013). The fuel properties are listed in table 1.

Table 1. Fuel properties

Species	$\alpha_s[-]$	σ_s [m^{-1}]	ρ_s [$kg.m^{-3}$]	$C_p[kJ.kg^{-1}.K^{-1}]$	$Y_{H2O}[-]$
P. resinosa	0.5	7024	776.6	1800	0.7

Numerical conditions

The set of transport equations in the gas phase are solved using a second order implicit Finite Volume (FV) method. Total Variation Diminishing (TVD) schemes have been adopted to avoid introduction of false numerical diffusion. The set of Ordinary Differential Equations governing the evolution of the solid fuel was solved using a second order explicit method. Two-dimensional calculations are performed to simulate ignition of pine needle litters in the FPA. BlockMesh and snappyHexMesh mesh generators supplied with OpenFOAM, generate robust meshes. However, geometrical complexities and rough edges can easily cause instabilities in the calculations. The pine litter is defined as a rectangular zone with the same dimensions as the sample holder. The pilot flame, located 10 mm above the top of the fuel litter, is represented by an area of size 50 mm x 10 mm providing 2 W to the fluid phase. The flow is simply induced by a pressure differential set at top of the FPA. The mesh is made of 0.8 mm by 0.8 mm square cells in the vicinity of the litter and near the lamps. The mesh is stretched vertically above the lamps and to the top, in order to reduce computational time. The domain geometry is presented in figure 1. Lamps were modelled by walls having the same location and orientation as the real lamps to obtain the same view factor. These walls have very high temperatures (see Table 2 in Results section), adapted in order to obtain the heat flux needed on the sample surface.

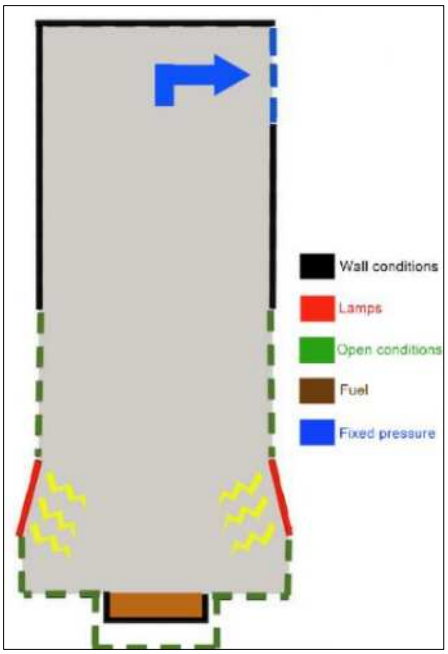

Figure 1. Simulated FPA configuration and boundary conditions

The radiative heat transfer equation is solved for a discrete number of finite solid angles. The accuracy can be increased by using a finer discretisation (Siegel & Howell, 1992):

$$n_{ray} = 4n_{\varphi}n_{\theta} \quad (14)$$

where n_φ and n_θ are the number of discretisation in azimuthal and polar angles, respectively. A sensibility study was carried to determine an adequate amount of discretisation because it is very computationally intensive. $n_\varphi = n_\theta = 8$ was found to be acceptable, providing a uniformly distributed radiative heat flux at the top of the fuel sample, as observed in the FPA.

3.3. Results

The computational time for simulating 10 seconds in parallel on 3 processors was 1h. After conducting a scalability analysis, it was found that the optimal number of cells per processor was 10,000. A snapshot of the temperature field at time t = 5 s after ignition is presented in figure 2.

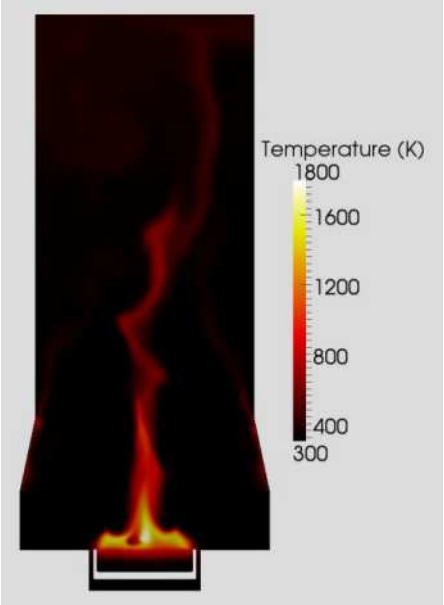

Figure 2. Temperature field 5 seconds after ignition

Preliminary results

In the first attempts to simulate the FPA experiments, the mass loss dropped very quickly. A large number of simulations were conducted to adjust the pyrolysis Arrhenius coefficients in order to have numerical mass loss rates matching the experimental ones. Further simulations were conducted with a maximum pyrolysis rate that could not be exceeded in order to prevent from a rapid mass loss drop. This particular behaviour occurs when the entire fuel is involved in the burning and temperatures become very high, hence the pyrolysis rate increases exponentially. Physically, it represents the fact that pine needles cannot expel all their pyrolysis gases at once. The maximum value of the pyrolysis rate is estimated TGA analysis (Safi, Mishra, & Prasad, 2004) by measuring:

$$\frac{\frac{dm}{dT}}{m} = 0.012\ K^{-1} \qquad (15)$$

with m, the fuel mass and T, the heating temperature. Finally, it was found that the temperature distribution inside the solid fuel was largely over estimated, as presented in figure 3.a and b. Indeed, the simulation for a heat flux of 20 kw/m^2 at the surface of the fuel, temperatures would provide results similar to the experiments done at 40 kw/m^2.

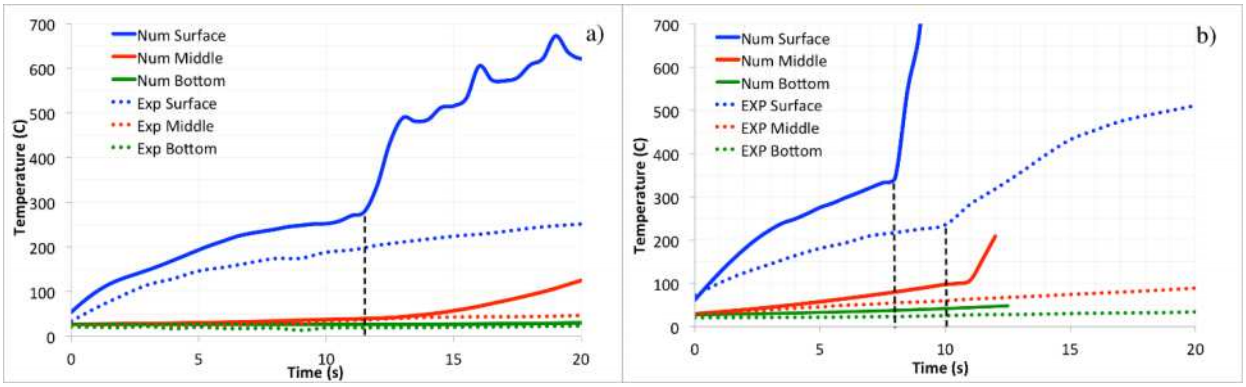

Figure 3. Experimental (dashed) and simulated (solid) temperature distribution in the surface, middle and bottom of the sample with dashed lines representing ignition time a) at 20 kW/m²b) at 40 kW/m².

This was due to the fact that the simulated lamps were assumed to radiate as a black body whereas the FPA heaters operate in very specific spectrum as observed [24, 25] and the fuel emissivity depends on the wavelength number (Monod *et al*., 2009). The halogen lamps of the FPA are very hot and their maximum of emission is shifted towards the lower values of the infrared spectrum, where the absorptivity of the fuels drops dramatically [24]. In consequence, the simulated temperature evolution and ignition times differed from the experiments. Therefore, in order to simulate the experiments performed in the FPA correctly, it was important to estimate the effective absorptivity of the vegetation under the FPA lamps and obtain the correct heat flux absorbed by the fuel.

The absorptivity of vegetation was provided from an experimental study of radiative properties of six vegetal species [18, 26]. Measurements were performed on a large spectrum that covers the spectral radiance spectrum of the FPA infrared heaters, which are very dominant in the near infrared field (0.7-2.5 μm). They can be considered as greybody radiators and the spectral intensity I can be represented by Plank's equation (Marcos Chaos, 2014). The averaged absorptivity is weighted over the normalised spectral radiative intensity at a specific temperature of interest. This temperature is the FPA lamps temperature, corresponding to a specific heat flux (Marcos Chaos, 2014). Simulations were conducted to fit the numerical effective absorptivity to best match the temperature distributions measured in the FPA for 20 kW/m^2 and 40 kW/m^2, as shown in figures 4.a and b, respectively. Experimental and numerical effective absorptivities are presented in Table 2. The main difference comes from the fact that the experimental effective absorptivities are obtained for the available species, whereas the numerical are fitted to match FPA experiments on red pine. Another study (Mcallister *et al*., 2012) using halogen/ quartz bulbs shows that the absorptivity of dry lodgepole pine needles is in the same range (0.576) under 50 kW/m^2 heat flux. The main difference comes from the fact that the experimental effective absorptivities are obtained for the available species, whereas the numerical are fitted to match FPA experiments on red pine.

Table 2. Experimental and numerical effective absorptivities for different heat fluxes

Heat flux (kW/m2)	Lamp Temperatures (K)	Experimental α_{eff}	Numerical α_{eff}
20	820	0.56	0.75
40	900	0.50	0.60

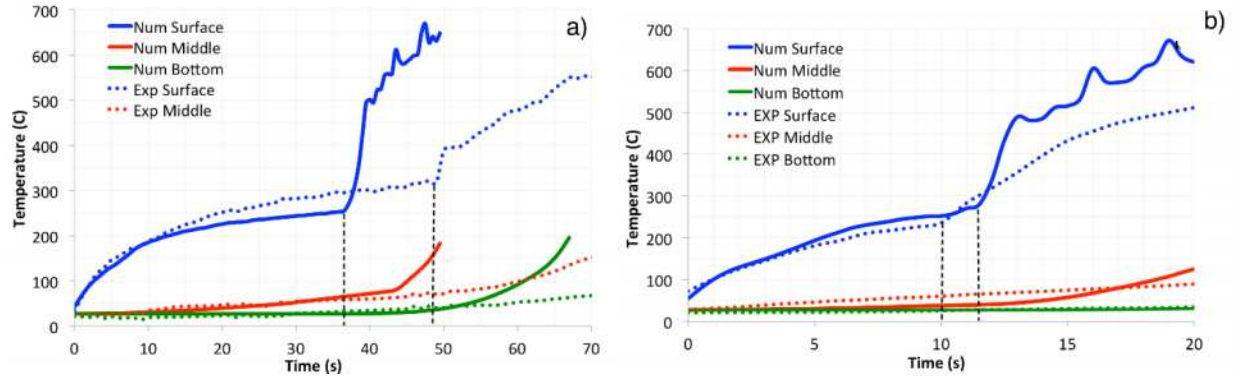

Figure 4. Experimental (dashed) and simulated (solid) temperature distribution in the surface, middle, and bottom of the sample with dashed lines representing ignition time. a) at 20 kW/m²b) at 40 kW/m²

The interesting part of figures 4.a and b covers mainly the temperature variations before ignition, during the heating of the sample only by the lamps of the FPA. In figure 4.a, the temperature evolutions are very similar until the fuel ignites in the simulation 15 seconds before the experiments. The small differences seen in the temperature distribution between experiments and simulations before ignition can be adjusted by modifying the extinction coefficient in equations (11) and (13), as done in (Acem *et al*., 2009). This effect is more pronounced for higher heat fluxes (see figure 4.b). These temperature distributions have large impact on the evaporation and pyrolysis rates, hence on the mass loss rate. The latter are presented for same conditions in figures 5.a and b for 20 kW/m^2 and for 40 kW/m^2, respectively.

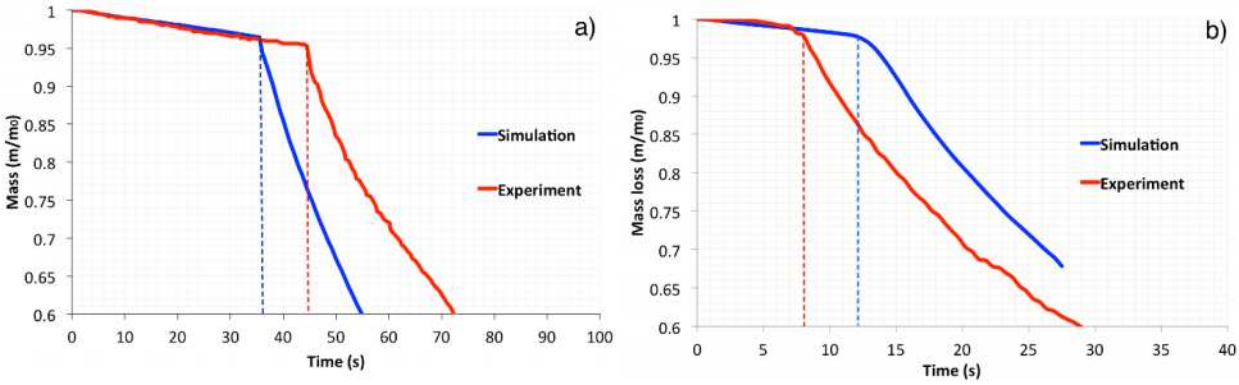

Figure 5. Experimental and simulated mass loss curves for a) 20 kW/m²; b) 40 kW/m². Dashed lines representing ignition time

The experimental ignition times are not exactly the same in figure 4 as in figure 5, since the experiments had to be done separately. Nevertheless, they have very similar tendencies. Mass loss curves are well reproduced until ignition, regardless of the imposed heat flux, but also right after ignition where pyrolysis is still very dominant. Indeed, if the ignition time is quite different, the slope is the same. It should be noticed that it is very difficult to match ignition times as they are happening due to a conjunction of marginal conditions [28, 29].

Conclusion

The use of a multiphase model to study the processes involved in piloted ignition of wildland fuels was found to be promising. However, the experimental conditions of the FPA are not easy to simulate. The fuel sample effective absorptivity has to be taken into account in the near infrared field, which is

quite low for pine needles (~ 0.5). The sub-models for the solid phase were able to describe sufficiently the heating (drying and pyrolysis) and ignition processes, including the mass loss rate prior to ignition for two different heat fluxes. Improvements in the models are currently in progress, such as better estimating the radiation extinction coefficient for pine needle litters, analysing pyrolysis gases with a Fourier Transform Infra Red spectroscopy (FTIR) in order to measure pyrolysis production in different conditions. These measured gases will improve the gas phase combustion modelling. Finally, the contribution of the smouldering phase due to char combustion will be studied, which will allow describing the processes involved at the end of the mass loss.

Acknowledgment

Professor Boulet is gratefully acknowledged for providing the spectral absorptivity of pine needles and the Méso-centre of Aix-Marseille University for providing computational resources.

Abstract
Wood cribs are often used as ignition sources for room fire tests. A fundamental understanding of the mechanisms that govern the burning rate of a wood crib may also have applications to wildland fires. The burning rate of unconfined cribs has long been identified to occur in two regimes: the densely-packed regime where the burning rate is proportional to the crib porosity and the loosely-packed regime where the burning rate is independent of porosity. Though the cribs used to define these burning regimes were primarily cubic in dimension, there are seemingly endless possible ways to build a crib with a given porosity. This work explores the burning rate of cribs with a wide variety of geometries in the loosely-packed regime to determine whether the porosity-burning rate relation in the literature holds. The porosity was kept approximately constant while the number of sticks per layer, number of layers and the length to thickness ratios (l/b) were varied. For l/b less than 36, the burning rate of all cribs matched the porosity-burning rate relation from the literature. For larger l/b, the burning rate was considerably reduced, implying that the crib porosity is a function of l/b above some critical threshold. A second set of experiments was performed to examine the effect of the spacing distance between the crib and the support platform. The critical spacing distance was shown to be larger than previously thought and a function of the length to thickness ratio. It was quite apparent that as the l/b ratio increases, a significant portion of the required oxidizer comes from the bottom of the crib, even for supposedly loosely-packed cribs. For the cribs with l/b = 48, a larger crib-platform spacing the increased the burning rate of these cribs so that the burning rate was closer to the cribs with smaller l/b. For cribs with l/b = 96, the burning rate was still well below the predicted value, even for large crib-platform spacing. Future work will focus on exploring the burning rate and the effect of the crib-platform spacing for cribs with large l/b.

Keywords*: burning rate, cribs, porosity, residence time*

Introduction

Wood cribs are often used as ignition sources in room fire tests (for example in UL 1715 and ISO 9705 test standards) and for various other tests requiring repeatable heat release rates, such as fire extinguisher performance (ANSI/UL 711). To vary the burning rate of the source fire, cribs can be built with different stick thicknesses and arrangements. Thus predicting the burning behavior of a crib a priori can be particularly useful when designing a new testing procedure. The prediction of the burning rate of a crib may also have applications outside of fire testing. The burning rate of wildland fuels, both in the litter layer on the forest floor and the trees and shrubs themselves is not well understood. Even though wildland fuels do not have the same predictable arrangement as wood cribs, it is possible that a fundamental understanding of what governs the burning rate of a crib will apply to the wildland fire context (Fons *et al*. 1963, Byram *et al*. 1964, and Anderson 1990). All wildland fuels are essentially individual fuel particles with some spacing distance between them. For the needle litter layer, this spacing is small and relatively homogeneous. For trees and shrubs, this spacing will be greater with more variability due to the needles and leaves occurring only along branches. Once the burning rate of wildland fuels is better understood, other aspects of wildland fire behaviour will

become more clear. For example, if the fuel loading and the burning rate of the fuel structure are known, the fireline intensity and flame zone depth can be estimated. These two parameters characterize the fluid dynamics and radiative and convective heat transfer that spread the fire. Thus the fire spread rate can be better predicted with a better understanding of the burning rate. One important complexity of wildland fires that is often overlooked is that most wildland fuels are not homogeneously distributed. Wildland fuels often occur in clumps, such as clumps of native grasses, shrubs, or trees. The residence time of the fire at a particular fuel clump can be determined from the burning rate of that fuel structure. This residence time is itself an important consideration for fire spread – if the residence time for a fuel structure is less than the ignition time for the next structure, the fire won't spread. This is of particular concern when discussing the thresholds for crown fire spread, a currently poorly understood aspect of wildland fire. And finally, this residence time is also important for fire ecologists when evaluating fire effects. An important key to predicting tree mortality is knowing the duration of heating. It is for these reasons that a closer look into the driving mechanisms of crib burning rates is currently being undertaken.

The burning rate of unconfined cribs has long been identified to occur in two regimes: open or loosely-packed and closed or densely-packed. In the loosely-packed regime, the burning rate is more closely approximated by the free burning rate of the individual sticks and is governed by heat and mass transfer processes near the surfaces. In this regime, the burning rate is more of a function of the stick dimensions, and is independent of the "porosity" of the crib. For cribs in the densely-packed regime, the burning rate is limited by availability of oxidizer within the fuel bed. In this regime, the burning rate increases with the inter-stick spacing or the "porosity" of the crib. There are many ways to evaluate the porosity of a crib (see for example Gross (1962), Block (1971), Heskestad (1973), and Anderson (1990)), but perhaps the most commonly used is that of Heskestad (1973). By recorrelating the data of both Gross (1962) and Block (1971), Heskestad suggested that the burning rate is a function of the crib porosity given by

$$\frac{R}{A_s b^{-1/2}} = f\left[\left(\frac{A_v}{A_s}\right) s^{1/2} b^{1/2}\right] \qquad (1)$$

where R is the burning rate (g/s), A_s is the exposed surface area of the sticks (cm^2), b is the stick thickness (cm), A_v is the area of the vertical shafts in the crib (cm^2), and s is the spacing between sticks (cm). This relation predicts the burning rates of the cribs burned in both Gross (1962) and Block (1971) well (±20%).

There are two important aspects that required close consideration when applying knowledge gained from crib theory to the wildland fire context. One is the effect of the crib size and layout. By necessity, wildland fuels will be represented by cribs with a wide range of external dimensions and stick spacing distances. The effect of the ratio of the stick length to the stick thickness will be important when considering different fuel types like needle litter versus slash fuels because this will change the fuel thickness (b) and flame zone depth (l). Another important aspect to consider is the effect of the spacing between the crib and the support platform. Ground fuels, like the needle litter layer, have no way of supplying oxidizer through the bottom surface. These fuels would thus be more like cribs placed directly on the support platform. On the other hand, crown fuels, like trees and shrubs, have ample oxidizer supply from the bottom. These fuels would be more like cribs with a large spacing distance between the crib and the support platform.

Unfortunately, the crib geometries tested by both Gross and Block that were used to generate the relation in Eq. 1 were fairly limited. Gross primarily tested cubic cribs, with ten layers with stick lengths equal to ten times the thickness. Block extended the length to thickness ratio of his cribs to 20. In the wildland context, the fuels clearly are not arranged in such cubic or nearly cubic designs. As one can imagine by looking at Eq. 1, there are seemingly endless possible ways to build a crib with a given porosity. Only a few others have considered a wider range of crib geometries and layouts. Byram

et al. (1964) tested the effect of crib footprint area by keeping the stick spacing (*s*) and crib height constant and increasing the length of the sticks. However, this was an early publication and no attempt was made to correlate the data. O'Dogherty and Young (1964) tested a wide range of crib designs, but were unsuccessful in using applying the Heskestad correlation to their data. Smith and Thomas (1970) and Thomas (1973) had more success in correlating the O'Dogherty and Young data with different relations that included the height of the crib. However, Thomas (1973) excluded cribs with "a large ratio of horizontal to vertical dimensions." In Smith and Thomas (1970), they included the results of Byram *et al*. (1964), but these data were poorly correlated. Clearly, the effect of crib geometry and layout is not well understood.

The only work in the literature found that considered the effect of the distance between the crib and the support platform is that of Block (1970). In this work, Block tested five crib designs with crib-platform spacing distance ranging from 0.159 cm (1/16") to 2.54 cm (1"). The burning rate of all cribs was seen to increase by about 15% as the spacing distance increased from 0.159 cm (1/16") to 1.27 cm (½"). For spacing distances larger than 1.27 cm (½"), no further change in the burning rate was seen. However, only five crib designs were tested and all cribs had a fixed stick length to thickness ratio (*l/b*) of 10, so it is difficult to say that these results are universal to all crib designs.

This work explores the burning rate of cribs with a wide variety of layouts and geometries to determine whether the correlation of Heskestad holds. The effect of the spacing distance between the crib and the support platform is also considered for a selection of crib designs.

Experiment description

The experimental chamber used was very large (12.4m x 12.4m x 19.6m) so that the airflow to the cribs was not restricted. Three load cells spaced equally apart were used to weigh the cribs during each test. As shown in Figure 1, two thin aluminum discs, separated by pins to reduce heat transfer to the load cells, were used as a support platform for the cribs. Multiple sheets of ceramic paper insulation were placed on top of the support platform to further minimize heat transfer to the load cells. A thermocouple was located near the load cells to assure that the temperature remained fairly constant. All cribs were conditioned in an environmental chamber at 35°C and 3% relative humidity for at least three days, resulting in an equilibrium moisture content of approximately 1%.

Simultaneous ignition of the cribs was achieved by quickly dunking the crib in isopropyl alcohol and allowing it to drain. The total mass of fuel used was 10% or less of the crib weight. The liquid fuel was observed to easily burn off before the steady state burning of the crib was achieved. Both mass and temperature were logged at 2 Hz. A sample of the raw data is shown in Figure 2, where four distinct phases of burning can be seen – burning off of the liquid fuel, stick ignition, steady burning, and burnout. Only data from the steady burning portion of the curve was used to calculate the burning rate. The burning rate was found from the slope of the best-fit line through the data.

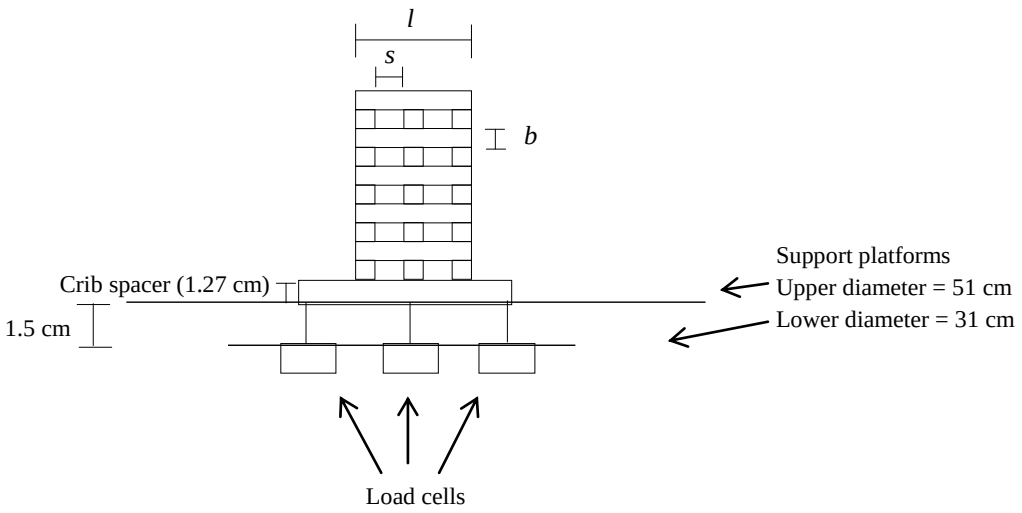

Figure 1. Sketch of apparatus for a crib with 3 sticks per layer (n = 3) and 10 layers (N = 10).

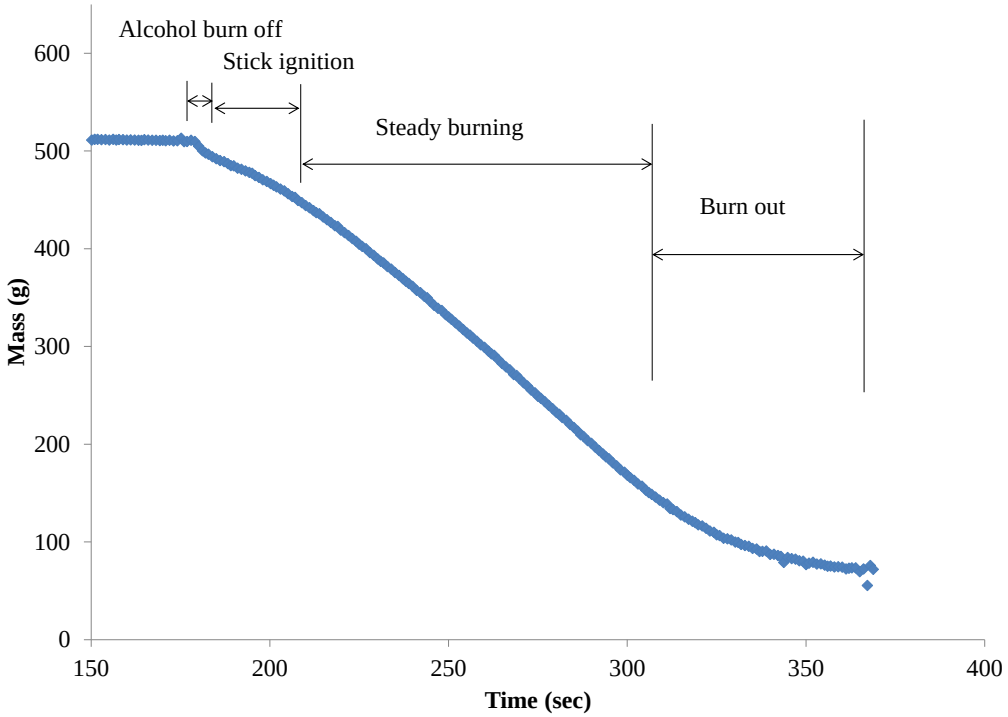

Figure 2. Sample raw data for 1.27-12-3-14 crib.

Wood cribs were built using square ponderosa pine sticks with thicknesses ranging from 0.159 cm (1/16 in) to 1.27 cm (0.5 in). In the first series of tests, a wide variety of crib designs were explored. Table 1 shows the details of all cribs burned. Each crib layout was tested three times and the results averaged. The first phase of experiments was performed to validate the testing apparatus against the known data of Gross (1962). In the second phase of experiments, the effect of crib layout in the loosely-packed regime was explored. The loosely-packed regime was chosen because it was indicated by Fons *et al*. (1963) that all wildland fuels would burn in this regime. For these experiments, the porosity factor of Heskestad (1973) (Eq. 1) was kept approximately constant while the number of sticks per layer, number of layers and the length to thickness ratios (*l*/*b*) were varied. The stick surface area was varied over an order or magnitude and (*l*/*b*) nearly an order of magnitude to really test the range of

validity of the Heskestad correlation. As indicated in Table 1, the number of layers must decrease to keep the porosity constant as more sticks per layer are added. For this set of experiments, the cribs were placed on two steel spacers of 1.27 cm (0.5 in) as this was the critical spacing distance indicated by Block (1970).

A second series of experiments was performed with a subset of the cribs to explore the effect of the spacing distance between the crib and the support platform. Spacing distances of 0 cm, 0.64 cm, 1.27 cm, 2.54 cm, and 7.62 cm were tested. The list of crib designs tested is listed in Table 2. Again, the cribs used here had an approximately constant porosity in the loosely-packed regime while a range of length to thickness ratios (*l/b*) was tested. Each crib layout was tested three times and the results averaged.

Results and discussion

Effect of crib geometry and layout

The burning rates of all cribs are listed in Table 3. As mentioned above, three replicates of each crib fire were performed. The average and standard deviation from these replicates are also shown in Table 3. The standard deviation ranged from less than 1% to about 10% of the mean value. The average burning rate for each crib layout is plotted in Figure 3 using the form of Eq. 1. The black line in Figure 3 is the correlation from Heskestad (1973).

As mentioned above, the first portion of the experiments were replicates of the experiments of Gross (1962) to validate the experimental procedure. The data from these experiments are marked in Figure 3 as solid diamond-shaped points. Heskestad's correlation fit the data of Gross (1962) and Block (1971) to within ±20% (Heskestad 1973), and the data here comfortably falls in that range. Some variation from the data of Gross is expected due to the differences in wood and moisture content of the cribs, in addition to the difference in spacing between the crib and the support platform. Gross used primarily Douglas-fir wood with average moisture content of approximately 9%, compared to the nearly dry ponderosa pine wood used here. Additionally, it appears that the separation distance used by Gross was equal to the fuel thickness (either 0.64 or 1.27 cm). A constant separation distance of 1.27 cm was used here. As mentioned above, Block noted that the burning rate changes up to 15% as the separation increase from none to a very large distance. These factors help explain the average difference 14% that was observed between the experiments here and those of Gross (1962).

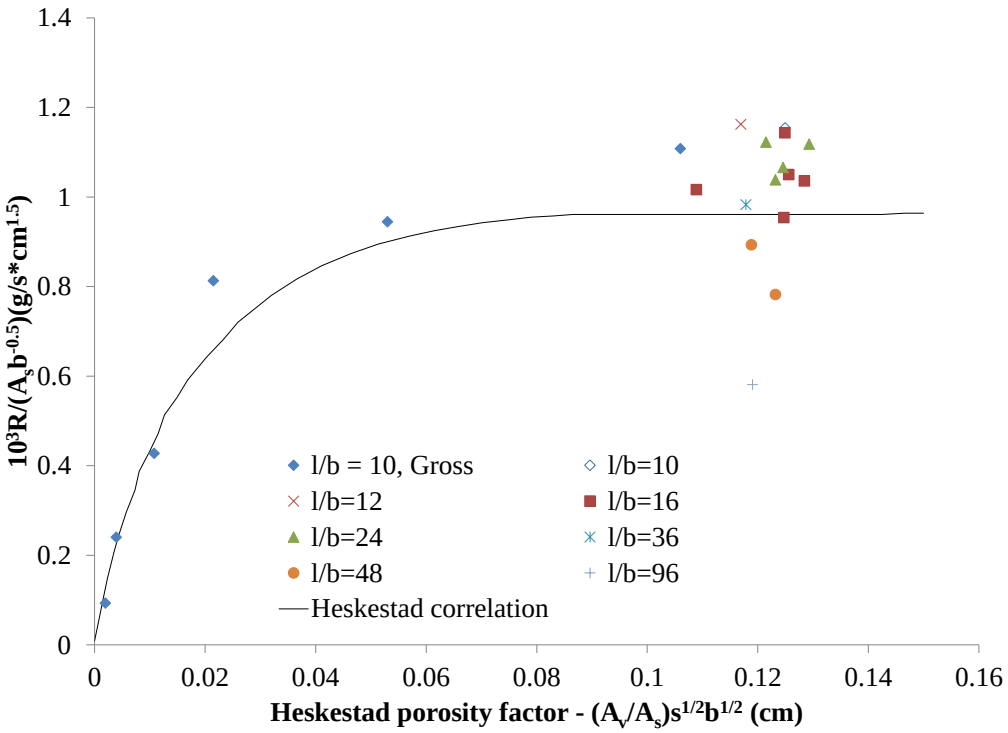

Figure 3. Burning rate results.

Because the layout of the cribs from the second set of experiments varied so widely, the burning rate results in Figure 3 were grouped by their length to thickness ratio (l/b) which ranged from 10 to 96. As listed in Table 1, a fairly wide variety of crib layouts for l/b ranging from 10 to 24 were tested. The burning rates from these cribs are shown in Figure 3 as diamonds for l/b =10, x's for l/b = 12, squares for l/b = 16, and triangles for l/b = 24. Interestingly, it appears that the burning rate of cribs within this range of l/b can be reasonably predicted with the Heskestad correlation, regardless of the crib layout. However, even though the porosity of all the cribs tested was approximately constant (and within the loosely-packed regime), the burning rate appears to decrease as the length to thickness ratio (l/b) further increases. For l/b less than or equal to 36, the burning rate is consistently above the Heskestad correlation. For l/b equal to 48, the burning rate falls below the Heskestad correlation by 7-19%, which is still in the noted range of variability of the correlation. However, for l/b equal to 96, the burning rate falls 40% below that of the correlation. Interestingly, this decrease in burning rate also corresponded to a visual change in burning regime. As this l/b ratio increased to 36 and above, it was observed that the cribs no longer burned simultaneously, but rather burned as propagating region from the outside edges inward as shown in Figure 4. A similar behaviour was noted when burning the densely-packed cribs in the first portion of the experiments. In other words, these loosely-packed cribs behaved like densely-packed cribs of a much lower porosity and the availability of oxidizer is controlling the burning rate as the l/b ratio increases. Thus, it appears that the crib porosity is also a function of the length to thickness ratio above some critical value of l/b.

Fig 4. Crib with l/b = 48 burning from the outside edges inward.

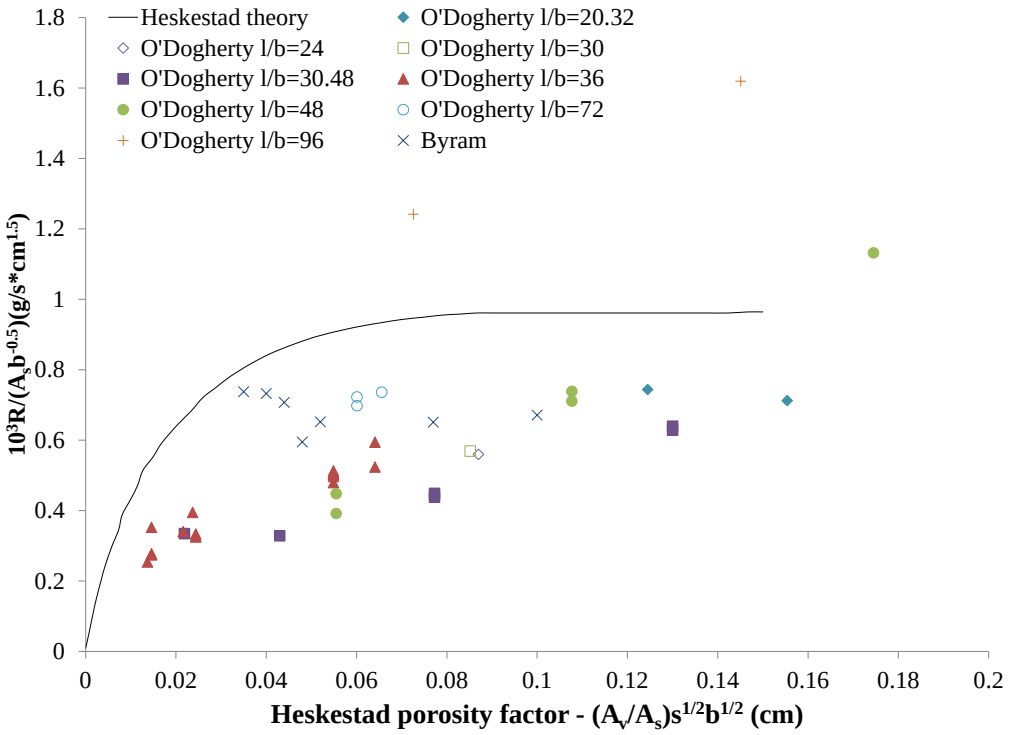

Figure 5. Burning rate data from O'Dogherty and Young (1964) and Byram et al. (1964).

To help clarify whether the porosity is a function of the length to thickness ratio, the results from O'Dogherty and Young (1964) and Byram *et al*. (1964) are considered. These are the only studies found in the literature that consider cribs with *l*/*b* greater than 40. Figure 5 shows the data of both O'Dogherty and Young (1964) and Byram *et al*. (1964) along with the Heskestad correlation. O'Dogherty and Young used white pine of 12% moisture content with *l*/*b* from 20.2 to 96. As mentioned earlier, their data was poorly predicted by the Heskestad correlation and the data is considerably scattered. The burning rate for cribs with (*l*/*b*) = 96 is significantly larger than the others and there is no clear trend in their data with (*l*/*b*). Byram *et al*. tested cribs of white fir with 10% moisture content. No spacing between the crib and support platform appears to have been used. In this study the stick spacing (*s*) and crib height were kept constant as the length of the sticks was increased. Consequently, the porosity of these cribs increased from a densely-packed crib to a loosely-packed crib as *l*/*b* increased from 9.1 to 61.4. As shown in Figure 5, when considered in the form of Heskestad

and Eq. 1, the transformed burning rate was relatively constant for all cribs considered. The densely-packed crib results with lower *l*/*b* ratios are reasonably close to the Heskestad correlation. However, as the *l*/*b* ratio increases above 25 (porosity of 0.048 cm) and the beds become more porous, the burning rates fall considerably below the Heskestad correlation. Interestingly, neither work mentions the spacing distance used between the crib and the support platform. The majority of the data from both studies falls below the Heskestad correlation suggesting that no spacing between the cribs and the platforms was used. Thus it is clear that a more thorough sampling of the burning rates from cribs with *l*/*b* greater than approximately 30 is needed to clarify whether a critical *l*/*b* ratio exists.

Though the studies of O'Dogherty and Young and Byram *et al*. don't help to clarify whether the porosity is a function of the length to thickness ratio, the low burning rates suggest that the spacing between the crib and the support platform could have a greater effect that that listed by Block (1971).

Effect of spacing distance between the crib and support platform

The results of the tests with variable spacing distance between the crib and the support platform are shown in Table 4 and Figure 6. As shown, the burning rate of cribs with *l*/*b* equal to 12 is virtually insensitive to the spacing between the crib and the support platform. In fact, a slight decrease in the burning rate was seen for the largest spacing distance tested (7.62 cm), possibly due to increased convective or radiative heat losses. As the ratio of *l*/*b* increases, however, the effect of that spacing drastically increases. In fact, at *l*/*b* equal to 96, the difference is over 60%. As in the experiments above, this decrease in burning rate is seen visually as well. As shown in Figure 7, cribs with a *l*/*b* ratio equal to or greater than 48 burn as a propagating region from the outside edges inward when the spacing between the crib and the support platform is small (0 to 1.27 cm). As the crib-platform spacing distance increases, the cribs begin to burn simultaneously, in a similar fashion to the cribs with *l*/*b* less than 48. It is quite apparent that as the *l*/*b* ratio increases, a significant portion of the required oxidizer comes from the bottom of the crib, even for supposedly loosely-packed cribs.

Table 4. Burning rate results for crib-platform spacing tests.

Shorthand (b-l/b-n-N)	l/b [ ]	Porosity (φ) [cm]	Mean R (g/s) 0 cm	Mean R (g/s) 0.64 cm	Mean R (g/s) 1.27 cm	Mean R (g/s) 2.54 cm	Mean R (g/s) 7.62 cm

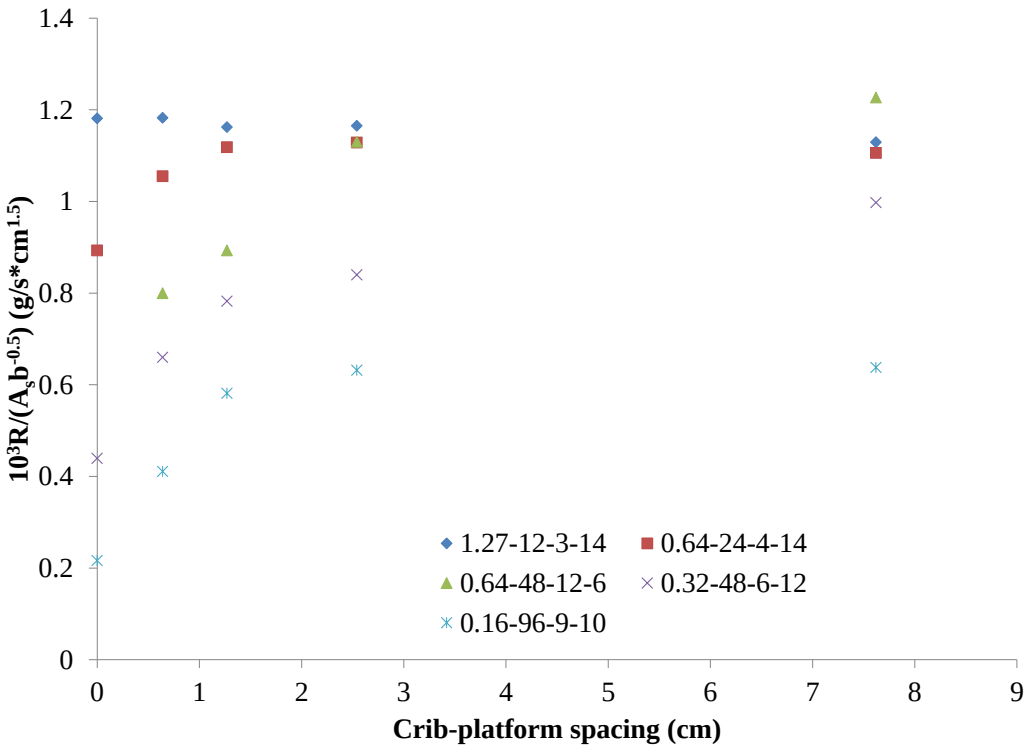

Figure 6. Effect of crib-platform spacing.

Figure 7. Visual change in burning regime for various crib-platform spacings for the 0.64-48-12-6 crib design. Top left: 0 cm spacing; Top right: 1.27 cm spacing; Bottom left: 2.54 cm spacing; Bottom right: 7.62 cm spacing.

Block (1971) noted a critical spacing of about 1.27 cm beyond which the burning rate of his cribs with *l/b* equal to ten did not change. By looking at Figure 6, this critical spacing distance seems reasonable for cribs up to *l/b* up to 24. For larger length to thickness ratios, however, the critical spacing distance is larger. For the cribs tested here with *l/b* of 48, the critical spacing distance appears to be over 2.5 cm. For these cribs, the burning rate increased by 7% for the 0.64-48-12-6 cribs and 15% for the 0.32-48-6-12 cribs as the spacing increases from 2.54 cm to 7.62 cm. Further tests are required at even larger spacing distances to identify the actual critical spacing distance, but it is clear that the change in burning rate is beginning to level off a value much larger than that identified by Block. Interestingly, the change in burning rate for the crib tested with a length to thickness ratio of 96 seems to level off earlier than the cribs with *l/b* of 48. In fact, the critical spacing distance seems to be around 2.54 cm. Because only one crib design with l/b of 96 was tested, it is difficult to know whether the reduction in the critical spacing distance as *l/b* goes from 48 to 96 is real or some artefact of the crib design, in particular the stick thickness. Either way, the critical spacing distance between the crib and the support platform is clearly a function of the length to thickness ratio and can be quite a bit larger than previously thought.

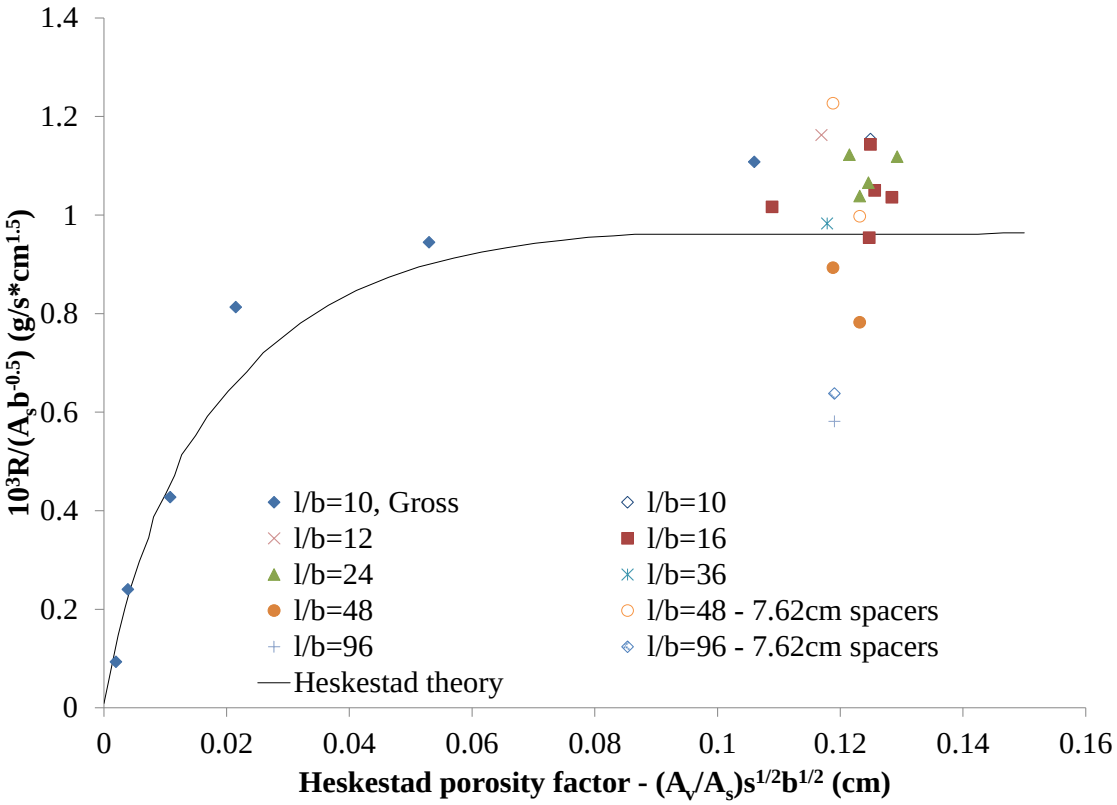

Figure 8. Burning rate including effect of crib-platform spacing.

Because such a large change in the burning rate for cribs with a large *l/b* ratio was seen with the increase in the crib-platform spacing, the Heskestad correlation was reconsidered to determine if the burning rate of these cribs would more closely match the correlation with a larger crib-platform spacing. Figure 8 shows the transformed burning rate as a function of the porosity with both the data from Figure 3 with a crib-platform spacing of 1.27 cm along with the data for cribs with *l/b* of 48 and 96 taken with a crib-platform spacing of 7.64 cm. As shown, the burning rates for the cribs with *l/b* of 48 and crib-platform spacing of 7.64 cm have indeed increased such that they are within the range of burning rate values measured for cribs with smaller *l/b*. However, the critical crib-platform spacing for crib design tested with *l/b* of 96 was much closer to the spacing used in the original series of tests,

so the burning rate for this crib design did not increase much and remains significantly below the Heskestad correlation. It is unknown whether this low burning rate is a real effect of the crib design, due possibly to the extremely thin sticks, or is the result of some effect of the experiment design. Because the sticks are so thin, the steady burning regime is very short (on the order of ten seconds), so it is possible that not all of the liquid fuel is immediately burned off. The measured burning rate would thus be dictated by the liquid fuel and not the sticks themselves and thus not as susceptible to changes in crib design. Additionally, the rate of data logging was fixed at 2 Hz, so fewer data points are available to perform a linear regression on so the error in these measurements may be larger. More crib designs with this stick thickness should be performed, particularly with smaller *l/b* ratios, to determine whether these results are due to the experimental protocol or are a true indication of the behaviour.

Summary and future work

Wood cribs are often used as ignition sources for room fire tests. A fundamental understanding of the mechanisms that govern the burning rate of a wood crib may also have applications to wildland fires. The burning rate of unconfined cribs has long been identified to occur in two regimes: the densely-packed regime where the burning rate is proportional to the crib porosity and the loosely-packed regime where the burning rate is independent of porosity. The cribs used to define these burning regimes were fairly limited in their design – either cubic (Gross 1962) or a fairly limited range of the stick length to thickness ratios (*l/b* = 10-20 in Block 1971). However, there are seemingly endless possible ways to build a crib with a given porosity. The first part of this work explored the burning rate of cribs with a wide variety of geometries to determine whether the porosity-burning rate relation defined by Heskestad (1973) holds. One round of experiments was performed to validate the testing apparatus against the known data of Gross (1962) and good agreement was found. A second round of experiments explored the effect of crib layout in the loosely-packed crib regime. The porosity was kept approximately constant while the number of sticks per layer, number of layers and the length to thickness ratios (*l*/*b*) were varied from 10 to 96. For *l*/*b* less than 36, the burning rate of all cribs matched the porosity-burning rate relation from Heskestad (1973), regardless of layout. For larger *l*/*b*, the burning rate was considerably reduced, indicating that there is an insufficient flow of oxidizer inside the crib even though the defined porosity indicates that it should in the loosely-packed regime. This implies that the crib porosity could be function of *l*/*b* above some critical threshold. The second part of this work explored the effect of the spacing distance between the crib and the support platform. The effect of spacing distance is strongly dependent on *l*/*b*, with no difference seen for *l*/*b* = 10 and over a 60% change for *l*/*b* = 96. From these experiments it was clear that cribs with a large *l/b* ratio require a significant amount of oxidizer to flow through the bottom of the crib. The critical spacing distance was shown to be larger than previously thought and a function of the length to thickness ratio. For the cribs with *l/b* = 48, a larger crib-platform spacing the increased the burning rate of these cribs so that the burning rate was closer to the cribs with smaller *l/b*. For cribs with *l/b* = 96, the burning rate was still well below the predicted value, even for large crib-platform spacing.
Because the number of cribs with *l*/*b* = 36 or larger was limited, future work will explore a wider variety of crib layouts with large *l*/*b* to see if the trends seen here hold and to determine if there is a threshold *l*/*b* where the porosity becomes dependent on *l*/*b*. As wildland fuels tend to be quite thin, more cribs with stick thickness of 0.16 cm should be tested. Understanding the effects explored here will be vital when applying crib theory to wildland fires. For example, the effect of crib spacing above the platform will be important when considering ground fuels versus crown fuels. The effect of (*l/b*) will be important when considering different fuel types (needle litter versus slash fuels will change *b*) and flame zone depths (will change *l*).

Acknowledgements

The authors wish to thank James McGuire for his tireless and careful construction of the cribs and Cyle Wold for setting up the data acquisition system. Funding for this work was provided by the National Fire Decision Support Center.

Abstract
Under conditions of extreme fire weather, bushfires burning in rugged terrain can exhibit highly atypical patterns of propagation, which can have dramatic effects on subsequent fire development. In particular, wildfires have been observed to spread laterally across steep, lee-facing slopes in a process that has been termed vorticity-driven lateral spread (VLS; also known as 'fire channelling'). Coupled fire-atmosphere modelling using large eddy simulation has indicated that the fire channelling phenomenon occurs due to a dynamic interaction between terrain modified winds and the fire's convective plume. This interaction creates pyrogenic vorticity that drives a fire laterally across a leeward slope. In this work we extend previous modelling, using the WRF-Fire coupled fire-atmosphere model, to specifically consider the environmental thresholds that define the likely onset of the VLS phenomenon. In particular we investigate the effects of wind speed and topographic slope on the occurrence of atypical lateral spread.
The simulated behaviour of fires on leeward slopes, and the implied transition in fire propagation that can occur when certain environmental thresholds are breached, highlight the inherent dangers associated with firefighting in rugged terrain. The propensity for dynamic interactions to produce erratic and dangerous fire behaviour in such environments has strong implications for firefighter and community safety. At the very least the research findings provide additional support for careful planning prior to prescribed burning operations and the use of well-briefed observers in firefighting operations undertaken in complex topography.

Keywords*: Dynamic fire propagation; environmental thresholds; wind-terrain-fire interaction; VLS*

Introduction

Dynamic escalation of wildland fires into large conflagrations represents a significant challenge to the management of fires in the landscape. Multi-scale interactions between a fire and the local environment, which includes fuels, weather and topography, can produce highly complex patterns of fire spread that are currently beyond the capabilities of operational fire spread models. Understanding the physical processes that underpin these complex modes of fire propagation is a key step in improving the way extreme bushfires are managed. Recent research into the behaviour of wildfires has identified a number of dynamic modes of fire propagation. These modes of fire spread are referred to as dynamic because they are manifestly at odds with quasi-steady fire propagation, whereby a fire spreads at an approximately constant rate given uniform environmental conditions.
Viegas (2005) and Dold and Zinoviev (2009) examined the ability of a fire to exhibit exponentially increasing rates of spread up steep slopes and canyons, while Viegas *et al.* (2012) discussed the abrupt increases in rate of spread that can occur when two lines of fires intersect at some oblique angle. Another form of dynamic fire propagation was identified by Sharples *et al.* (2012) in connection with the 2003 Canberra bushfires. This phenomenon, which they referred to as *fire channelling*, involved the rapid lateral propagation of a fire across a lee-facing slope in a direction approximately perpendicular to the prevailing wind direction. Sharples *et al.* (2012) conjectured that the lateral spread was due to an interaction between the wind, the terrain and an active fire.

Simpson *et al*. (2013) found support for this conjecture using the WRF-Fire coupled fire-atmosphere model through simulation of the interaction of the terrain modified flow with the fire's convective plume. It was found that this interaction resulted in the intermittent generation of vertical vorticity, which drove the fire laterally across the top of the slope in the immediate lee of the ridge line. As such, Simpson *et al*. (2013) permitted the characterisation of fire channelling as vorticity-driven lateral spread (VLS). Farinha (2011) conducted a number of combustion tunnel experiments to examine the behaviour of fires burning on the leeward slope of a small triangular ridge. He found that in the absence of wind the fires burnt uniformly across the slope at a distinctly quasi-steady rate of spread. In the presence of combustion tunnel winds of 1.5 m s^{-1}or greater Farinha (2011) found that the fire spread rapidly across the top of the leeward slope at a significantly accelerated rate. The rate of lateral spread varied with the speed of the wind, with the greater rates of lateral spread coinciding with the fastest wind speeds.

In the present paper, the study of Simpson *et al*. (2013) is extended to examine the effect of variation in wind speed and topographic slope on the occurrence of VLS across a lee-facing slope. Fires burning on lee-facing slopes under different wind speed and topographic slope regimes were simulated using WRF-Fire. Two sets of simulations were considered. In the first, the winds were taken as coming from the west with the ambient wind speed characterised in terms of a reference wind speed U_0. The topography was taken to be an idealised triangular mountain with a north-south oriented ridge line, such as was considered by Simpson *et al*. (2013). The windward and leeward slopes were taken to be 20° and 35°, respectively. The reference wind speed U_0 was prescribed values of 0, 2.5, 5, 7.5, 10 and 15 m s^{-1}. The aim of this part of the study was to ascertain if there is a wind speed threshold, below which VLS does not occur.

In the second set of simulations, the reference wind speed was fixed at U_0 = 15 m s^{-1}. The topography was again taken to be an idealised triangular mountain with a windward slope of 20°, but with a leeward slope α° that was varied between 10° and 45°. This part of the study was designed to examine the existence of a threshold topographic slope, below which VLS does not occur. Such environmental thresholds are hypothesised to exist based on the role that flow separation in the lee of the ridge plays in driving the VLS phenomenon (Simpson *et al*. 2013). Flow separation is only expected to occur when wind speeds are sufficiently strong and the leeward slope is sufficiently steep (Wood, 1995).

The 'deep flaming' associated with the VLS phenomenon (Sharples *et al*., 2012) can act as a strong source of pyro-convection, and so systematically establishing the environmental thresholds relating to VLS will provide improved guidance for predicting the onset of extreme pyro-convection and blow-up fire behaviour. As such, the present study has direct implications for firefighter and community safety.

Methods

Version 3.5 of the Weather Research and Forecasting (WRF) model (Skamarock *et al*., 2008) is used in a large eddy simulation (LES) configuration (Moeng *et al*., 2007) and coupled to the SFIRE fire spread model (Mandel *et al*., 2011). This coupled atmosphere-fire numerical modelling system, commonly referred to as WRF-Fire, is suited to modelling turbulent atmosphere-fire interactions on length scales of tens of metres to kilometres. The WRF-LES model explicitly resolves grid-scale atmospheric eddies, whereas the effects of subgrid-scale motions are modelled using a subfilter-scale stress model. WRF utilises fully compressible nonhydrostatic equations and has a mass-based terrain-following coordinate system. The WRF-LES model domain has dimensions of 15 km × 5 km × 5 km with open radiative boundaries. The horizontal and vertical grid spacing are both 50 m, although due to the use of mass levels the vertical grid spacing is not constant. A triangular mountain is located within the model domain, as shown in Figure 1, with its ridge line oriented perpendicular to the prevailing wind. The windward and leeward slope angles are 20° and 35°, respectively, and the mountain height is 1 km. The initial and lateral boundary conditions are specified using a 1D sounding

with a vapor mixing ratio of zero, a constant potential temperature of 300 K and a wind profile given by U0, which expressed as a function of the Cartesian coordinates (x,y,z), is

$$\mathbf{U}_0(x, y, z) = U_0 P(z)\mathbf{x} \quad (1)$$

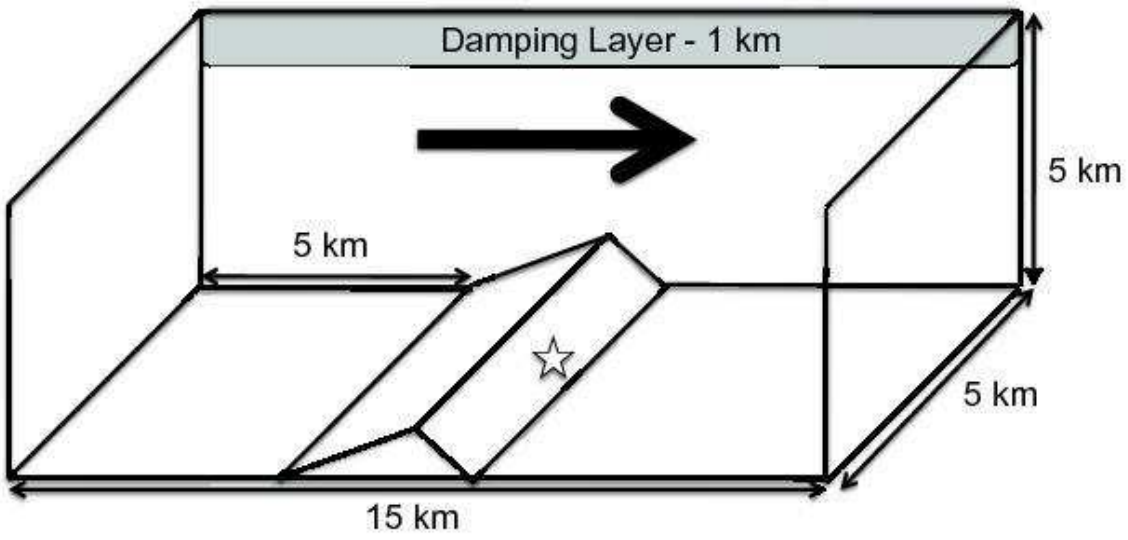

Figure 1. Model domain showing the triangular mountain with its ridge line oriented perpendicular to the input wind field. The windward slope is inclined at 20° and the leeward slope is inclined at an angle of α° (α = 35° in the first set of simulations and is variable in the second set of simulations). The star on the leeward slope indicates the approximate location of the ignition used in the simulations.

Here U0 denotes the reference wind speed – the main variable of interest in this study, and x denotes the unit vector in the x-direction (which coincides with east). The function P(z) in equation (1) prescribes the vertical structure of the initial wind field profile, and is defined as:

$$P(z) = \begin{cases} \left(\frac{z}{200}\right)^2, & z \leq 200, \\ 1, & z > 200. \end{cases} \quad (2)$$

We use a quadratic profile here, rather than the usual logarithmic profile, for the sake of simplicity and, more importantly, so that our results are directly comparable with those of Simpson *et al*. (2013). WRF offers either a physical (not used) or free-slip (used) bottom boundary condition. Since the lowest model level is still above the actual ground level, we don't have a completely zero wind speed on any WRF model level. However, it should be noted that a fuel-dependent roughness length is used in vertically interpolating the wind speeds down to the mid-flame height.

The WRF-LES model is used in an idealised configuration and there is no modelling of the microphysics, radiation physics, cumulus physics and the surface and planetary boundary layers. However, it should be noted that a fuel-dependent roughness length is used in vertically interpolating the wind speeds down to the mid-flame height. Diffusion in physical space is calculated using the velocity stress tensor and the eddy viscosities are calculated using a 3D prognostic 1.5-order turbulence closure scheme. A Rayleigh damping layer in the top 1 km is used to prevent reflection of the pyro-convective plume from the model top. The primary model time integration is performed using a third-order Runge-Kutta scheme and a secondary time step is used to handle acoustic waves. The primary and secondary model time steps are 0.1 s and 0.0125 s, respectively.

A small circular fire is ignited in the SFIRE model near the base of the leeward slope (Figure 1), after a WRF-LES spin-up period of 20 min. The subsequent fire spread is modelled on a 10 m × 10 m

horizontal grid as a temporally evolving fire perimeter using a level set method. The spatially and temporally varying fire spread rate, S, is calculated using the Rothermel equation (Rothermel, 1972):

$$S = R_0(1 + \varphi_W + \varphi_S). \quad (3)$$

The base rate of spread, R_0, is dependent on the parameterised fuel properties. The slope correction factor, φ_S, is calculated using the local terrain in SFIRE. The wind correction factor, φ_W, is calculated from the WRF modelled wind speeds, which are vertically interpolated to an estimated mid-flame height. The "heavy logging slash" Anderson fuel category (Anderson, 1982) is used to initialise the fuel conditions homogeneously across the SFIRE model domain. The parameterised fuel properties include the initial mass loading, fuel depth, surface area to volume ratio, moisture content of extinction and rate of mass loss following ignition.

The two-way atmosphere-fire coupling between SFIRE and WRF-LES is achieved through the release of latent and sensible heat from the modelled fire. For 1 kg of fuel combusted in SFIRE there is 17.43 MJ of sensible heat released into the WRF-LES model, which is about a factor of ten higher than the latent heat released for the fuel type used. These heat fluxes are distributed throughout the WRF-LES vertical levels using an exponential decay function and directly modify the atmospheric conditions surrounding the modelled fire. The two-way coupling in WRF-Fire allows it to directly model atmosphere-terrain-fire interactions down to length scales of tens to hundreds of metres.

Results

Wind speed threshold

Sharples *et al*. (2013) considered the lateral spread characteristics arising for different reference wind speeds. Specifically, they considered reference wind speeds of U_0 = 0.0, 2.5, 5.0, 7.5, 10.0 and 15.0 m s^{-1}. In each case the model output was examined for instances of significant lateral spread (i.e. spread in the north-south direction). Figure 2 summarises the lateral spread rates for each of these cases. For the U_0 = 0.0 m s^{-1} simulation the lateral propagation of the fire occurs at a quasi-steady rate of around 0.2 km h^{-1}. In this case the fire spread predominately towards the west, without any indication of dynamic fire spread. Similarly, Figure 2 shows that the U_0 = 2.5 m s^{-1} case exhibited lateral fire spread consistent with the quasi-steady assumption.

In the U_0 = 5.0 m s^{-1} simulation, the fire spread exhibited a small lateral bulge towards the north (most notably at around 70 minutes after ignition). However, the rate of lateral spread displayed in this case was not significant compared to the other cases for U_0 > 5.0 m s^{-1}. Figure 2 indicates that for all of the cases with U_0 > 5.0 m s^{-1} the fire spread laterally at a significant faster rate. Moreover, this atypical lateral spread occurred immediately after the fire reached the ridge line at about 20-25 minutes after ignition. For the U_0 = 10.0 m s^{-1} and 15.0 m s^{-1} cases the lateral spread rates reach values as a high as 5 km h^{-1}, which is approximately 25 times larger than the quasi-steady lateral spread rates seen in the U_0 = 0.0 m s^{-1} and 2.5 m s^{-1} cases.

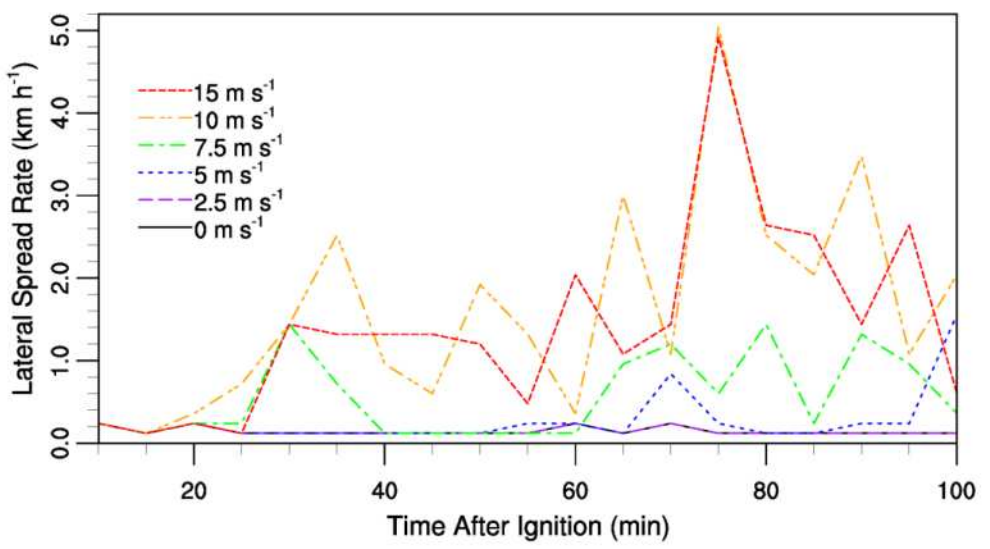

Figure 2. Maximum lateral spread rate for different reference wind speeds.

Topographic slope threshold

The simulations were conducted using a reference wind speed of U_0 = 15.0 m s^{-1}, but assuming different lee slope angles. Specifically, we considered α = 10°, 15°, 20°, 25°, 30°, 35°, 40° and 45°. The resulting patterns of fire spread can be seen in Figure 3, which shows the time of ignition of various points within the domain of interest. Figure 3 shows that for lee slope angles α < 25°, the pattern of fire spread does not exhibit any significant lateral spread beyond what might be expected from a fire spreading under a quasi-steady regime. The simulated fire spread for the α = 25° case indicates some propensity for lateral fire spread, though the pattern of spread is quite different to that observed in the α > 25° simulations. The α = 25° case may therefore be viewed as marginal with regards to the onset of dynamic fire behaviour. For the remaining cases, for which α > 25°, the pattern of fire spread exhibits a clear tendency for significant lateral spread. Moreover, for larger values of α the lateral spread is more confined near the apex of the idealised ridge.

Interestingly, the threshold slope angle of $\alpha \approx 25°$ identified here is in good agreement with the threshold value determined by Sharples *et al*. (2012) in their empirical analysis of VLS events in the 2003 Canberra fires.

Discussion

The propagation of a fire burning on a lee-facing slope was simulated using the WRF-Fire model under a number of different wind speed and topographic slope conditions. In the first set of simulations the fires exhibited two different modes of behaviour. Under the two lowest wind speed regimes the fires did not exhibit any atypical lateral spread, in stark contrast to the two highest wind speed regimes, for which the simulated fires exhibited significantly faster lateral spread. The results suggest the existence of a threshold wind speed, below which the prevailing winds are too weak to drive the vorticity-generating interaction between the wind, the terrain and the fire's plume, so that no atypical lateral spread occurs. The model simulations further suggest that this threshold occurs for wind regimes characterised by $U_0 \approx 5$ m s^{-1} (approx. 20 km h^{-1}).

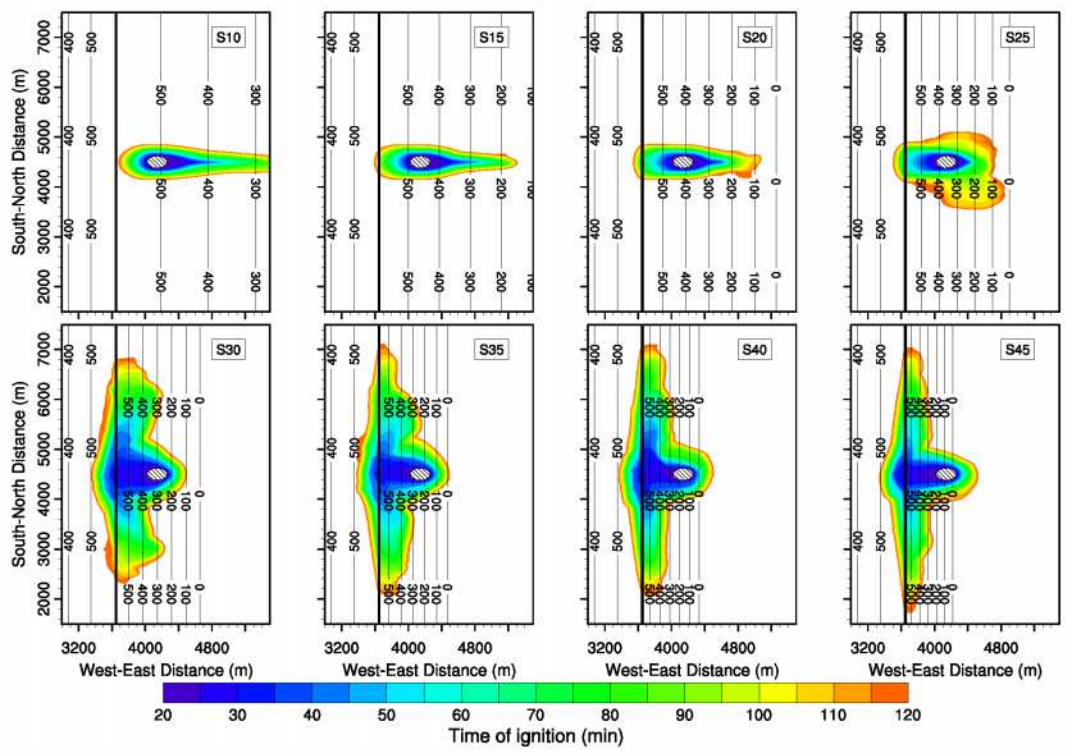

Figure 3. Time of ignition for different lee-facing slope inclinations. The various inclinations are indicated in the top right of each panel; for example, "S15" denotes a lee slope angle of 15°.

In the second set of simulations, in which the wind speed was fixed at U_0 = 15 m s^{-1}, the fires again exhibited two different modes of behaviour. For leeward slope angles less than 25° the fires did not exhibit any significant lateral spread, while for leeward slope angles above 25° the fire spread was dominated by lateral propagation across the leeward slope.

The threshold values determined in this study are in good agreement with the empirically determined values given by Sharples *et al*. (2012). In their study they reported a threshold topographic slope threshold of ~ 26° and a wind speed threshold of 20-25 km h^{-1}. The thresholds determined in the present study are also in general agreement with the values of wind speed and leeward slope angle required for separation of the prevailing winds from the terrain surface (Wood, 1995). As such, the modelling results presented above tend to support the role of flow separation in driving the VLS phenomenon.

Farinha (2011) reported a threshold wind speed of ~ 1.5 m s^{-1} for the occurrence of VLS in their laboratory scale experiments. Although more work is clearly required, comparison of Farinha's value of 1.5 m s^{-1} with the threshold wind speed of ~ 5 m s^{-1} determined above provides preliminary insight into scaling requirements when translating between the laboratory and landscape scales.

The present study has considered the environmental thresholds relating to wind speed and topographic slope. However, this consideration treated the two environmental variables independently, whereas it is quite likely that there is some interdependence of wind speed and topographic slope in defining the threshold to VLS occurrence. For example, for a fixed leeward slope of α = 30°, it is quite possible that the threshold wind speed will be different to that determined for the α = 35° case. These issues will be addressed in ongoing research along with consideration of other environmental variables such as wind direction and topographic aspect.

Conclusions

The existence of environmental thresholds relating to the onset of VLS established here has a number of implications for fire operational and firefighter safety. Indeed, the results obtained here imply that significant changes in fire behaviour can result from relatively small changes in the environmental factors that drive wildfires. For example, with a slight increase in wind speed or a small variation in topographic slope, firefighters working on leeward slopes could very rapidly find themselves in great peril, when only a short time before their safety had not been in doubt.

Abstract
Wildland fire behavior models are commonly used to augment expert opinions, experiments and field observations by both the research and management communities. However, modelling wildfires is challenging in part due to complex set of coupled processes that drive the properties of a spreading wildfire. Further these processes occur over a vast span of spatial and temporal scales that further complicate the development and validation of models. Due to these complications there has been a variety of model types developed for a variety of specific applications. Regardless of the type and purpose of a model, well quantified fire behavior data from wildland fires and field and laboratory experimental fires are necessary for a variety of reasons including the calibration of empirically based models, the evaluation of physically based or theoretical models, and to provide model developers with potential areas to improve model performance by identifying inadequacies in the code. Here we utilize a compiled data set of crown fire rate of spread from Alexander and Cruz (2006) to evaluate published crown fire rate of spread predictions from two physics-based fire behavior models HIGRAD/FIRETEC developed at Los Alamos National Laboratory and the Wildland Urban Interface Fire Dynamics Simulator (WFDS) developed by the National Institute of Standards and Technology and the USDA Forest Service. Our preliminary results suggest that physics based models reasonably predict the crown fire rate of spread given the current data set. In addition we discuss the sensitivity of physics based models to a variety of parameters which likely influence crown fire rate of spread.

Introduction

Wildland fire behaviour models are commonly used to augment expert opinions, experiments and field observations by both the research and management communities. However, modelling wildfires is challenging in part due to complex set of coupled processes that drive the properties of a spreading wildfire. Further these processes occur over a vast span of spatial and temporal scales that further complicate the development and validation of models. Due to these complications there has been a variety of model types developed for a diversity of specific applications. Along with these developments has also come a wide array of assumptions, simplifications and approximations that are employed in the development of the models to achieve the desired level of detail and calculation time. Regardless of the type and purpose of a model, well quantified fire behaviour data from wildland fires as well as field and laboratory experimental fires are necessary for a variety of reasons including the calibration of empirically based models, the evaluation of physically based or theoretical models, and to provide model developers with potential areas to improve model performance by identifying inadequacies in the code. If model limitations and uncertainties are understood model simulations can provide insights into the interpretation of experimental data, help inform the design of future experiments and be utilized as a cost-effective and safer way to study wildland fire behaviour. However, large field-scale fire experiments or wildland fires can be expensive to conduct, often have limited data about the environmental conditions and fuels complex and rarely if ever have replication;

whereas laboratory-scale experiments, though less expensive and easier to replicate, generally do not provide data that cover the range of spatial and temporal scales typical of free burning wildfires.
The speed at which a fire propagates across a landscape, referred to as the rate of spread, depends upon interactions between a number of processes including the heat transfer rate, moisture evaporation and combustion rates and is one of the most commonly predicted metrics of fire behaviour. Recent studies have compiled empirical data from wildland fires and large-scale experimental fires on the rate of fire spread for surface and crown fires. This data has been utilized to evaluate current empirical surface and crown fire rate of spread models and to suggest potential inadequacies in current empirical fire behaviour modelling systems. However to date there have been no comparisons of simulations performed with physics-based models. Instead these evaluations have primarily involved empirical fire behaviour models.
In this paper we utilize a compiled data set of crown fire rate of spread from Alexander and Cruz (2006) to evaluate published crown fire rate of spread predictions from two physics-based fire behaviour models HIGRAD/FIRETEC developed at Los Alamos National Laboratory and the Wildland Urban Interface Fire Dynamics Simulator (WFDS) developed by the National Institute of Standards and Technology and the USDA Forest Service. In addition to evaluating crown fire rate of spread predictions from physics-based models we also utilize our results to investigate the potential sources of variation in crown fire rate of spread measurements and provide guidance on future research needs.

Description of physics based models

Physics based models such as HIGRAD/FIRETEC and WFDS use a computational fluid dynamics approach and a three-dimensional grid to describe to model the critical physical phenomena and their interactions that control the behaviour of a wildland fire through a set of coupled partial differential equations. This approach allows for the evolution of various quantities such as temperature, velocity of gaseous species and the characteristics of the fuel to be described spatially and temporally in the simulation domain. The vegetation in physics-based models is often described as a porous medium with mean or bulk quantities such as surface area to volume ratio, moisture content and density within the 3-d grid. Such an approach allows for the simulation of fires in areas with complex fuel beds (i.e. varying at small spatial scales) and variable topography.

Methods

Database Compilation

Alexander and Cruz (2006) compiled a total of 57 wildfire observation from North American forests. The data set consisted of 43 fires from Canada primarily occurring in boreal forest fuel types and 14 fires from the United States that occurred in pine dominated fuel types in the interior Rocky Mountains, the Lake States and the south-eastern U.S. During the development of this data set, any case study that lacked adequate data, occurred in areas with a mix of fuel types that do and do not support crown fire or occurred in areas with complex topography (>10% slope, or cross slope fire spread) were removed. For the remaining observations they reported the major fuel type, the temperature (°C), the relative humidity (%), the effective fine fuel moisture (%), the Canopy Bulk Density (kg m^{-3}) and the 10-m open wind speed (km h^{-1}). Although this data set did have a relatively large amount of detailed information regarding the rate of fire spread several calculations were performed by Alexander and Cruz (2006) to ensure a complete data set. Specifically they: 1) adjusted the 6.1 meter open wind speed for the U.S. data by a factor of 15% to approximate the 10-m open wind speed, 2) inferred the canopy bulk density using a variety of methods on a case-by-case basis, and estimated the effective fine fuel moisture content using equations published by Rothermel (1983) and assumed that all fuels were

shaded from solar radiation. Despite the need for additional calculations to complete the data set, this remains the largest data set assembled to date on crown fire rate of spread.

3.2. Crown Fire Rate of Spread Predictions From Physics-Based Models

Because various models require data in different forms and with different levels of details, it was not possible to directly simulate the wildfires contained in the Alexander and Cruz (2006) data set. Rather we identified published crown fire rate of spread values from physics based simulations and developed a data base that included their rate of spread (m s^{-1}), the 10-m open wind speed (m s^{-1}), the maximum canopy bulk density (kg m^{-3}), and the effective fine fuel moisture content (%). We identified a total of 50 simulations from physics based models, 22 of which were conducted using HIGRAD/FIRETEC and 28 of which were conducted using WFDS. These simulations were conducted using primarily fuels data from pine dominated or mixed conifer systems.

3.3. Analysis

Because we were not able to directly simulate the 57 fires contained within the Alexander and Cruz (2006) data set we used linear regression to evaluate the relationship between the 10-m open wind speed and the crown fire rate of spread and predicted non-simultaneous 95% confidence bounds for a new observation. We than compared the simulated crown fire rates of spread from HIGRAD/FIRETEC and WFDS to these bounds.

Results and Discussion

Our results to date show that overall crown fire rate of spread predictions from HIGRAD/FIRETEC and WFDS perform fairly well as compared to the field derived estimates of crown fire rate of spread from Alexander and Cruz (2006). Of the 50 physics-based simulations we compared, 12% (6 total simulations) did not fall within the 95% confidence prediction bounds (figure 1). These 6 points represented 21% of the WFDS simulations and over-predicted the expected rate of spread. There are a variety of reasons that could explain the larger than expected number of points that fall outside the 95% predictive bounds including the sensitivity of the simulated results to wind flow parameters, horizontal and vertical fuel distribution, ignition methods, and fireline shape. Our future work will explore the sensitivity of physics-based models to these parameters. In addition uncertainties in measurements for field experiments such as those compiled by Alexander and Cruz (2006) need to be better documented.

Experimental and numerical study of fire behaviour: effects of the width on the rate of spread

Alexis Marchand, Nicolas Trevisan, Anthony Collin and Pascal Boulet

LEMTA, 2 Avenue de la Forêt de Haye TSA 60604 54518 Vandoeuvre-lès-Nancy cedex,
alexis.marchand@univ-lorraine.fr

Abstract
This study focuses on the influence of the fuel bed width on the rate of spread. An experimental set-up based on visible cameras combined with image processing was used and a direct linear transformation (DLT) algorithm was developed in order to quantify fire propagation features such as the rate of spread, the fire length, ... The present work gathers results aimed at demonstrating the dependence of the rate of spread on the fire front morphology. A new cellular automaton was developed to better understand the heat transfer mechanisms, investigating in particular the role of radiative transfer.

Introduction

Every year, several million hectares of vegetation are burnt by forest fires or bush fires, ravaging both flora and fauna. The knowledge of the fire behaviour is an important issue in order to prevent from disaster or to try to control the fire propagation. In this frame, the accurate estimation of the propagation rate is of major interest for the fire prevention.
It is commonly accepted that the rate of spread depends on the vegetation properties, the topography and the meteorological conditions. Some fire propagation codes, such as Farsite [1] and Behave [2], take these parameters into account when simulating the fire behaviour. However, these models are unable to include the real fire front morphology (fire length, shape ...) in their predictions. The rates of spread are evaluated only for linear fire fronts and can overpredict the fire propagation in many other configurations. Only physical models involving space varying terms in balance equations, namely in radiation or convection models, are really able to reproduce the real fire behaviour.
Fingering (burnt areas with small fire front widths) is an example of a non linear configuration in real fires. In 2001, pictures of real fires taken from satellite were analysed by Caldarelli [3], focusing on the fractal dimension and lacunarities observed in fires. Indeed satellite images show the existence of fingerings. At this scale, the fire propagation is affected by the fire front morphology, as it was already observed experimentally by Anderson in 1968 [4]. It is very important to model efficiently the fire behaviour at small scale (meter scale) in order to predict accurately the fire front evolution against time.

The aim of this contribution is to demonstrate through experimental data or numerical results that the rate of spread depends on the fuel bed width. Moreover this paper gives some issues to explain this phenomenon.
This contribution is divided as follows: Section 1 presents the platform PROMETHEI used to generate surface fires and the experimental data on the fire front. Section 2 details and analyzes the obtained experimental results. Section 3 presents the fire propagation model developed using the concept of cellular automaton. Section 4 proposes some comparisons between experimental and numerical results, giving some issues for a better understanding of the interaction between the fire front morphology and the rate of spread. Section 5 draws some conclusions and perspectives concerning this work.

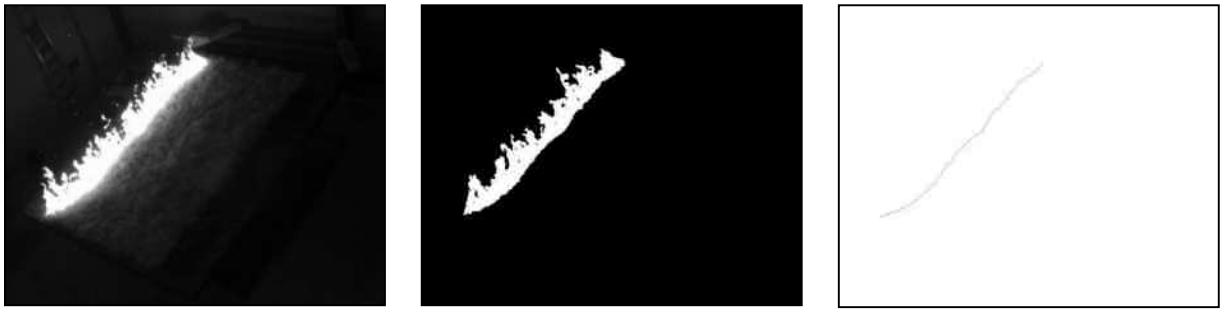
Experimental set-up

Our experimental fire platform, named PROMETHEI, was used to provide a database on surface fires. This platform was built to better understand the fire behaviour and to calibrate or to validate the fire propagation model.
Experiments were carried out on a combustion table using excelsior as fuel bed (Figure 1). In order to observe different fire front morphologies, the fuel bed width was varied in the range between 25 cm to 3.5 m, the fire being ignited on a line along the whole bed width. In such configurations, the fire fronts are near-parabolic, but the front curvature varies with the line width and the rate of spread is also affected. The vegetation load was set at 0.5 kg/m².

Figure 1. Picture of surface fire front propagation

Image analysis

Pictures of the flame front during the fire propagation were taken with 4 visible cameras, 2 cameras for the back edge and 2 for the leading edge. Typical images are presented in grey-scale in Figure 2(a). The post-processing algorithm which was used, is based on an Otsu algorithm [5]. When this approach is applied, the flame volume is then clearly identified (Cf. Figure 2(b)). The leading edge and the back edge are then localized by two pixel swaps, horizontal and vertical crossing pixel method (Cf. Figure 2(c)). This method was repeated on all the pictures taken during the fire propagation.

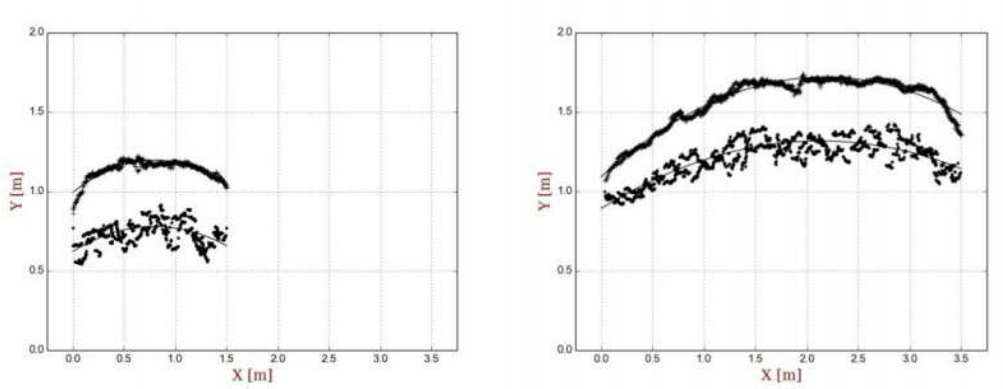


(a) (b) (c)

Figure 2. (a) Image in grey-scale obtained from one camera (b) Binary image after Otsu algorithm application (c) Detected fire front

Front reconstruction

The leading edge and the back edge were first localized on each picture, through pixel coordinates (Cf. Figure 2(c)). A direct linear transformation (DLT), method based on the work by Pastor *et al.* [6] was then applied on each pixel to merge the fire front in a real space in meter. Two examples of fire front detection are given in Figure 3(a) and Figure 3(b) for two different fuel bed widths (*L*).



(a) ***(b)***

Figure 3. Fire front (top and back front) reconstructions after DLT algorithm (a) L = 1.5 m at t = 75.1 s after ignition (b) L = 3.5 m at t = 106.3 s after ignition

Repeatability and validation

In order to evaluate the accuracy of the image analysis, the results (in terms of rate of spread) provided by the Otsu-DLT algorithm were compared with the ones obtained using three other methods : (i) evaluation using chronometers (simple measurement of the distance with time of the most advanced point of the fire front) (v_{ch}), (ii) registration based on thermocouples (v_t), (iii) evaluation using dedicated photo-resistors (adapted from the work by Catchpole *et al.* [7]) (v_p). All these techniques were involved on the same experimental conditions, repeated 4 times. For the evaluations based on thermocouples and photo-resistors, the method consists in detecting a peak (of temperature or intensity) at several locations on the combustion table, allowing the estimation of the fire front location and then of the rate of spread. For this test, the experiment involved a fuel bed 2 m wide and 3 m long, with the vegetation load set at 0.5 kg/m². Results are gathered in Table 1.

The results obtained with the Otsu-DLT algorithm (v_{ca}) are first discussed. For the same experiment, the results vary in the range between 1.49 and 1.6 cm/s and the average rate of spread is estimated at 1.55 cm/s. The mean discrepancy is then evaluated at 2.7% which proves the good repeatability of the experimental device. Concerning the comparison with the other experimental methods, the mean

discrepancies are in the range from 1.7 to 4.6%. These small differences demonstrate the good accuracy of the Otsu-DLT algorithm involved in this work.

Table 1. Comparison of the different methods for rate of spread measurements [cm/s]

Experiment number	v_{ca}	v_{ch}	v_p	v_t	Mean discrepancies [%]
#1	1.6	1.51	1.45	1.63	4.6
#2	1.49	-	1.42	1.51	1.7
#3	1.53	1.49	1.45	1.50	3.4
#4	1.59	1.58	1.51	1.59	1.9

2.4. Environmental conditions

The physical properties (Lower Heating Value, Higher Heating Value, Residual Humidity, Residual Vegetation Ratio and Heat Capacity) of E*xcelsior* used in this study were characterized by the LERMAB laboratory, France. All these features are gathered in Table 2.

Table 2. Characteristics of the excelsior combustible

16180	20180	12.4	0.27	1430

In order to study the change in the rate of spread as a function of the fuel bed width, two series of experiments were carried out in different environmental conditions (see Table 3). For each experiment, relative humidity and temperature were given by a weather station. The environmental conditions were near constant during each experiment as it can be observed in Table 3.

Table 3. Environmental conditions

Width Fire [m]	Relative Humidity [%]	Temperature [°C]
0.25	64	6.1
0.5	66	6.4
0.75	67	6.9

Results

Rate of spread

Figure 4 gives an example of results provided by the Otsu-DLT algorithm (for experiment #1 with a 3.5 m fuel bed width). The locations of the leading edge and the back edge were estimated as a function of time. The evolution is clearly linear, even at the first instants when the propagation starts. The rate of spread was deduced from the slope of the lines using a least squares method.

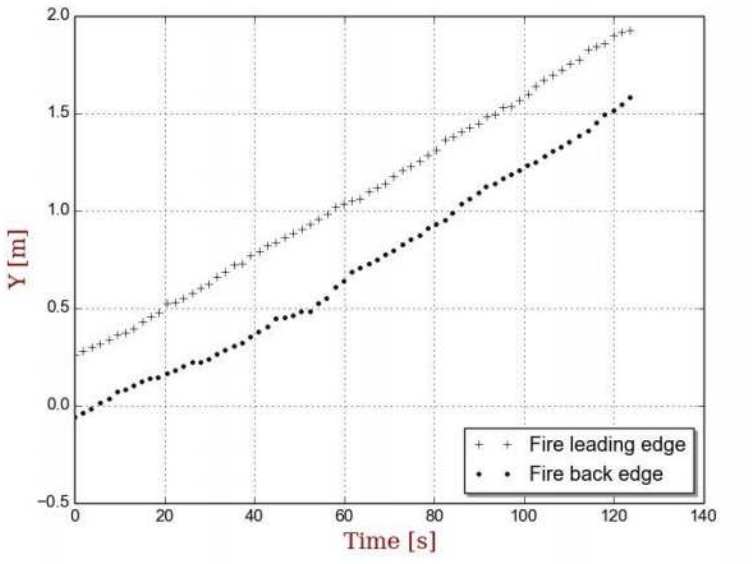

Figure 4. Example of fire front locations as a function of time, fire leading edge and back edge for a bed width L = 3.5 m

The evolution of the rate of spread (ROS) as a function of the fuel bed width is plotted in Figure 5 for Experiments #1 and #2. The ROS quickly increases for small fuel bed widths (between 25 cm to 100 cm) and reaches an asymptotic value above a 100 cm width. The limiting ROS is 1.6 cm/s for Experiment #1 and 1.3 cm/s for Experiment #2. As results tend to follow an exponential law, a fit of the ROS was sought for each experiment with the following relationship

$$ROS(L) = A_1\left(1 - exp\left(-A_2 L\right)\right)$$

The parameters A_1 and A_2 were estimated using a least squares method, yielding the following values:

- Experiment #1: A_1 = 1.28 cm/s and A_2 = 3.04 m^{-1}
- Experiment #2: A_1 = 1.62 cm/s and A_2 = 2.24 m^{-1}

The predictions based on these parameters are in good agreement with the experimental results as presented in Figure 5. A_2 parameter seems to be universal for this kind of experiment (for given vegetation and load) whereas A_1 parameter clearly depends on environmental conditions.

Fire thickness

The fire thickness was measured for the different experiments using the Otsu-DLT algorithm. For a given fire, the two fronts are interpolated with a second order polynomial, such as $Y(X) = aX^2 + bX + c$ (X and Y are the two coordinates associated with the combustion table). Such polynomial interpolations were presented in Fig 3(a) and Fig 3(b). The fronts were represented using

100 points equally spaced along the fire line. The thickness was then defined as the average distance between the two lines for a given *X* coordinate. Figure 6 gives the thickness evolution against the fire width. The fire thickness seems to be independent of the fire width. The average fire thickness is estimated at 33 cm (with average discrepancy of 7%) for Experiment #1 and at 24 cm for Experiment #2 (with average discrepancy of 4%). It can be observed that the ROS of Experiment #1 is slower than the one of Experiment #2, whereas its thickness is larger than the one of Experiment #2.

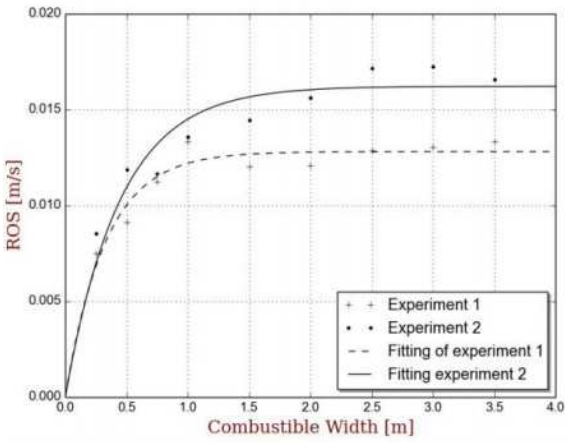

Figure 5. Evolution of the ROS with combustible width

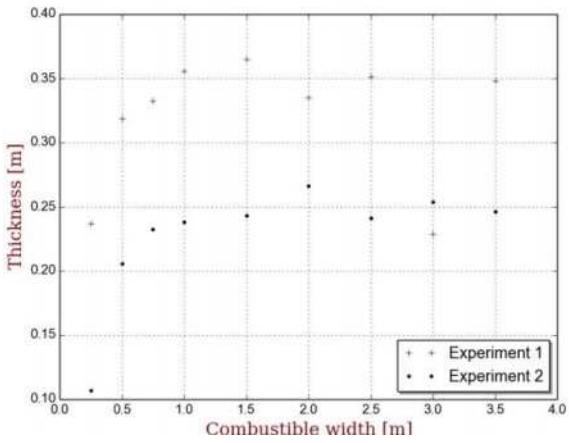

Figure 6. Evolution of the fire thickness with combustible width

3.3. Fire leading edge length

During the fire propagation, for a given time, the fire front is here modelled by a second order polynomial ($Y(X) = aX^2 + bX + c$). The total length of the fire front is then calculated as:

$$Length = \int_{Fire\ Front} ds = \frac{1}{4a}\left(Argsh(2aL+b) - Argsh(b) + (aL+b)\sqrt{(aL+b)^2} - b\sqrt{b^2+1} \right)$$

The evolution of the fire front total length against the fuel bed width is represented in Figure 7. The total length of the fire front is the same for the two experiments. Its evolution is linear with a slope close to 1 (accurate value equal to 1.02). The results demonstrate that the shape (or the length) of the fire front is independent of the environmental conditions.

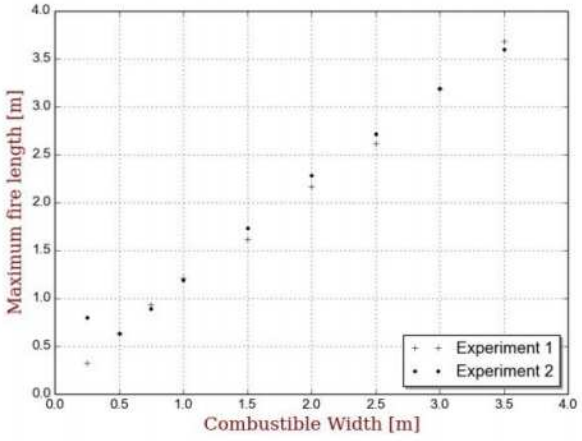

Figure 7. Evolution of the flame front length against the fuel bed width

Automaton model

4.1. Method

This model is based on the work by Porterie *et al.* [8]. The fuel bed is represented by a set of elementary hexagonal cells. The physical properties are assumed to be constant on the numerical domain. Radiation is supposed to be the main heat transfer involved in the fire propagation.

A cellular automaton model consists in associating a given state to each cell. The state of a cell is governed by a dimensionless time, τ. In the present work, the cells are described by one of these states:

(1) raw material ($\tau=0$) **(2)** heating ($0<\tau<\tau_d$)

(3) burning ($\tau_d<\tau<\tau_d+\tau_c$) **(4)** burned vegetation ($\tau_{d+}\tau_c<\tau$)

This kind of models requires a clear definition of the transition law between two states *i* and *j*, and the model parameters τ_d and τ_c. These transition laws can be experimentally defined or they can be extended from a physical model.

When the radiative transfer coming from the flame front is incident on the raw vegetation, the cell state switches from 1 to 2. The cell is heated due to the radiative transfer until a flame appears above the studied cell. At each iteration, an additional $\Delta\tau$ is associated to the characteristic time τ of the considered cell, with $\Delta\tau$ defined as,

$$\Delta\tau = A \sum_{Flame\ cell} \varphi_{Flame\rightarrow vegetation}$$

where *A* is a model parameter and $\sum_{Flame\ cell} \varphi_{Flame\rightarrow vegetation}$ is the total radiative contribution of the fire front toward the studied cell.

$\varphi_{Flame\rightarrow vegetation}$ is the radiative flux from one of the cells located on the fire front toward the "vegetation" cell. The flame is assumed to be represented by an equivalent cylinder with an absorption coefficient κ and a flame temperature T_f. The radiative contribution is evaluated thanks to a view factor calculation and $\varphi_{Flame\rightarrow vegetation}$ is defined by :

$$\varphi_{Flame\rightarrow vegetation} = 4\,F\,\kappa\,\sigma\,{T_f}^4\,V_f S_{cell}$$

V_f is the flame volume, S_{cell} the cell "vegetation" surface and *F* is the view factor evaluated as

$$F = \frac{1}{4\pi V_f}\sum_{\theta i}\left(g\left(Lc,R_f,H_f,\theta i\right) - g\left(Lc,R_f,0,\theta i\right) - g\left(Lc,0,H_f,\theta i\right) + g\left(Lc,0,0,\theta i\right)\right)\Delta\theta$$

where θi is discretized between 0 and 2π using a $\Delta\theta$ step. *Lc* is the distance between the burning cell and the "vegetation" cell. The *g* function is defined by

$$g(l,r,z,\theta) = \sqrt{l^2 - 2rl\cos(\theta) + r^2 + z^2} + l\cos(\theta)\ln\left(r - l\cos(\theta)\right) + \sqrt{l^2 - 2rl\cos(\theta) + r^2 + z^2}$$

The main advantage of this quasi-analytical relationship for *F* is to avoid the use of an accurate but time-consuming numerical method, such as a Monte Carlo Method to model the radiative transfer.

When τ is equal to τ_d (which represents the time of pyrolysis) the cell switches to state (3). It stays in state (3) during a time τ_c which describes the time during which the cell is burning. After burning, the state of cellular changes to (4).

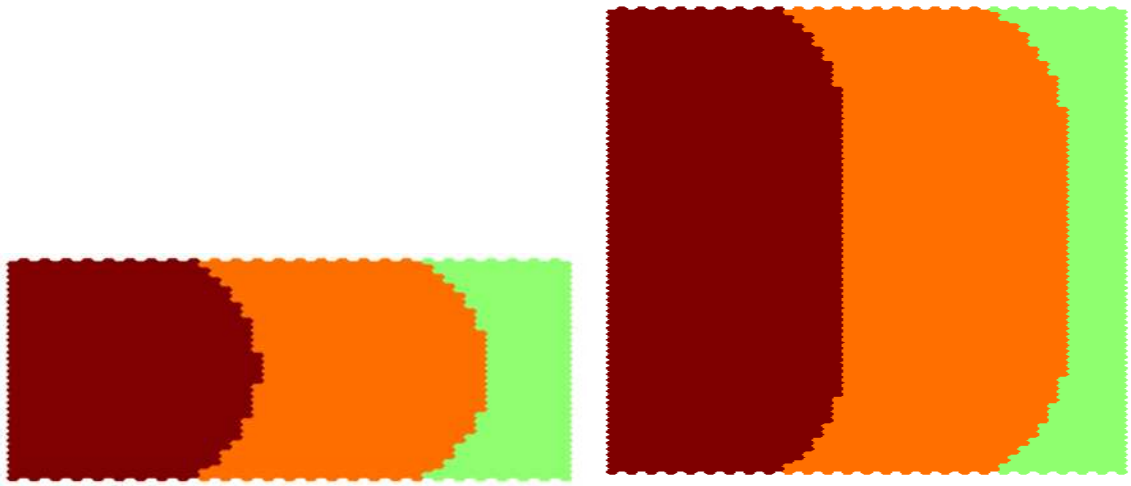
Table 4. Cellular automaton model parameters

Edge of Hexagon [m]	Flame temperature T_f [K]	Absorption coefficient κ [1/m]	Flame height H_f [m]	$\tau_{d/A}$	τ_c
0.025	1733	0.1	0.4	50	13

The parameters used for the numerical study are gathered in Table 4. T_f, κ and H_f are identified using a PSO (Particle Swarm Optimization) algorithm with experimental data on radiative heat flux measured during a fire propagation test.

4.2. Numerical results and comparisons

Numerical simulations were done considering the fuel bed width in the range between 0.25 m and 4.0 m. Figure 8 gives two examples of fire propagations for fuel bed widths equal to 1.5 m and 3.5 m.
At this stage, the present model is able to capture some qualitative trends experimentally observed; in particular the model captures the parabolic shape of the fire fronts. These shapes must be compared with experimental measurements given in Figure 3 (a) and 3(b).



(a) ***1.5 m fuel bed width*** ***(b) 3.5 m fuel bed width***

Figure 8. Fire front spread simulated with the automaton model. Green: cellular in state (2) Orange: cellular in state (3) Brown: cellular in state (4) at 38th iteration.

One aim of the study was to show the ROS dependence on the bed width. As it was previously mentioned, the ROS depends on the environmental conditions, which are not directly involved in the present model. However, as it was observed in Figure 5, the ROS for the two experiments seem to follow the same trend. Hence, in order to compare the results, each rate of spread was divided by its asymptotic value. The corresponding evolution of the normalized ROS with the width is represented in Figure 9 (experimental fits and numerical values). The agreement is quite satisfactory. The evolution of the ROS with the fuel bed width is well described by the cellular automaton model, despite the fact that only the radiative transfer is considered in the heat transfer. Moreover, as the ROS does not vary for a fuel bed width above 1 m, this demonstrates that the radiative transfer coming from the fire front does not affect the vegetation which is located at a distance beyond 1 m. In other words, 1 m is the cut off distance for the radiative transfer in this kind of experiment.

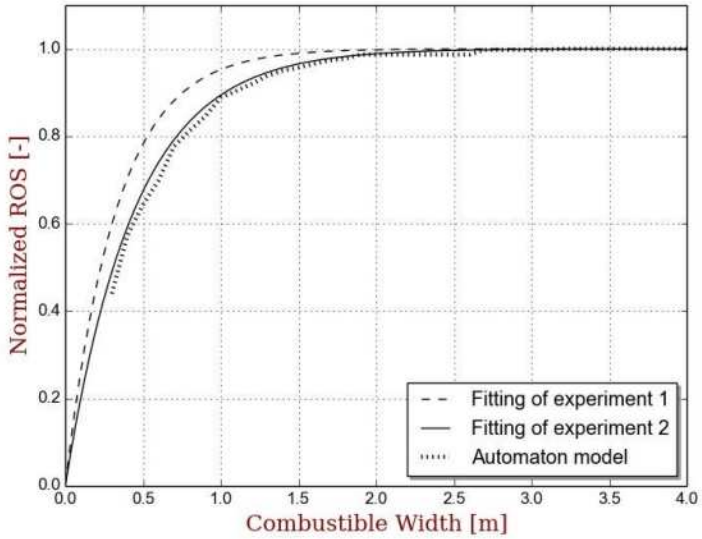


Figure 9. Normalized rate of spread for the two experiments and for the numerical model

Conclusion

A method based on image processing and direct linear transformation was used in order to reconstruct the leading edge and the back edge of a fire spreading in a fuel bed of excelsior. Several experiments were done and the ROS values obtained with the visible cameras were compared with other results obtained using standard methods with a chronometer, thermocouples and photo-resistors. This comparison demonstrated the efficiency of the present method.

The experiments showed a dependence of the ROS with the fuel bed width. Two series of experiments with a fuel bed width varying between 0.25 m and 3.5 m were done in different environmental conditions. These experiments exhibited the same evolution for the rate of spread: an increase with the bed width up to an asymptotic value. The global evolution was well approximated with an exponential law involving two parameters. One parameter was found to be constant for this kind of experiment while the other depends on the environmental conditions (surrounding temperature and humidity).

A simulation was conducted based on a cellular automaton. Only radiative transfer was considered as the heat transfer leading to the fire spread. Radiative transfer between two cells was modeled with view factors between flames represented as cylinders above the burning cells and the surface of a “raw vegetation” cell.

Numerical results showed that the parabolic shape of the fire front is well captured. The evolution of the normalized numerical ROS with the fuel bed width was also found in agreement with the experimental results.

Future work will now extend this fire propagation model in considering the effect of slope or/and wind on the fire propagation in including a convective heat transfer contribution.

BP 52, 20250 Corte, France, tihay@univ-corse.fr

Abstract
In this work, the effect of the diameter on the ignition of twigs of *Cistus Monspeliensis* was studied experimentally and theoretically. For this, piloted ignition experiments were carried out in a cone calorimeter. In the first part of the study, the location of ignition, the ignition time and the flame residence time were investigated according to the twig diameter. Different modes of ignition were observed. The ignition could be due to: glowing of embers; flaming near the solid; spark of the pilot. The ignition time and the flame residence time increase strongly with the diameter. For small diameters, ignition time can be considered as proportional to the diameter. For high diameters, the ignition time tends to stabilize around a constant value (about 80 s). The second part of the study was devoted to the modelling of the temperature evolution in a twig. A one-dimensional nonhomogeneous heat-conduction problem was considered in finite medium. An optimization was performed to determine the model parameters (ignition temperature, twig emissivity and total heat transfer coefficient). From the expression of temperature in the twig, the ignition time was calculated for the various diameters. The comparison between these values and the experimental data shows a good agreement. Finally, a sensitivity analysis was carried out highlighting the influence of the ignition temperature and of the total heat transfer coefficient on the results.

Keywords*: ignition time, piloted ignition, ignition modelling*

Introduction

Over the last decades, modelling of wildfires was increasingly used to provide support decision tools for forest management. Among the models of propagation of forest fires, many use the ignition properties of forest fuel such as the ignition temperature (Rothermel 1972, Koo *et al*. 2005, Santoni *et al*. 2011) and the heat required for ignition (Adou 2010). Some also assume that only small fuel particles contribute to the fire dynamics (Morvan *et al*. 2009). Despite the extensive use of ignition properties, misunderstandings persist even if the first works go back into the 19th century (Hill 1887) and have continued until the present time (Simeoni *et al*. 2012). As pointed out by Babrauskas (2001), literature offers a huge quantity of data and it is difficult to extract relevant values for the ignition properties of forest fuels. Among the studies on ignition, there are little works concerning the diameter influence. Studies realized by Mc Arthur (1962) and Peet (1965) suggested that fuels less than 6 mm diameter contribute most to fire behaviour. For them, the rate of spread of the head fire is directly proportional to the load of fine fuel consumed. In 2001, Burrows (2001) studied the flame residence time and the rate of weight loss for different dimensions of Eucalypt twigs. He concluded that round twigs less than 6 mm in diameter and leaves are the most flammable. Given this state of art, it seems necessary to realise new studies to complete the knowledge about ignition. We propose in the present paper to focus on the effect of the diameter on the piloted ignition of twigs of *Cistus Monspeliensis.* This work is composed of two parts. In the experimental study, the location of ignition, the ignition time and the flame residence time are investigated according to the twig diameter. In the numerical study, an ignition model is proposed. An optimization is used to determine the model parameters (ignition temperature, twig emissivity and total heat transfer coefficient) and a sensitivity analysis is

performed to evaluate the influence of these parameters on the numerical results. The aim of this preliminary work is twofold. Firstly, it brings additional data on the ignition of forest fuels. Secondly, it highlights the difficulties encountered during the experiments, leading to new protocols for further study.

Materials and Methods

Piloted ignition experiments were carried out in a cone calorimeter (Figure 1a). Twigs of *Cistus Monspeliensis* oven-dried at 60°C during 24 hours were employed as fuel. Table 1 presents the fuel properties. The twigs of *Cistus* were cut to a length of 10 cm and then sorted according to their diameter (Figure 1b). In this study, only diameters between 2 and 17 mm were investigated. The sample holder was an open basket of 10 cm by 10 cm made on stainless steel. It was maintained over an insulating ceramic by a thin metal support. This device reduces the heating process due to the ceramic and metal while allowing air to circulate under the basket. For each experiment, a mass of 15 g of fuel was placed in the basket with a parallel arrangement. A radiant heat flux of 50 kW/m² was imposed on the top of the fuel sample. To ensure that the radiant flux remained the same for all experiments, the heat flux was calibrated using a fluxmeter prior each experiment. The piloted ignition was obtained by using a spark igniter. The time of ignition was determined visually from the appearance of flaming combustion. A visible camera with a rate of 29 frames per second (Lumix ZS19) was placed in front of the cone calorimeter to observe the ignition location. The flame residence time was also recorded. The ambient temperature was 23°C and relative humidity was 40 %. At least 3 repetitions were performed for all the tests.

Experimental Results

3.1. Ignition description

After the shutter opening, the twigs of *Cistus* begin to dehydrate (due to the cone heating) and release white smoke. Once the ignition conditions are met, the ignition occurs. Figure 2 shows the first images recorded by the camera at the time of ignition. According to the pictures, the location of ignition seems to vary. The ignition could be due to: glowing of embers (Figure 2a), flaming near the solid (Figure 2b) or spark of the pilot (Figure 2c). However, these observations should be taken with caution.

Because of the recording speed of the camera, it is possible that the ignition actually occurs between two recorded images. In this case, the picture does not represent the ignition location, since the flame spreads. To refine these results, the use of a high-speed camera seems necessary.

a b c

Figure 2. Location of ignition for different experiment

Ignition time and flame residence time

Figure 3 presents the evolution of the ignition time according to the twig diameter. For diameters under 5 mm, the ignition time increases strongly with the diameter. For a diameter of 2 mm, the mean ignition time corresponds to 25 s whereas for twigs with a diameter of 5 mm, the ignition time reaches 60 s. For these diameters, the evolution of the ignition time can be considered as proportional to the diameter. This is consistent with the ignition theory for thermally thin solids, for which the ignition time t_{ign} is given by the following expression (Quintere 2006):

$$t_{ign} \approx \frac{\rho.c_p.D.(T_{ig} - T_\infty)}{q''} \qquad (1)$$

where ρ is density, c_p is the specific heat, D is the diameter, T_{ig} is the ignition temperature, T_∞ is the ambient temperature and q" represents the incident radiative heat flux.

From a diameter of 9 mm, the ignition time tends to stabilize around a constant value (about 79.5 s). This result is in agreement with the ignition theory of thermally thick solids. In this case, the ignition time is indeed independent of the diameter (Quintiere 2006):

$$t_{ign} \approx \frac{\pi.\lambda.\rho.c_p}{4}\left(\frac{T_{ig} - T_\infty}{q''}\right)^2 \qquad (2)$$

where λ is the thermal conductivity.

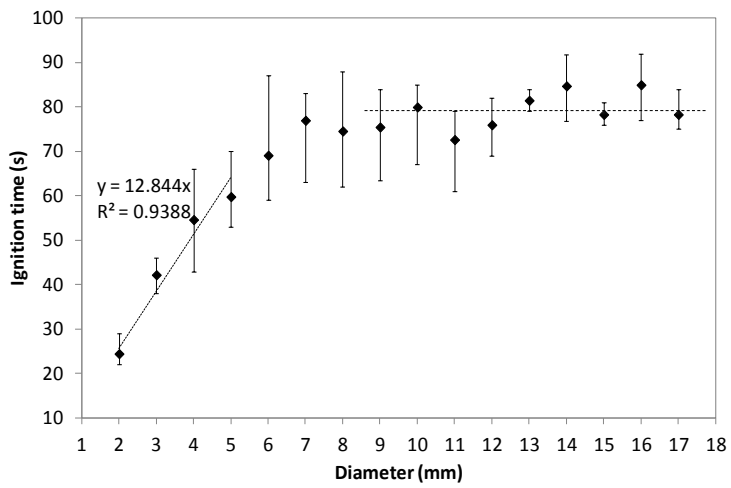

Figure 3. Ignition time according to the twig diameter

Flame residence times for the different diameters are shown on Figure 4. The flame residence time of the twigs increases with the diameter according to the following equation:

$$t_r = 13.2D^{0.96} \quad (3)$$

where t_r is the flame residence time.
This correlation is in agreement with literature (Burrows 2001) even if the increase of the flame residence time with the particle diameter is less significant than that found by Burrows (2001) for eucalypts ($t_r = 0.871D^{1.875}$). This variation is probably due to the fuel but also to the experimental method.

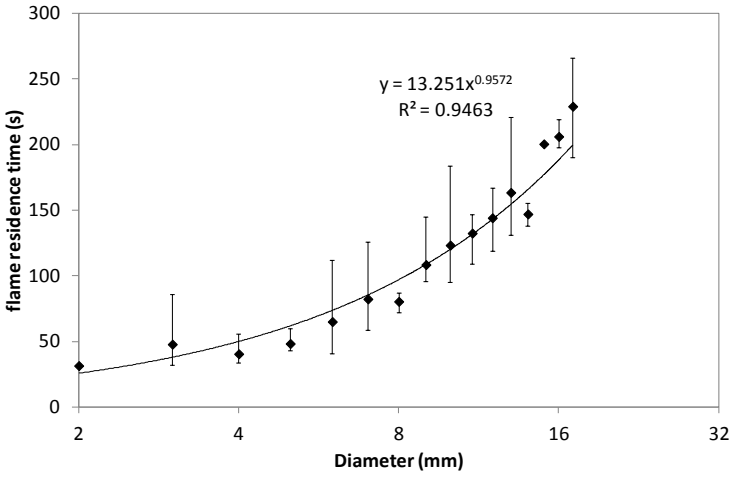

Figure 4. Flame residence time according to a) the twig diameter b) the surface to volume ratio

Given the previous results, it seems that the twigs of C*istus Monspeliensis* can be divided into 3 classes: diameters less than 5 mm, diameters between 5 and 9 mm and diameter above 9 mm. However, these results have to be taken with caution since they depends on our experimental procedure. Indeed, to compare our data with those of Burrows (2001), we kept a same mass for each test. But, this choice has significant consequences. By keeping the same mass, the twig arrangement varies with the twig diameter. For a diameter of 2 mm, the twigs are arranged on three layers on the whole holder surface (Figure 5a). From 4 mm in diameter, twigs are arranged on a single layer (Figure 5b). However, by

increasing the diameter, the number of twigs decreases and they cover no longer the entire surface of the holder (Figure 5c). Above 15 mm, there is only one twig (Figure 5d). Therefore, the energy received by the samples is not the same, since it depends on surface exposure that varies from several small twigs at one side to one big twig at the other side. In addition, for small diameter, the set of twigs can be considered as a porous medium. This is no longer true for larger diameter. These variations of twig arrangement certainly affect the ignition and it is difficult to compare the results between the diameters. For a better understanding of the phenomena, rather than using a same mass, a same area exposed to the radiant heat flux appears to be a better alternative.

Ignition model

4.1. Mathematical formulation

The mathematical model for ignition considered in this article is based on the following assumptions:

- Heat flow in the twigs is one-dimensional, i.e. perpendicular to the exposed surface.
- Chemical effects prior to ignition are negligible, i.e., the delay due to kinetics is neglected.
- Delay due to mixing is neglected.
- Ignition occurs when the surface reaches a given temperature
- The twigs are opaque and the Kirchoff's law is valid for the total absorptivity α, emissivity ε and reflectivity r, i.e., $\alpha=\varepsilon=1-r$
- The value of α, ε and r remain constant between the start of exposure and the ignition.
- The heat losses from the surface are partly radiative and partly convective with a constant convection coefficient h_c. The radiative loss term is linearized using an effective coefficient h_{rad} (Quintiere 2006). A total heat transfer coefficient h including the convective and radiant heat transfers is introduced: $h=h_c+h_{rad}$. This coefficient was considered as constant for all experiments.

Under these assumptions, the ignition problem corresponds to a thermal problem with the following mathematical form:

$$\frac{\partial^2 T}{\partial x^2} = \frac{1}{a}\frac{\partial T}{\partial t} \quad \text{for } 0 < x < D,\ t > 0 \qquad (4a)$$

$$-\lambda \frac{\partial T}{\partial x} = \varepsilon . q'' - h(T - T_\infty) \quad \text{for } x = 0,\ t > 0 \qquad (4b)$$

$$-\lambda \frac{\partial T}{\partial x} = h(T - T_\infty) \quad \text{for } x = D,\ t > 0 \qquad (4c)$$

$$T = T_\infty \quad \text{for } x \geq 0,\ t = 0 \qquad (4d)$$

where T is the temperature, T_∞ is the ambient temperature, a is the thermal diffusivity and σ is the Stefan-Boltzmann constant.

To resolve this one-dimensional nonhomogeneous heat-conduction problem in a finite medium, a variable change $\theta = T - T_\infty$ is used. Then, the problem is decomposed into two simpler problems (Ozisik 1993):

- a steady state problem for θ_0(x) given as:

$$\frac{\partial^2 \theta_0}{\partial x^2} = 0 \quad \text{for } 0 < x < D \quad (5a)$$

$$-\lambda \frac{\partial \theta_0}{\partial x} + h\theta_0 = \varepsilon.q'' \quad \text{for } x = 0 \quad (5b)$$

$$\lambda \frac{\partial \theta_0}{\partial x} + h\theta_0 = 0 \quad \text{for } x = D \quad (5c)$$

- a homogeneous problem for θ_1(x,t) given by:

$$\frac{\partial^2 \theta_1}{\partial x^2} = \frac{1}{a}\frac{\partial \theta_1}{\partial t} \quad \text{for } 0 < x < D,\ t > 0 \quad (6a)$$

$$-\lambda \frac{\partial \theta_1}{\partial x} + h\theta_1 = 0 \quad \text{for } x = 0,\quad t > 0 \quad (6b)$$

$$\lambda \frac{\partial \theta_1}{\partial x} + h\theta_1 = 0 \quad \text{for } x = D,\quad t > 0 \quad (6c)$$

$$\theta_1 = -\theta_0(x) \quad \text{for } x \geq 0,\ t = 0 \quad (6d)$$

- Then, the solution of the original problem (5a-d) is determined form:

$$T = T_\infty + \theta_0(x) + \theta_1(x,t) \quad (7)$$

The solution of the steady-state problem (5a-c) is given as:

$$\theta_0(x) = -\frac{\varepsilon.q''}{2.\lambda + h.D}\left(x - \frac{\lambda}{h} - D\right) \quad (8)$$

The solution of the homogeneous problem (6a-d) is obtained as:

$$\theta_1(x,t) = -\frac{2}{D}\sum_{m=0}^{\infty} e^{-a.\beta_m^2 t}\,\frac{1}{N(\beta_m)}\,X(\beta_m,x)\int_0^D X(\beta_m,x').\theta_0(x')dx' \quad (9a)$$

with

$$X(\beta_m,x) = \beta_m.\cos(\beta_m.x) + \frac{h}{\lambda}\sin(\beta_m.x) \quad (9b)$$

$$\frac{1}{N(\beta_m)} = \frac{2}{D\left(\beta_m^2 + \frac{h^2}{\lambda^2}\right) + \frac{2.h}{\lambda}} \quad (9c)$$

$$\tan(\beta_m.D) = \frac{2.\beta_m.h.\lambda}{\beta_m^2.\lambda^2 - h^2} \quad (9d)$$

The temperature T(x,t) of the problem (4a-d) is obtained by performing the integration:

$$T(x,t) = T_\infty - \frac{\varepsilon.q''}{2.\lambda + h.D}\left(x - \frac{\lambda}{h} - D\right) + \frac{2.\varepsilon.q''}{2.\lambda + h.D}\sum_{m=0}^{\infty} \frac{e^{-a.\beta_m^2 t}\left[\beta_m.\cos(\beta_m.x) + \frac{h}{\lambda}\sin(\beta_m.x)\right].\left[\frac{h^2 - \lambda^2.\beta_m^2}{h.\lambda.\beta_m}\sin(\beta_m.D) + 2.\cos(\beta_m.D) - 2 - \frac{h.D}{\lambda}\right]}{\beta_m.\left[D\left(\beta_m^2 + \frac{h^2}{\lambda^2}\right) + \frac{2.h}{\lambda}\right]} \quad (10)$$

At the surface and at the ignition (x=0 and t=t_{ign}), the ignition temperature is given by:

$$T_{ign} = T_\infty + \frac{\varepsilon.q''}{2.\lambda + h.D}\left(\frac{\lambda}{h} + D + \sum_{m=0}^{\infty} \frac{2.e^{-a.\beta_m^2 t_{ign}}.\left[\frac{h^2 - \lambda^2.\beta_m^2}{h.\lambda.\beta_m}\sin(\beta_m.D) + 2.\cos(\beta_m.D) - 2 - \frac{h.D}{\lambda}\right]}{D\left(\beta_m^2 + \frac{h^2}{\lambda^2}\right) + \frac{2.h}{\lambda}}\right) \quad (11)$$

4.2. Numerical results

The calculation of the ignition time with equation 11 is only possible when the three following parameters are known: the ignition temperature T_{ign}, the twig emissivity □ and the total heat transfer coefficient h. To determine the most suitable set of parameters, we decided to realize an optimization based on the gradient descent method. Several values were tested. For each set of values, the experimental ignition times ($t_{ign}^{\exp}$) were compared to the calculated values (t_{ign}^{model}).

The optimized model parameters correspond to the values for which the sum

$$S = \sum_{i=1}^{N}\left(t_{ign,i}^{\exp} - t_{ign,i}^{model}\right)^2 \quad (12)$$

is minimal. Here N is the number of diameters considered.

The set of parameters best describing the experiments is: T_{ign}=491°C, ε=0.982 and h=21.4 W.m².K. For piloted ignition and under radiant heating, the temperature ignition for wood ranges between 296 and 497°C (Babrauskas 2001). This scattering can be explained by the definition used for the ignition, the design of the test apparatus, the specimen conditions and the species of wood. The optimized ignition temperature (T_{ign}=491°C) is therefore in the range of the data found in literature. There is little data concerning the emissivity of forest fuel. Boulet *et al*. (2011) performed experiments using Fourier transform infrared spectrometers to determine the absorption of radiation for different species of forest vegetation. They found values of absorptivity for the vegetation matter between 0.90 and 0.95. The optimized emissivity (ε=0.982) seems therefore to be coherent with these values. In literature, the total heat transfer coefficient is often evaluated by means of the following relationship (Quintiere 2006, Torero and Simeoni 2010):

$$\varepsilon.q''_{ign,crit} = h(T_{ign} - T_\infty) \quad (13)$$

where $q''_{ign,crit}$ is the critical heat flux for ignition

For needles of *Pinus halepensis*, Torero and Simeoni (2010) obtained a value of 22 W/m².K. By using the data given in Quintiere (2006), the total heat transfer coefficient ranges between 34 and 39 W/m².K for wood. As for the other parameters, the value h=21.4 W.m².K is in agreement with literature.

•

Figure 6 presents the ignition times obtained with the experiments and with the optimized set of parameters. The comparison between these data shows a good agreement. Both curves follow the same trend. An increase of the ignition time with the diameter appears for low diameters. Then, the curves

reach an asymptote for larger diameters.The most significant errors appear for diameters of 2 and 3 mm. As described in section 3.2, for these diameters, the twigs are arranged on several layers. Our modeling considering a thickness D is therefore quite away from the experiments and tends to overestimate the time of ignition. Despite these approximations, the two curves are very close. The mean error is indeed less than 8.3%. However, to ensure the validity of this model, an experimental determination of T_{ign}, h and ε is necessary in order to compare the values found with the optimization and with the experiments.

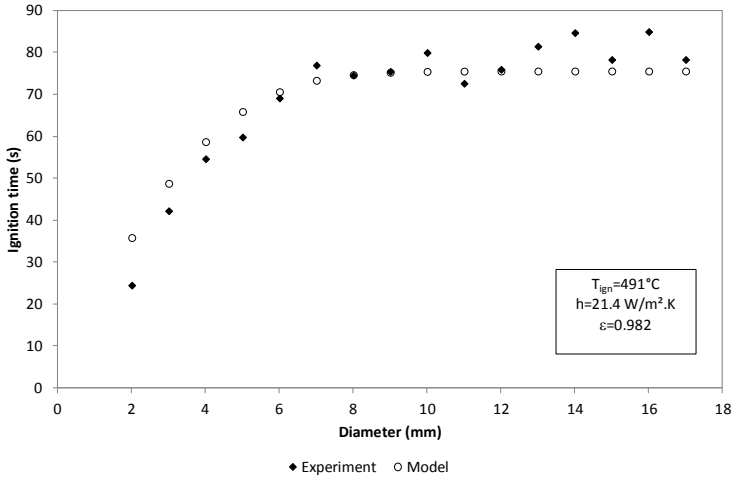

Figure 6– Comparison between the experiment and the numerical simulation

4.3. Sensitivity analysis

To study the effect of the three missing parameters on the ignition time, a sensitivity study was performed. Table 2 shows the three input parameters with their low and high values corresponding to the data found in literature. The interactions between the parameters being unknown, only the interactions between two factors are considered. The factorial design with two levels is therefore built and 2^3 simulations are performed. The software Statgraphics Centurion XVI (StatPoint Technologies) was used to define the numerical design of experiments (Table 3) and to draw the standardized Pareto Chart. The ignition time obtained for high diameters (corresponding to the asymptote of the curve of time ignition according to the diameter) was considered as the output parameter for each case.

Table 2. Variables used for the sensitivity study

Parameter	Low value	High value
T_{ign} (°C)	296	497
ε (-)	0.90	0.95
h (W/m².K)	22	39

Table 3. Numerical design of experiments (DOE)

Test n°	T_{ign} (°C)	ε (-)	h (W/m².K)	Output parameter (Max)
1	497	0.95	22	85.5
2	296	0.95	22	23.7
3	296	0.9	22	26.8

4	497	0.9	22	97.6
5	497	0.9	39	148.8
6	497	0.95	39	126.2
7	296	0.95	39	28.6
8	296	0.9	39	32.7

Figure 7 shows the numerical ignition times according to the diameter for the set of tests. Figure 8 shows the standardized Pareto Chart and the main effects plot. The ignition temperature is therefore the most influent parameter. This is not surprising since this is the parameter which induces the ignition. Increasing the temperature ignition implies an increase of the ignition time. The total heat transfer coefficient affects also the results. By increasing h, the ignition time increases as well. This is due to an increase of the heat losses at the surface. This sensitivity analysis highlights therefore the need to determine accurately the ignition temperature and the total heat transfer coefficient. Specific experiments dedicated to this objective must be considered in the future to obtain these data. This analysis reveals also that the emissivity effect can be neglected in comparison to the effects of ignition temperature and heat transfer coefficient.

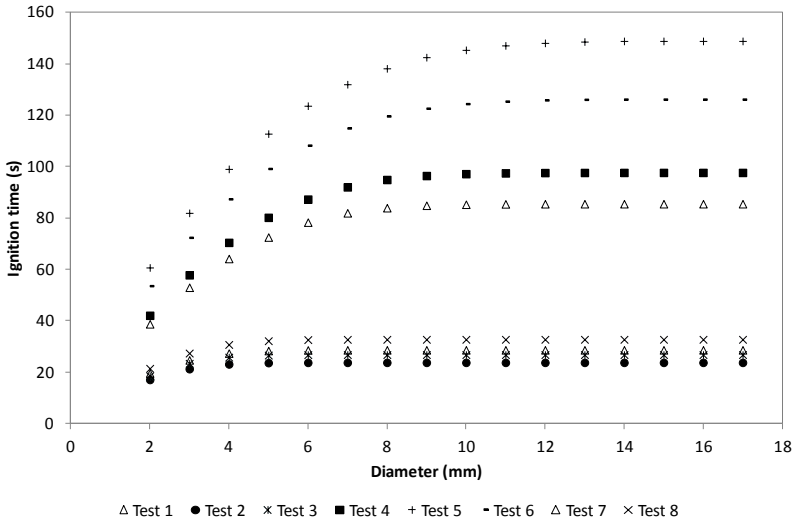

Figure 7– Experimental and numerical time of ignition

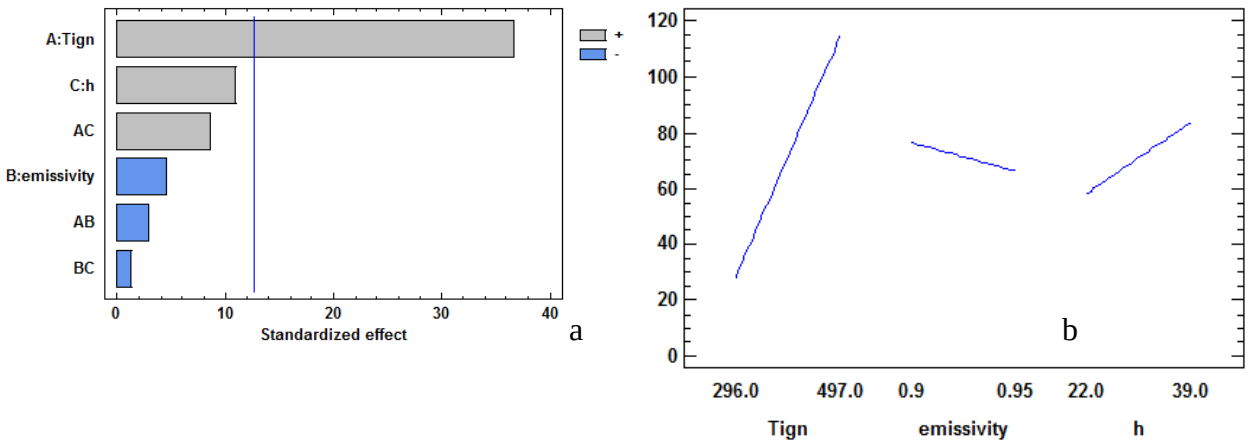

Figure 8– a) Standardized Pareto Chart b) Main effects plot

Conclusion

In this article, the first results of the study of diameter effect on the ignition of *Cistus Monspeliensis* twigs are presented. The location of ignition, the ignition time and the flame residence flame in function to diameter were investigated and a model of ignition was proposed. The main results can be summarized as follows:

- The location of ignition seems to vary. The ignition could be due to: glowing of embers, flaming near the solid or spark of the pilot.
- The ignition time increases strongly with the diameter. For small diameters, the evolution of the ignition time can be considered as proportional to the diameter. For high diameters, the ignition time tends to stabilize around a constant value.
- The flame residence time of the twigs increases with the diameter.
- A model based on one-dimensional nonhomogeneous heat-conduction problem in a finite medium allows modeling the ignition time according to the diameter.

In addition, this study also pointed out the necessity to modify the experimental procedure and to perform specific experiments to better understand the phenomena and to obtain the parameters of the ignition model. Based on these observations, a new study will begin soon, for which:

- A high-speed camera will be used
- A same area exposed to the radiant heat flux will be employed rather than a same mass.
- The ignition temperature will be measured for each experiment
- The model of ignition will be tested with the new set of experimental results.

Abstract
Laboratory fires spreading through laser-cut cardboard fuel beds were instrumented and analyzed for physical processes associated with spread. Flames in the span-wise direction appeared as a regular series of peaks-and-troughs that scaled directly with flame length. Flame structure in the stream-wise direction fluctuated with the forward advection of coherent parcels that originated near the rear edge of the flame zone. Thermocouples arranged longitudinally in the fuel beds revealed the frequency of temperature fluctuations decreased with flame length but increased with wind speed. The behaviors are remarkably similar to those of boundary layers, suggesting a dominant role for buoyancy in determining wildland fire spread.

Keywords*: Flame Structure, Buoyancy, Instability, Flame Spread*

Introduction

Despite decades of research on wildland fires, a common understanding has not emerged as to how heat transfer processes are organized to produce fuel particle ignition and flame spread. This has left physical modelling of wildland fires without an experimental basis for the many assumptions, including radiation and convective heat transfer. Strong experimental evidence has now suggested a secondary role for radiation in flame spread in fine fuel beds because 1) the optical attenuation through the fuel bed diminishes irradiance to particles, and 2) cooling by forced or natural convection efficiently prevents fine fuels from reaching ignition. Thus, we focus here on recent laboratory and field experiments designed to determine how convective heating occurs. We found clear evidence that non-steady heating by flame contact produces fuel particle ignition.

Methods

Laboratory fire spread experiments were conducted in uniform fuel beds made of laser-cut cardboard. Cardboard and paper strips have been used previously (Emmons and Shen, 1971) and offer advantages of known homogenous properties such as density and customizable physical dimensions of discrete particles (length, surface area etc.). Fuel beds were burned in the wind tunnel at the Missoula Fire Sciences Laboratory. The wind profiles of the 3m cross-section have been described previously (Rothermel and Anderson 1966, Catchpole *et al*. 1998) and are laminar except along the bottom surface where an upstream trip-fence produces a turbulent boundary layer. Wind speeds were varied from 0.22 m s^{-1} to 2.3 m s^{-1} with relative humidity of approximately 25%.

Figure 1. Picture of laser-cut cardboard laboratory fuel bed. Note that the scale is graduated in inches.

Fuels for the laboratory burns were engineered from cardboard with a commercial CO_2 laser system to produce fuel elements that are connected at regular spacing along a common spine. The cards or "combs" could then be arranged in rows at various spacing to form a fuel bed with vertically standing particles (**Erro! A origem da referência não foi encontrada.**1). The cardboard used was brown "chip board" 1.27mm (0.05 inch) thick with approximately 60% recycled content. Fuel particles were created at different lengths and widths and arranged at different row spacing to achieve specific fuel bed properties. The laser cutter/engraver system was a Universal Laser Systems Inc. ILS12.150D model equipped with two 60W laser cartridges. The beams from both lasers were collimated for cutting. The table accommodates sheets of cardboard 0.61m X 1.22m (2 ft X 4 ft) so that multiple combs can be cut from the same sheet in one operation.

Fuel beds constructed of these cardboard combs were 1.22m to 2.45m in width and 3.05m to 6.1m in length (Figure 1). The combs were supported and arranged on a foundation of cement-board strips (Hardy Board) 0.635cm x 5.08cm (1/4 in. x 2 in) each separated by a steel spacer 0.158cm x 2.54cm (1/16 in x 1.0 in). The steel spacers rested on the floor to preserve a slot at the upper surface which pinched the spine of the fuel combs such that only the vertical tines were exposed (**Erro! A origem da referência não foi encontrada.**). Tine lengths of 2.54cm (1in), 10.1cm (4in), 20.3cm (8in), and 35.6cm (14in) were used in the burns. The longitudinal spacing of the combs could be adjusted every 1.43cm (5/16in). To limit inflow to the combustion zone along the lateral edges during burning, the sides of the beds were lined with paper that was treated with the flame retardant Diammonium Phosphate ($(NH_4)_2HPO_4$). This technique was described by Byram *et al*. (1964), where fire retardant limits independent flaming combustion but allows the paper to burn in conjunction with the advancing fire front. The consumption of the paper sideliners at the trailing edge of the burning zone avoids channelling of air inflow to the rear of the fire which has been shown to affect fire spread on slopes (Smith 1992). Cutouts of the sideliner permitted filming of the ignition process within the fuelbed.

Field-scale fires were assessed to determine potential scaling relationships beyond those possible within the laboratory. At Fort Swift, Texas, grass 1 m deep was burned on separate plots with average winds of 1.7 m s^{-1} and 4.5 m s^{-1} and produced flames of approximately 3m tall. A rectangular wooden crib was also constructed of square ponderosa pine lath 0.025 m thick at 0.12x0.12 m square spacing with overall dimensions of (1.2m wide, 1m tall, and 17m long) and was burned to provide stationary flame source with approximately 6 m flames.

Results

The unprecedented uniformity of the fuel beds from engineered cardboard allowed us to observe flame structure and behaviour isolated from environmental heterogeneity. The first and most obvious characteristic of flame fronts in these flame sources is the peak and trough pattern of the flame edge (Figure 2). This geometry is similar to instabilities in boundary layer flow caused by Taylor-Görtler vortices, oriented in the flow direction, that arise when air inflow to the flame zone is lifted by buoyancy (Floryan 1991). From the literature (*e.g.* Sparrow and Husar 1969), studies of flow over heated plates and of boundary layer transition, pairing of counter-rotating Taylor-Görtler vortices form an alternating series of convergence zones in the transverse direction – with downward force creating the flame trough and up-ward convergence in flame peaks (Figure 2). The significance of these vortices is that they force flame down and forward into the fuel bed and advect secondary instabilities forward through the flame zone. Data from spreading wind tunnel fires, prescribed grassland burns, and stationary crib fires all reveal that the transverse wavelength of these vortices is about ½ the flame length (Figure 2D).

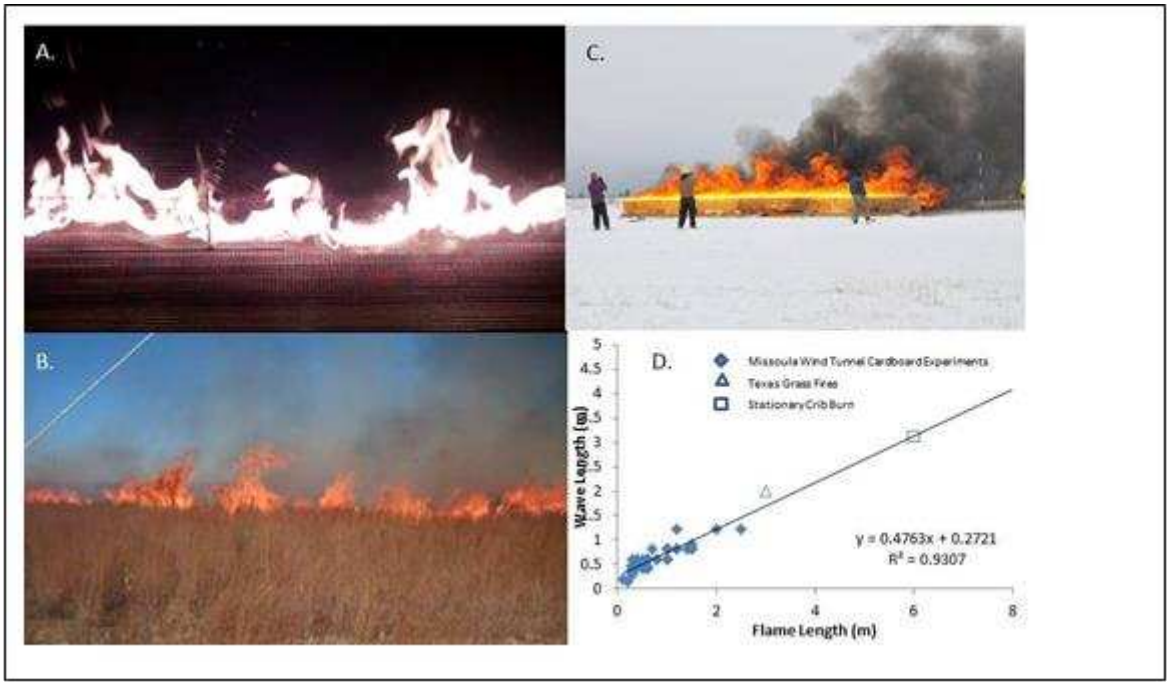

Figure 2. Flame structure in laboratory-scale cardboard fuel beds (2A) reveal the same sawtooth flame structure as grass fires (2B) and stationary crib fires (2C) because of Taylor- Görtler vortices. The transverse wavelength of these flame peaks appears to be about ½ the flame length from all of these fires (2D).

The second dynamic discovered in these experiments is a series of flame parcels (Figure 2a) which are first seen to originate near the back edge of the flame zone. These parcels remain coherent on video and move forward through the flame zone to burst forward and impinge fuel particles for some considerable distance ahead of the combustion interface. Thermocouple temperatures measured in the fuel beds (Figure 3b) fluctuate with predictable average frequencies that showed strong Strouhal-Froude scaling (Figure 3c) similar to the pulsing frequency from pool fires (Malalakasera 2006). This scaling, using the variables of wind speed and flame length, means the bursts frequency increases with wind speed and decreases with flame size. The origin of the bursts appears to be from instabilities arising at the upstream edge of the flame zone similar to Tollmien-Schlichting waves observed in boundary layer instabilities (Floryan 1991). These are visible first as transverse ridges and concave

packets in the upper flame surface (Figure 3A). With downstream movement through the flame zone they are drawn into the circulations from Görtler vorticity and expelled forward past the leading flame edge into the fresh fuels ahead. This bursting frequency was recorded as temperature spikes on thermocouple arrays embedded in the fuel bed (Figure 3B) which demonstrate the coherency of the flame structures as they advect through the flame zone. Remarkably, data from all field sources suggests consistent Str-Fr scaling as laboratory-scale fires (stationary or spreading) (Figure 3C).

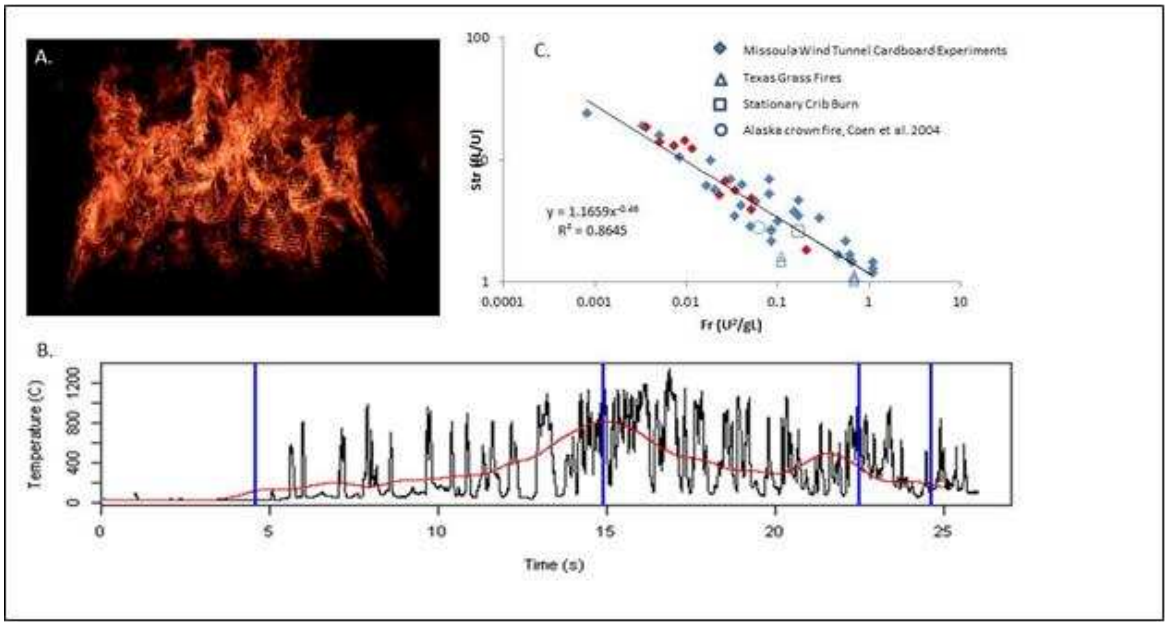

Figure 3. Instabilities in the flame zone are revealed in experimental fires burning in cardboard fuel beds as dish-shaped patterns originating near the rear edge of the flame zone (3A). These produce forward bursts of flame ahead of the combustion interface that result in a pulsing-type temperature signal on thermocouples (3B). Average burst frequencies (f) scale with a Strouhal-Froude correlation (Str-Fr, 3C) using windspeed (U) and flame length (L) of laboratory and field-scale fires (see Figure 2).

Discussion

This research reveals instabilities of the flame that are similar to buoyant dynamics of non-reacting flows (Floryan 1991). These instabilities appear responsible for creating flame intermittency at the leading edge of spreading fires and forcing flames downward into the fuel bed. Similar flame structure and intermittency was recently found using stationary gas flames, with and without forced flow[1]. The use of the Str-Fr scaling of non-steady flame behaviours in both studies suggests broad applicability across a wide range of wildland fire sizes and fuel[2]. The strong dependency of intermittent convective

heating to thermal behaviour and ignition of individual fuel elements to radiation and convection is revealed in two other studies[1],[2].

Quasi-periodic flame behaviour in spreading fires has been noticed previously for trench fires for pine needle beds, but the role of such non-steady flame impingement in igniting fuel particles and flame spread has not been considered (Atkinson *et al*. 1995, Woodburn and Drysdale 1998, and Dupuy *et al*. 2011). The Strouhal-Froude scaling suggested by our data is consistent with buoyant dynamics of stationary fire phenomena (Malalasekera *et al*. 1996) but new to spreading fires. These findings suggest that the difficulty of identifying an integral length scale for convection related to ignition (Anderson *et al*. 2010) comes from assuming away the time-dependency of particle heating. It also suggests by virtue of the inverse dependency of average pulse frequency on flame dimensions that slower buoyant dynamics of larger flame zones compensate for the increases in energy release and convective heating distance to avoid runaway spread. If buoyant instabilities are responsible for the flame behaviours and particle ignition, then it strongly suggests that laboratory-scale fire spread processes should extend readily to field proportions because flame temperature in diffusion flames (and thus buoyancy) remains approximately the same regardless of fire size. At this time, our limited field-scale experiments and observations seem to be in agreement with this scaling. Much work is yet to be done to understand useful scaling relationships, but the ultimate goal is to someday incorporate these findings into practical tools for wildland fire managers.

Conclusions

These findings may have profound influence on understanding of the flame spread process in wildland fires because they suggest that buoyant dynamics govern the heat transfer processes. Thermocouple measurements on fuel particles show that ignition commences after a series of flame contacts that increase the particle temperature in discrete jumps. This is far from the normally assumed steady processes of particle heating. Even large particles in uniform fuel beds show these temperature jumps from flame contact and do not ignite by radiation because optical attenuation reduces irradiance dramatically.

Abstract
Accumulation of gas inside a valley exposed to a light crosswind is experimented in this paper to evaluate the influence of gas in accelerating forest fire phenomena. Experimentations were done inside a wind tunnel using a 1/400 forest model configured as a valley with two different internal angles. The forest is modelled so that a parallel is possible with a real forest thanks to a similitude law. The emission of gas is ensured by 400 tubes introduced inside the mesh cylinders supplied with ethane. The 400 tubes are divided into four independent parts of 100 tubes to be able to study independently the influence of the different zones before and inside the valley on the accumulation of gases. We focused on the measurements of velocity by Laser-Doppler Velocimetry (LDV) and concentration with a Flame Ionization Detector (FID). Analyzing the velocity, turbulence and concentration results, we observed a stagnation point in the thalweg for the flattest valley and a recirculation zone for the deepest one where gas accumulation reached up to 4 times the concentration measured outside the valley. The study of the influence of the different emission zones showed that gas accumulation mainly comes from the zones inside the valley.

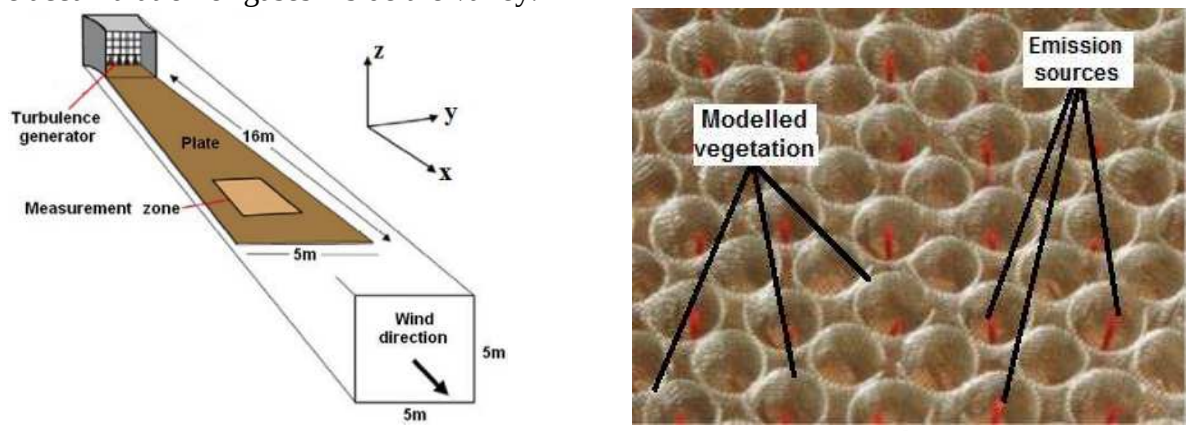
Keywords*: V-shape forest model; gas accumulation; gas emission; Laser-Doppler Velocimetry; concentration*

Introduction

During a forest fire, high concentrations of gases, which may come from fire smoke, pyrolysis products and emissions of vegetation (BVOCs), can be found inside a valley depending mainly on the meteorological conditions and the topography [1,2]. It is noteworthy that some experimented firefighters decide to run away from a forest fire when the surrounding odor is too strong and when the vision becomes hazy. This lets us think that a high concentration of gases is present at that moment. The problem encountered is the observation of Accelerating Forest Fires (AFFs) inside valleys or canyons. Indeed, numerous mortal accidents like those which happened in Mann Gulch (USA, 1949, 13 victims), La Gomera (Spain, 1984, 20 victims) or Kornati Island (Croatia, 2007, 11 victims) are described in the literature [1]. Initially, these AFFs appear to be classic forest fires but change unexpectedly their behavior with impressive rates of spread and heat releases letting behind them large burning areas. One of the possible causes of this phenomenon is the accumulation of gases in narrow areas like thalwegs or canyons with, in one hand, the fire smoke dispersed by complex air flow above and around the forest fire and, on the other hand, BVOCs and pyrolysis products emitted by heated plants because of the fire front radiation. The goal of this project is to have an idea of what happens inside a valley before the arrival of fire regarding the potential of accumulation of both smoke coming from above and BVOCs emitted inside the valley. To address these questions, we reproduced the spatial distribution of gas inside a valley (V-shaped) with a forest model exposed to a light crosswind. Experiments were performed to give information on the location of gas accumulation and whether or not it can be sufficient to form flammable gas pockets to catalyze the fire propagation. Some research studies have been done for street canyons to focus on the dispersion of pollutant [3,4] but, to our knowledge, there is no work on valley configuration with forest models.

Experimental section

Investigations were made in the wind tunnel "Lucien Malavard" of PRISME Laboratory, with a 1/400 forest model configured as a valley with varying angle in order to study the effect of geometry on the global air-flow. The wind tunnel has a 16 m-long rough development plate. Turbulence generators are fixed at the entrance of the test section to develop an atmospheric boundary-layer flow. The forest is modelled using 50 mm-high metallic mesh cylinders which are rolled up to their top to represent the higher leaf density of the tree crown. The cylinder arrangement was chosen to avoid any forced flow direction to the flow going through the canopy [5]. The biogenic emission coming from the forest canopy is represented by a surface source, which is modelled through a series of point sources of a passive tracer. The passive tracer is ethane, chosen for its density close to air. The release height is 40mm (80% of the tree height) and the distance between each point source is 50mm (tree height). Figure 1 illustrates a schematic overview of the wind tunnel and the modelled forest located in the measurement zone. The gas distribution comes from an ethane bottle linked to a first distribution device with which we can chose which of the four emission zones are active (Figure 2). This first distribution device is linked to four other ones built with enough pressure loss to permit an homogeneous surface source when the gas comes out from the tubes (Figure 3). Preliminary testing showed that, right above the canopy, the source was horizontally homogeneous. Consequently, the source is representative of a surface source. The emission zone of 400 tubes, is divided into four independent parts of 100 tubes (Figure 2). This allows us to study the effect of each zone of emission on the accumulation of gases inside the valley.



(*a*) (*b*)

Figure 1. Overview of the experimental setup of modelled forest in a wind tunnel: (a) Scheme of the wind tunnel; (b) Metallic mesh cylinders and ethane emission tubes (in red) constituting the model placed in the measurement zone.

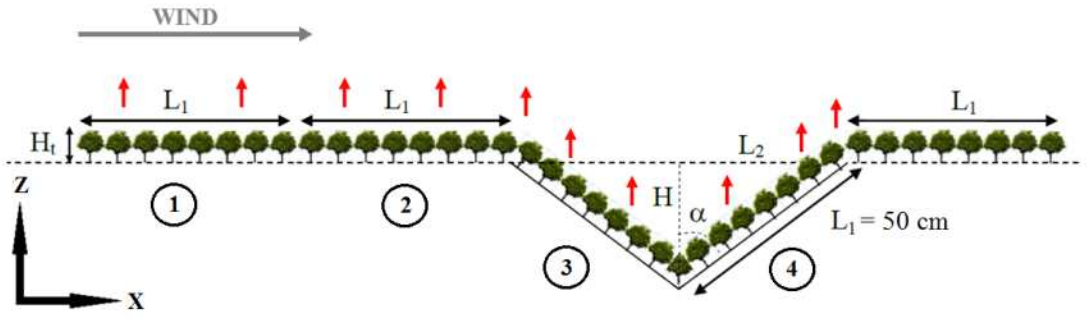


Figure 2. Simplified 2D scheme of the forest model and the four zones of ethane emission, zone 3 is called the lee side and zone 4 the wind side

Figure 3. The two photographs depict the distribution device of ethane placed under the model

Experimentations in the wind tunnel gather two types of measurements above the canopy of the four zones: measurements of velocity with a Laser-Doppler Velocimetry (LDV) and measurements of concentration with Flame Ionization Detector (FID) (Figure 4).

Figure 4. LDV on the left and FID on the right above the V-shaped forest model

For the velocity measurements by LDV, the flow was seeded with olive oil micro-particles upstream of the turbulence generators. By referring to Viegas's work [6], we have chosen two different half internal angles of valley α = 50° and α = 80° (Figure 3). The forest model permits then to make a parallel with a real forest thanks to a similitude law [5]. Indeed, the measured concentrations will be given at reduced scale in a dimensionless form (Eq.1) in order to extrapolate them to full scale situations using real parameters (Eq.2):

$$c^* = \frac{c[m^3/m^3_{mix}] \times U_{ref}[m/s]}{Q_{source}[m^3/s/m^2]} \quad (1)$$

$$c_{full\ scale} = f\left(x, z, c^*, U_{ref}, Q_{source}, \alpha, H_t\right) \quad (2)$$

3. Results

3.1. Velocity

From our different experiments, we measured velocity, turbulence and concentration obtaining grids of values above and inside the valley for the two different angle configurations. To normalize our measurements, we divided them by a reference speed located before the forest at ten times the canopy height. Analyzing the results with the velocity streamlines we observe on the left of Figure 5 below

that there is no recirculation with the flattest valley even if we have a potential of accumulation in the thalweg where the horizontal component of the velocity (U) is almost null. On the right of Figure 5, we observe clearly a clockwise recirculation for the deepest valley. Regarding the turbulence intensity with the Figure 6, we notice that it is located above the canopy for the flat part of the forest and that it increases a lot above the valley with the detachment of the boundary layer. For the 80° angle, the turbulence intensity inside the valley is multiplied by four if we compare it to the flat forest, with a maximum of 1.4%. Turbulence intensity is much stronger for the 50° angle, and reaches up 76% above the valley (Figure 6 and 7) even if there is not so much turbulence near the thalweg. Thus, gas accumulation is possible in this place.

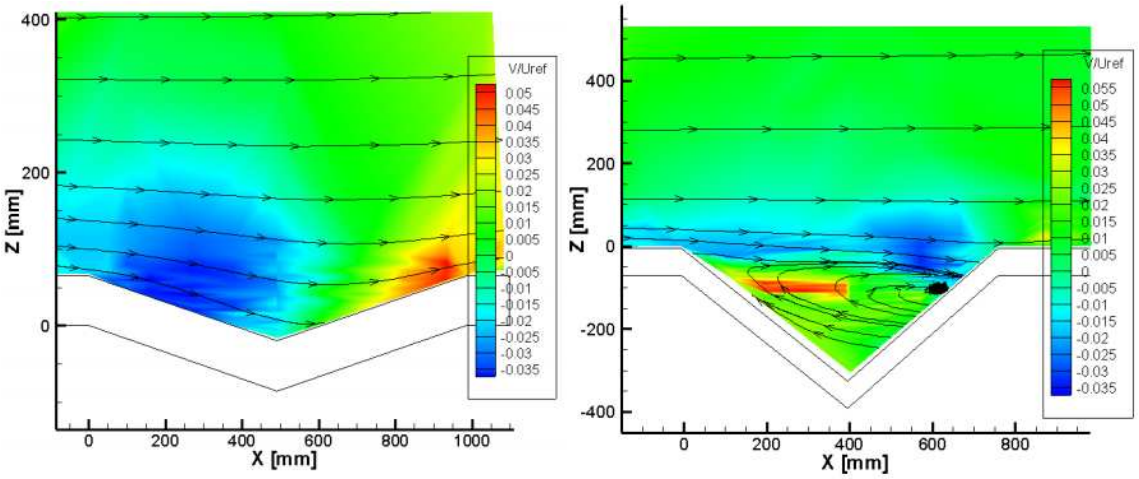

Figure 5. Vertical component of the velocity (V) normalized by Uref with streamlines of the velocity, for α = 80°on the left and α = 50° on the right

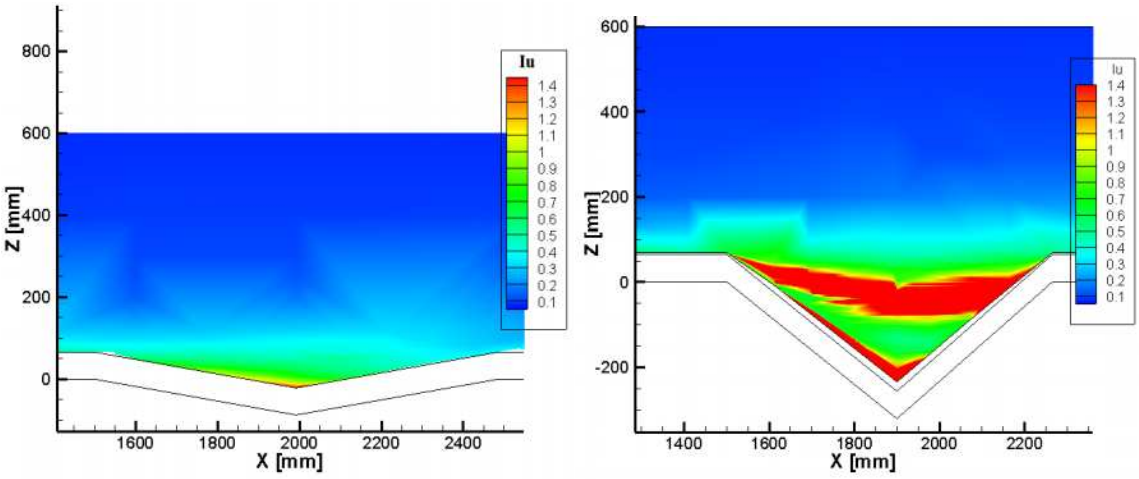

Figure 6. Turbulence intensity on U for α = 80° on the left and α = 50° on the right

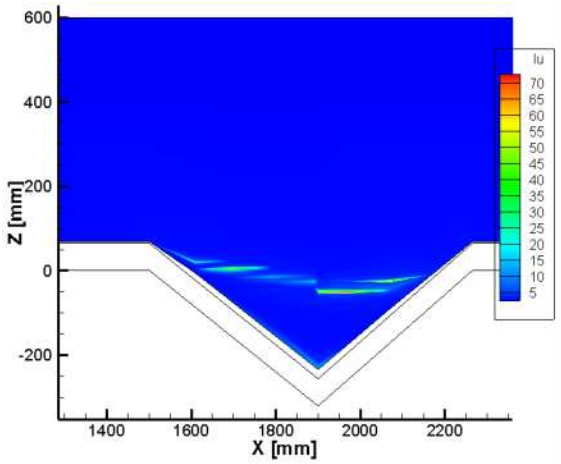

Figure 7. Turbulence intensity on U for α = 50°

3.2. Concentration

If we look now at both concentration and velocity, we obtain the Figure 8 below for 80° and 50°. We notice at 80° that accumulation is located in the thalweg due to the weak velocity in this zone. The maximum concentration is measured at 980 ppm almost twice the concentration measured above a flat forest. At 50°, an accumulation of gas is visible above the lee side due to the recirculation. We reach up a maximum of 1790 ppm increasing the concentration by more than 3.5 times if we still compare to the flat forest.

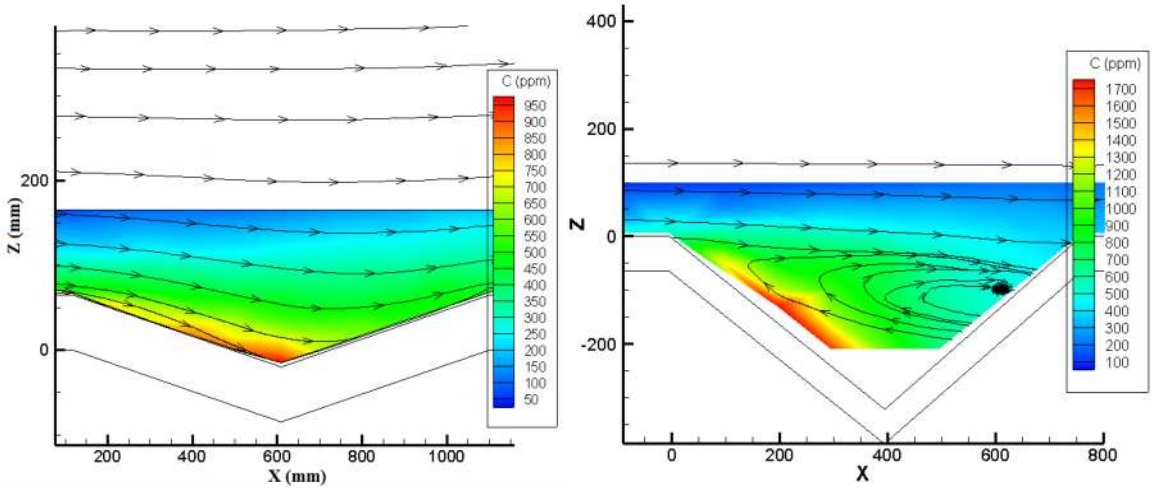

Figure 8. Concentration with velocity streamlines for α = 80° on the right and for α = 50° on the left

3.3. Footprint of the different forest model zones

The following experiments were carried out to know the footprint of the different zones, to know which zones of the forest model are more influent on the gas accumulation. To this end we plugged and unplugged the different emission zones from the distributor. Figure 9 below presents the concentration with all zones emitting on the left graph and only zone 3 on the right. To compare the results we normalized the concentration following the equation 1 page 4. With the 80° angle, we concluded that the inlet part (zone 1 and 2) does not influence the accumulation inside the valley. Focusing on the angle 50° (Figure 9) with the recirculation zone, we observed that it is mainly the lee side (zone 3) which influences the accumulation with a maximum at C* = 152 whereas with all zones emitting we

obtained a maximum of C* = 194. This maximal accumulation is located just above the canopy at the middle of the lee side. Letting now only the wind side emitting (zone 4), we have a maximal accumulation located in the thalweg with a maximal normalized concentration found at 79.

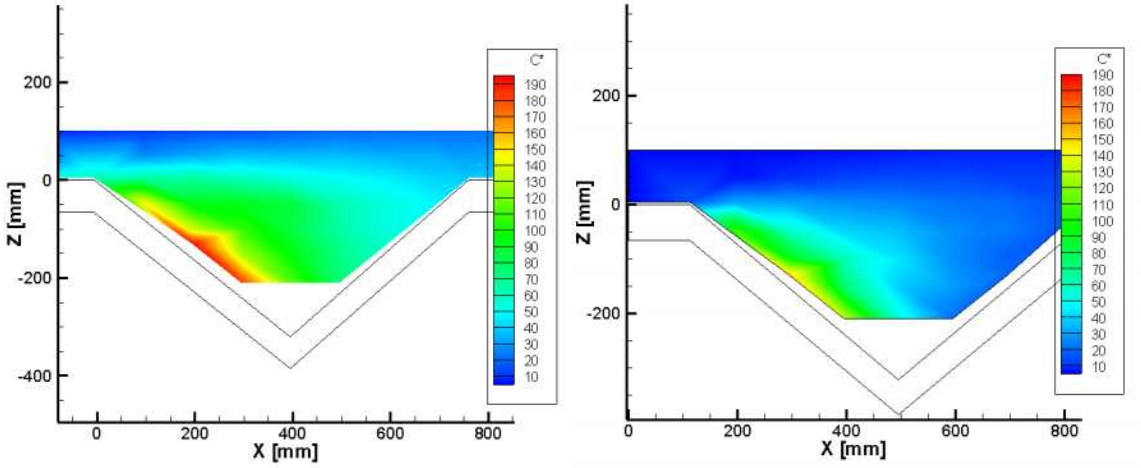

Figure 9. Normalized Concentration all zones emitting on the left and lee side only on the right for 50°

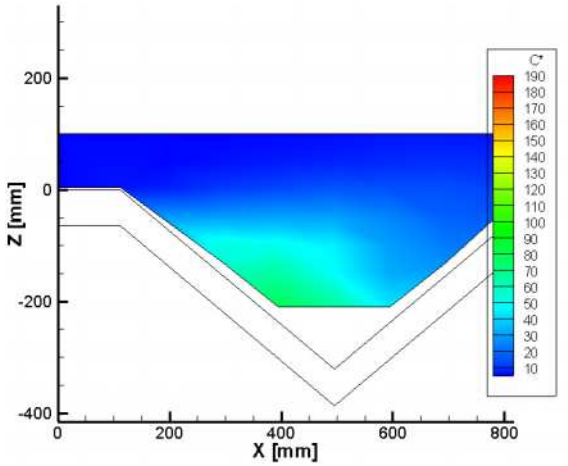

Figure 10. Concentration (ppm) of only wind side emitting for 50°

3.4. Extrapolation to real case

Knowing the influence of each zone, we observe that the risk of accumulation is present if there are emissions from the inside the valley with heated vegetation for example. With the arrival of the fire it is the wind side which will be directly exposed to the radiation and will emit more than the lee side. We could then imagine adding coefficients for each zone to analyze a real case. By plotting the normalized concentration, we see that concentration just above the canopy is multiplied by 3.5 to 4 inside the valley.

Studies of BVOC emissions from real forests evaluate the emission at about 1 g/m².h in favorable regions (dry summers and wooded areas) [7]. Since 50% of emissions are released in July and August, emissions grow to 3 g/m².h during this period. Knowing that *Rosmarinus officinalis*, one of the Mediterranean plant species involved in AFFs, emits eight times more at 175°C than at 50°C [8], we can estimate emissions superior than 24 g/m².h when a forest fire is approaching heating the vegetation with radiation. If we consider now that vegetation is heated during one hour then we have emissions of 24 g/m². If we hypothesize that there are not so much air flow and that emissions are dispersed in 100 m^3. Thus we can evaluate that VOC emissions can reach 0.24 g/m^3 near a forest fire. Then we

know that if these VOCs are emitted near a narrow valley, they can accumulate up to 4 times to get around 1 g/m^3. Studies show that VOCs like α-pinene have a lower flammability limit (LFL) around 1% volumetric [2,9]. According to the density of air and α-pinene we obtain around 0.6% which is rather close to the LFL. Knowing that there are many approximations, the chance of being in presence of a flammable atmosphere inside a narrow valley is still imaginable.

Conclusion

We analyzed velocity, turbulence and concentration results for two different half internal angles of a valley model. Velocity permitted us to observe a potential of accumulation in the thalweg where the velocity is almost null for α = 80°. For α = 50°, we highlighted a recirculation zone inside the valley. Analyses of the turbulence showed that there could be an accumulation of gas in the thalweg of the 50° angle where turbulence is lower than above. By measuring the concentrations, we observed an accumulation in the valley up to twice more than a flat forest for α = 80° and up to four times more for α = 50°. The study of the zone footprint permitted us to say that emissions outside the valley do not have an impact of accumulation inside the valley in our case. Focusing on the 50° angle and studying the emissions of lee side (zone 3) and the wind side (zone 4) independently, we concluded that these are mainly the emissions of the lee side which influence the gas accumulation. Due to the recirculation, gas accumulation is located just above the canopy in the middle of the lee side. Emissions from the wind side accumulate in the thalweg. Numerical study with a Computational Fluid Dynamics code could permit to obtain further results varying the angle (α) with which we could obtain, for example, the threshold of the angle not to overcome to stay in safe concentration, below the LFL of VOCs. The fact that concentration inside the valley is four times the one measured for a flat forest shows that LFL is not so far and that the hypothesis of gas accumulation is still relevant.

Abstract
Accelerating forest fire phenomenon is studied in this paper. This phenomenon characterizes fires with a sudden increase of the rate of spread and of the energy released without any changes in the meteorological and topographic conditions. The thermochemical explanation is investigated in this study: acceleration of the rate of spread could be the consequence of the ignition of Biogenic Volatile Organic Compounds emitted by fire heated vegetation. Two experimental setups are used to perform very simple experiments in order to give validation elements to this thermochemical approach. The first experimental setup used permits to show that gases emitted by vegetation (even if they are hot) are diffused mainly in the direction of the ground. The second one shows that the gases emitted by heated *Rosmarinus officinalis* needles can be ignited with a pilot flame. *Rosmarinus officinalis* is a typical vegetal species involved in accelerating forest fires. This work does not prove neither that this hypothesis has been validated nor that this is the only explanation for accelerating forest fire accidents, it only brings arguments for future discussions and for a possible validation of the thermochemical approach.

Keywords: *α-pinene; BVOCs flame; accelerating forest fire.*

Introduction

The main purpose of this work is to give experimental data that would permit to take into account in a better way the combustion process in forest fires models. The aim is of course to better control and prevent wildland fires. A particular care is taken to a special type of accidents, named accelerating forest fires (AFF) and characterized by a sudden increase of the rate of spread and of the energy released. These accidents have been reported and detailed in the literature for several years (Arnold and Buck, 1954; Rothermel, 1993; Dold *et al*. 2009). Different hypothesis have been developed to explain these accidents. During the last ten years, two interesting explanations have been proposed. One suggests that these accidents are the consequence of the feedback effect of the convection induced by the fire (Viegas, 2005). Another explanation suggests that fire acceleration is caused by flow attachment in the direction of the fire propagation (Dold and Zinoviev, 2009). We suggested in previous works (Courty *et al*. 2012; Chetehouna *et al*. 2014) a possible explanation for these accidents, named thermochemical hypothesis to explain accelerating forest fires. This hypothesis is based on the fact that Biogenic Volatile Organic Compounds (BVOCs) emitted by heated vegetation could accumulate near the ground to form with air a flammable mixture. AFF would therefore be the consequence of the ignition of such gas clouds. We identified in previous works the BVOCs emitted by different vegetal species and determined combustion characteristics of these BVOCs by measuring their laminar burning speeds, Markstein lengths and flame thicknesses (Courty *et al*. 2012; Chetehouna *et al*. 2013). We worked with vegetal species typical of the Mediterranean climate, often involved in

forest fires. This work aims at presenting some experimental studies that we performed in order to show that the ignition of BVOCs accumulated in a canyon can be plausible. The thermochemical approach to explain accelerating forest fires is a controversial topic in the wildland fire safety scientific community. This work does not prove neither that this hypothesis has been validated nor that this is the only explanation for AFF, it only brings arguments for future discussions and for a possible validation of the thermochemical approach.

Methods

BVOCs diffusion direction

The main issue we want to solve concerning accelerating forest fires thermochemical approach is to know if BVOCs can accumulate at terrain scale in sufficient concentration to form with air a flammable mixture. One of the necessary conditions to form this flammable mixture is that emitted gases diffuse in the direction of the ground and do not dissipate in the air. Indeed, if BVOCs diffuse in the direction of the ground, it is possible that in canyons the low value of lower flammability limit (1% vol. in air) of BVOCs/air mixtures is reached. We have shown in previous works (Courty, 2012; Courty *et al*. 2012; Chetehouna *et al*. 2014 among others) that the amount of gases emitted is very dependant of temperature and is increasing with the increase of temperature. It is therefore important to prove that the BVOCs diffuse in the direction of the grown, even if they are hot.

To prove it, we used an experimental setup that consisted in a cubic hermetic enclosure made of cellular concrete (Siporex). Its volume is around one cubic meter and it is equipped with a radiant panel simulating an ongoing fire front. It is also equipped with two electrodes providing the ignition energy. The radiant panel is made of sixteen black ceramic plates, each of them providing a maximal thermal power of 1200 W. The maximal power per unit area provided by the panel is around 83000 $W.m^{-2}$. Let us notice that this hermetic enclosure is the same used by Chetehouna *et al*. (2009) to study the gaseous emissions of *Rosmarinus officinalis* vegetal species at plant scale.

Different amounts of different BVOCs (99 % pure from Sigma Aldrich) initially liquid, are placed in a cup inside the enclosure, 50 cm from the radiant panel and at the centre of the enclosure. Different tests are done, the cup being placed above or below the ignition source (i.e. the electrodes). The distance cup-electrodes and the amounts of BVOCs are varied. Figure 1 presents a schematic overview of the experimental setup. Five BVOCs are studied, they correspond to the major component emitted by each of the species studied in Courty (2012): α-pinene, limonene, *p*-cymène, 3-hexen-1-ol and l-fenchone.

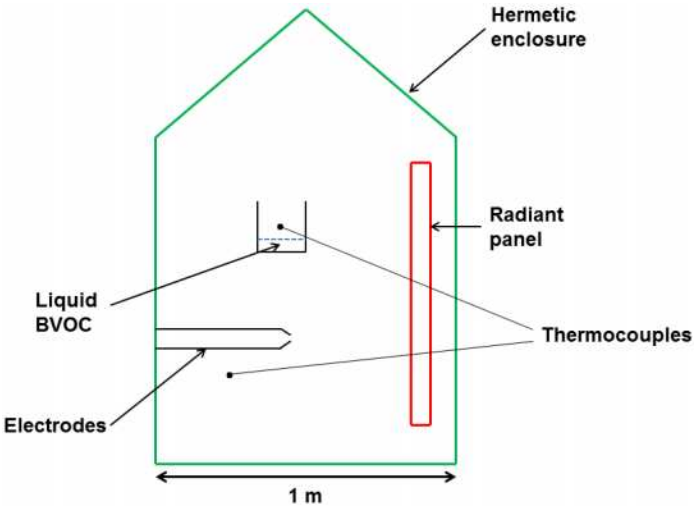

Figure 1. Schematic overview of the experimental setup showing the diffusion direction of BVOC.

BVOCs ignition

This subsection aims at proving with very simple experiments that gas mixtures emitted by vegetal species can ignite. To do so, we just used some heated needles of *Rosmarinus officinalis*. The setup consists in a necked flask of 500 mL heated with a heating mantle. Around 50 g of needles of *Rosmarinus officinalis* vegetal species are placed inside the flask and heated up to a temperature around 443 K. Temperature is measured thanks to a thermocouple placed in the needles bed. Emitted gases are collected in a beaker thanks to a transfer hose connected to the necked flask. Beaker is then placed next to a pilot flame, a candle is used. This setup is illustrated by a schematic overview in Figure 2.

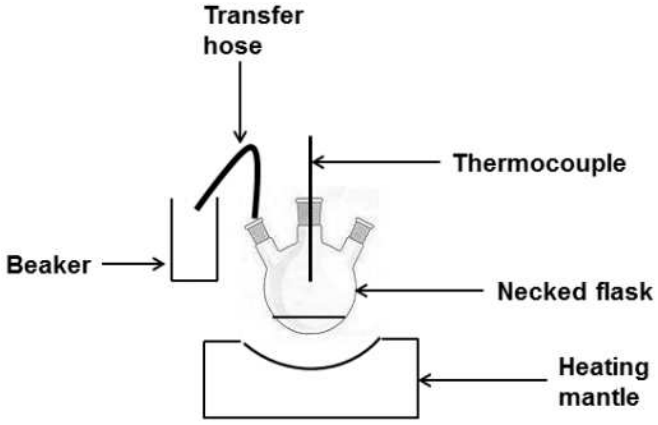

Figure 2. Schematic overview of the experimental setup used to study the ignition of BVOCs.

Results

BVOCs diffusion direction

Two thermocouples, one next to the electrodes and the other in the liquid, are used to study temperature as a function of time. Clearest results are obtained with 7 mL of BVOCs and results will be presented with this amount of BVOCS. Liquid samples are introduced at ambient temperature and spark is ignited at the temperature of maximal emissions. This temperature depends on the BVOCs and is around 443 K (Courty *et al.*, 2014). Ignition is observed or not thanks to the window situated on right side of the enclosure.

We observed that when the spark is situated below the cup, we managed to ignite up to a distance of 40 cm between the electrodes and the cup. On the contrary, when the spark is situated above the cup, no ignition occured for distances electrodes-cup higher than 14.5 cm. This clearly shows that the direction of the VOCs diffusion is downward (even if a small amount is diffusing upward). These results are valid for the 5 studied BVOCs and similar conclusions are obtained with different amounts of BVOCs placed initially in the cup.

A high speed digital camera Photron Fastcam APX RS operating at 2000 images/second has been used to illustrate this phenomenon. Figure 3 illustrates the ignition of α-pinene placed in a cup 3 cm above the electrodes. It is clear reading Figure 3 that the α-pinene vapours are diffusing downward.

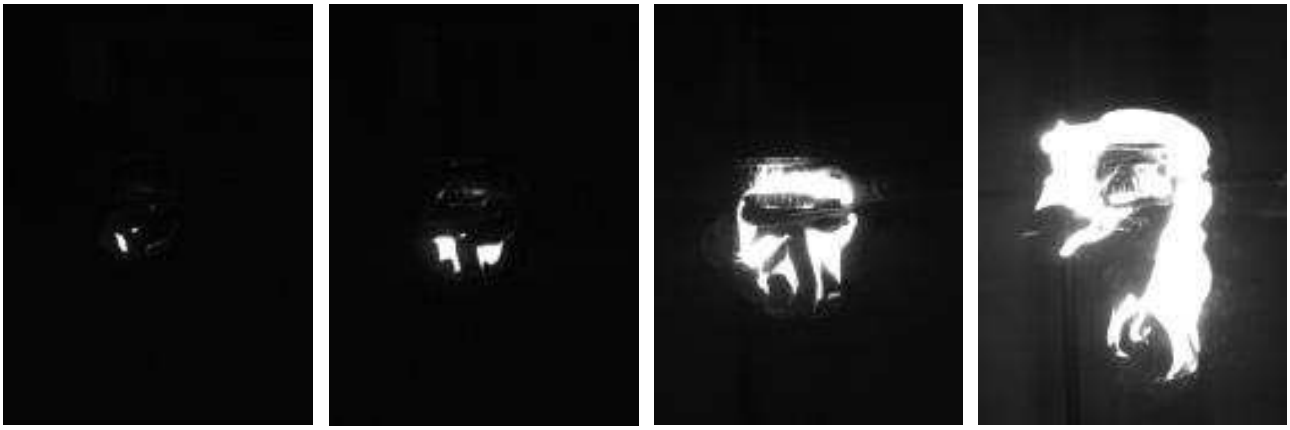

Figure 3. Ignition of α-pinene in the heated hermetic enclosure.

Other experiments have been performed in the same enclosure, with the electrodes placed in a box situated below the cup (filled with α-pinene). In this configuration, emitted gases are concentrated in a box and it is interesting to observe the differences with the previous configuration (without concentrating gases). Electrodes are placed at the center of the box. A color high speed digital camera Phantom V310 operating at 400 images per second is used to follow the flame propagation. Example of flame propagation is presented in Figure 4. This phenomenon was very rapid and not very luminous; this is the reason why we had to use a color high speed camera. Spherical propagation and blue color are characteristics of premixed flames: we actually created a premix α-pinene/air by diffusion of α-pinene in air.

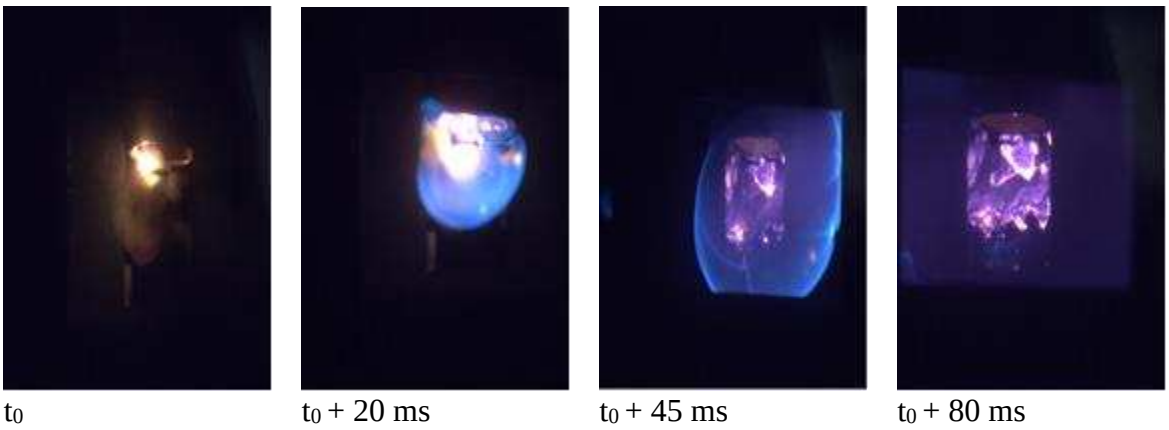

Figure 4. Ignition of α-pinene vapours concentrated in a box.

We have therefore shown that BVOCs are diffusing in the direction of the ground and for this reason they can accumulate at the bottom of a canyon. We have also shown that liquid BVOCs when heated can create with air a flammable mixture. It is now interesting to see if it possible to ignite directly BVOCs mixture emitted by a vegetal species.

3.2. BVOCs ignition

One of the necks of the flask is let open at the beginning of the heating in order to let water vapor going out of the flask. From 393 K, this neck is closed and the gases are transferred in the line that

leads to the beaker. An ignition occurs when the beaker is placed next to a candle. This is illustrated in Figure 5.

Emitted gases are concentrated inside a beaker and of course diffusion effects that can be observed at canyon scale are not taken into account with this very simple experiment. Nevertheless, we can see that heated needles can emit enough BVOCs to create an ignition.

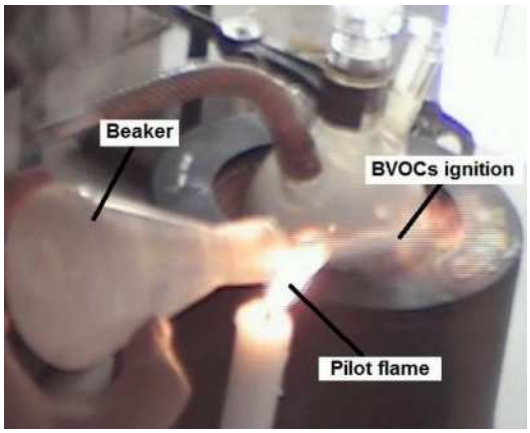

Figure 5. Picture of the ignition of BVOCs emitted by heated Rosmarinus officinalis needles.

Conclusion

Very simple experiments were performed in this study in order to give validation elements to the thermochemical explanation for accelerating forest fires. This hypothesis is based on the fact that almost all vegetal species involved in forest fires emit BVOCs that can form with air a flammable premix. The acceleration of the fire rate of spread could therefore be the consequence of the transition between a diffusion flame characteristic of forest fires and a premixed flame. We have shown in this work that gases emitted by vegetation are diffused mainly in the direction of the ground and that BVOCs mixture emitted by *Rosmarinus officinalis* needles can be ignited with a pilot flame. It will be of course necessary to validate the thermochemical hypothesis for accelerating forest fires to prove that BVOCs are emitted in concentration sufficient to create with air a flammable mixture, this will be investigated in a future work. Up to now, we just proved that this hypothesis can be possible.

Abstract

Tropical mountain cloud forests (TMCFs) are becoming new fire-prone areas in the Neotropics due to ongoing climate change. TMCFs are increasingly suffering from drought episodes during which fires starting at the puna grasslands that occur immediately above the forest, tend to penetrate into the TMCFs causing irreversible damage. Moreover, when the fire reaches the puna-forest treeline it frequently exhibits smouldering propagation consuming the humic soil layer resulting in large carbon emissions.

This paper presents an experimental program set up to study critical conditions that favour fire spread in the puna-TMCFs interface. The objective is twofold: to provide understanding of the threshold environment and fuel conditions allowing sustainable back-fire propagation in puna grasslands when advancing towards the TMCFs and to investigate the onset of smouldering combustion of the humic layers of the puna soil near the TMCFs treeline.

The study area was located at tropical Andean puna grasslands at the Cusco region (Southern Peru, bordering Manu National Park). It involved two different locations, one for the ground fire experiments and the other for the grassfire sustainability and behaviour tests. The first site comprised 20 paired ground plots (0.5 m x 0.5 m) which were ignited by a purpose-standardized ignition procedure and monitored by thermocouples during 48 h. The second site was divided in 12 grassland plots (20 m x 5 m) of two different fuel ages. Each grassfire was recorded with video and infrared cameras and witnessed by ground observers to detect fine scale changes in fire activity due to fuel and wind variability. Environmental conditions were constantly monitored in both type of experiments.

The ground tests provide novel information about smouldering fires in a real environment, going beyond classic laboratory experimentation. Soil temperatures higher than 100ºC were observed to last for around 20 hours with maximum temperatures around 450 ºC. The surface fires experiments revealed dead fuel load and fuel moisture content thresholds (0.2 kg m^{-2} and 20% respectively) that would explain back-fire sustainability, reaching those go-fires pseudo-stationary rates of spread of around 0.4-0.6 m min^{-1}.

These results will allow a more accurate estimation of the magnitude of the fire impact into the TMCFs ecosystems and help envisaging primary fire management policies and recommendations for the correct use of fire by the Andean indigenous communities.

Keywords*: grass fires, smouldering combustion, Peruvian Andes, fire sustainability, infrared imagery.*

Introduction

Fires are one of the largest disturbances in the Neotropics leading to severe environmental impacts in terms of carbon and biodiversity losses. One of the most threatened ecosystems in this ecozone are the tropical mountain cloud forests (TMCF), that albeit they only represent about 2.5% of all tropical forests (Bubb, 2004) they harbour the highest levels of biodiversity of the world (Myers, Mittermeier, Mittermeier, da Fonseca, & Kent, 2000).

TMCFs are mountain forests frequently covered by clouds or mist, and are usually found at altitudes between 1,500 m and 3,300 m a.s.l. (Stadmüller, 1987). Immediately above the forest, high altitude "puna" grasses are found. These grasslands have been populated for millennia by indigenous communities among which the use of fire has been a common practice for agricultural and grazing purposes as well as for supporting cultural and religious beliefs (Sarmiento & Frolich, 2002). Despite their high moisture levels, TMCFs are increasingly suffering from drought episodes due to climate change (Román-Cuesta *et al*., 2011) during which anthropogenic fires starting at the puna grasslands tend to penetrate into the TMCFs causing irreversible changes to the forests structure and composition and pushing the forest-puna treeline downslope (Oliveras, Anderson, & Malhi, 2014). Regardless of the erratic behaviour of fire in complex environments in terms of topography, fuel and wind dynamics, when a fire starts and a self-sustained flame front is formed in the puna grasslands, it usually exhibits backwards downslope flame propagation with high ratios of fuel consumption. Furthermore, under certain conditions, it can also involve smouldering propagation within the humic soil layer. Both the TMCFs and the high-altitude grasslands store large quantities of carbon. Recent studies have quantified the storage at the TMCF humic organic soil layer of 100 Mg C·ha^{-1} and 280 Mg C·ha^{-1} in the first 30 cm of the puna soil in the South-Eastern Peruvian Andes (Gibbon *et al*., 2010; Zimmermann *et al*., 2009), becoming then carbon losses through smouldering fires, a potentially substantial CO_2 emission source.

Notwithstanding the importance of fire activity in the tropical Andes, biomass burning dynamics are still poorly understood (Oliveras *et al*., 2014). Firstly, little is known about the onset environmental conditions for a self-sustained flame propagation in the high-altitude grasslands. Backing fire propagation is hardly affected by wind speed but mostly influenced by fuel moisture and fuel continuity (Cheney & Sullivan, 2008). This is particularly noteworthy in puna grasses, which are organized in discrete clumps favouring discontinuous fire behaviour. Likewise, the puna-tree line exhibits complex water dynamics among fuel and soil moisture and air relative humidity due to persistent ground-level clouds, which may result in an increased catchment water yield compared to other types of fuel (Wård, 2007). Secondly, the knowledge of the critical conditions that determine smouldering fire spread in the humic layers of the puna-tree line is very scarce. Moisture content of the carbon-rich humic layer is a key factor in controlling ignition and the subsequent spread of a smouldering front. Research in lowland rainforests has suggested a moisture content of 65% as a critical threshold for fire ignition and spread (Cochrane, 2003) but high elevation humic layers may have very different flammability characteristics, both because of the nature of the fuel and the low ambient atmospheric pressure and absolute oxygen concentration (Planas *et al*., 2013).

This paper presents an experimental burning program set up to advance our understanding of the critical conditions that favour fire spread in the puna-TMCFs interface. The program was performed at the south-eastern Peruvian Andes during July 2012 (mid dry season) and its objective was twofold: *i)* to investigate the threshold environment and fuel conditions allowing sustainable backing fire propagation in puna grasslands when advancing towards the TMCFs; and *ii)* to study the onset of smouldering combustion of the humic layers of the puna soil near the TMCFs treeline. The main highlights of these experiments are presented and preliminary results are summarized and briefly discussed.

Materials and methods

Experimental sites

The study area was located at tropical Andean puna grasslands at the Cusco region (Southern Peru, bordering Manu National Park). It involved two different locations, one for the ground fire experiments (13°10'50.28''S, 71°35'19.95''W) and the other for the grassfire sustainability and behaviour tests (13º9'4.26''S, 71º38'25.19''W) (**Erro! A origem da referência não foi encontrada.**1). This region experiences a tropical rainforest climate. Average annual rainfall ranges from 1,900 to 2,500 mm, with a wet season spanning from October to April. Mean annual temperature is approximately 11°C at 3,600 m a.s.l. (Gibbon *et al*., 2010). Both sites were covered by typical puna vegetation type, dominated mainly by tussock-forming grasses (*Calamagrostis longearistata, Ageratina sternbergiana, Juncus bufonius, and Scirpus rigidus* (Oliveras *et al*., submitted) with soils typically composed of an organic-rich A-layer, stony B/C-layers, and no Oh-layer (Gibbon *et al*., 2010; Zimmermann *et al*., 2009).

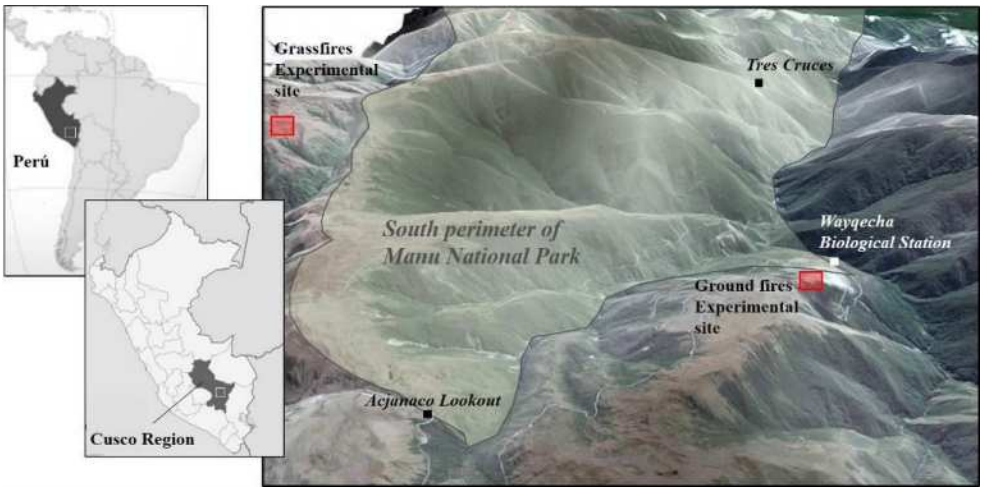

Figure 1. Study area

Ground fire test experimental design

An experimental program of smouldering fires was designed and performed in-situ. To the best of our knowledge, field burns experimentation for studying ground fires is a completely novel approach, far beyond the controlled conditions of laboratories set-ups (e.g. (Frandsen, 1998; Rein, Cleaver, Ashton, & Pironi, 2008)) where the soil usually losses its natural compactness and state. A randomized block of 20 plots (0.5 m x 0.5 m) was designed and replicated once. Five plots in every block were randomly selected as control plots (to be left unburned). Metal plates inserted 0.5 m deep bound all the plots (excepting the control ones), in order to avoid propagation outside the plots. The planning consisted on burning 6 plots at the same time (3 at every block) having then 5 sets available for five burning days. Due to meteorological constraints, only 3 sets were tested (Table 1, **Erro! A origem da referência não foi encontrada.**Figure 2).

Table 1. Random distribution of paired plots burned at each burning day (control plots in brackets)

Date of tests start	Plots in Block W1	Plots in Block W2
Day 1	A1, B2, D1 (CP4)	B1, C1, C2 (CP4)
Day 2	A4, B4, B5 (CP1)	B4, D4, C5 (CP1)
Day 3	B1, D3, D5 (CP2)	A1, A3, A5 (CP2)

An ad-hoc ignition procedure was implemented, which consisted on introducing glowing charcoal in a 30 cm x 10 cm x 20 cm deep dug hole at one of the sides of the plot. An educated guess of the power supply of the ignition source was done according to data available on charcoal heat of combustion and burning rate (Shafizadeh, 1978)(Andreatta, personal communication). 98% of the charcoal energy was assumed to be released within the first 6 hours and a mean heat transfer rate per unit area of 8,4 $kW \cdot m^{-2}$ was found, being only during the first two hours above the minimum necessary for the propagation of a smouldering front, suggested at 10 $kW \cdot m^{-2}$ (Ohlemiller, 2002).Weather data (ambient temperature, relative humidity and wind speed and direction) was measured by a portable weather station placed between the two experimental blocks. Soil moisture content was read at 12 cm and 20 cm deep before ignition at the control plot using a Hydrosense Soil Water Measurement System (Campbell Scientific, Inc.). Grass was clipped at the experimental plots before ignition and some soil samples were extracted from the control plots and sent to the laboratory in order to obtain inorganic content and bulk density. An array of K-type metal-sheathed thermocouples of 0.5-mm diameter, 30-cm length was used to monitor soil temperatures at two deferent depths (5 cm and 15 cm) during the tests, following Figure 3 distribution scheme. This layout was designed in order to both detect ignition (by observing the thermocouple evolution placed 5 cm apart from the ignition source) and pick any possible heat front propagation main direction (by observing the evolution of the rest of the sensors). The plots were left 48h untouched letting the data loggers (HOBO Onset Computer Corp.) connected to the thermocouples register temperatures at a frequency of one datum per minute.

Grassfire sustainability and behaviour tests experimental design

Concerning the experimental grassfires program, it covered thirteen backing fires designed to study the effect of the different weather and fuel variables in grassfire sustainability and behaviour. We stablished two 20 m width by 30 m length plots in a 40º slope spot, one in 3-year old grassland (named P3) and the other in a 7-year old grass (named P7). Six experimental fires were planned in each plot, leaving 5 m for the fire to spread downslope. Every test was ignited with drip-torches along the leeward side of the plot. If the flame front failed to propagate, i.e. exhibited a discontinuous perimeter that tent to self-extinguish, the fire was considered a no-go, and a subsequent ignition was planned for when a significant change of meteorological conditions was observed. If the fire propagated, we would monitor its behaviour until the fire advanced 5 m and proceed to suppress it immediately afterwards using hand firefighting tools.

For planning purposes prior to the experiments, weather records (June-July 2011) from a local station located at 1.5 km from the site (Pumataki weather station) were obtained to analyse rainfall probabilities and to study relative humidity daily variation. Before the experiments, we characterized fuel loads, cover, height and degree of curing, involving a variety of sampling methods (i.e. destructive sampling and point intersect method following a systematic sampling grid within each experimental plot). During burning days, fire weather was monitored every 30 seconds, using a portable weather station located in the vicinity of the experimental plot. Fuel moisture was obtained in-situ before each burn by using an infrared-heated moisture analyser (Sartorius MA-45). Fire direct observation alongside the flame front was performed in order to have fire behaviour information. Two groups of fire observers at each plot would record flame front position, flame length and flame angle at time intervals between 30-60 seconds.

3. Preliminary results and discussion

3.1. Ground fire tests results

Ignitions were performed in eighteen plots in three days (7th, 10th and 11th July 2012) between 10:30h and 14:30h. Ambient conditions followed a similar trend at night time, with stable temperature (around 8ºC), relative humidity (above 90%) and wind speed (below 2 km·h^{-1}) for the whole experimental period. During the day, and particular at noon (from 11h to 14h), weather variables had more

fluctuations. Table 2 shows the experimental range of these environmental parameters coupling the three experimental days, together with soil properties and moisture content values at two different depths.

Table 2. Environmental parameters associated with the ground fire tests

Variable	Measures
Mean midday temperature (ºC)	10.7 – 18.3
Mean midday windspeed ($km \cdot h^{-1}$)	3.4 – 7.8
Mean midday relative humidity (%)	37.7 – 95.9
Soil moisture content at 12 cm (SMC, d.b. %)	90.89 – 130.76
Soil moisture content at 20 cm (SMC, d.b. %)	83.29 – 122.96
Soil inorganic content (IC, %)	18
Soil bulk density (BD, $kg \cdot m^{-3}$)	830

d.b.: dry basis

Ground fire ignition is known to be controlled by soil bulk density, inorganic content and soil moisture content (Frandsen, 1997). The two first parameters were considered constants in all our study area (i.e. no differences per plot) whereas we assumed that soil moisture content could had a variation during burning days responding to meteorological changes at least at the first centimetres of soil depth. Statistical analysis was performed in order to peak possible characteristic soil moisture values per day or plot (data not shown). Significant differences were observed in soil moisture content at the two different depths but this parameter did not show any statistical significant dependence between days or blocks. This result led us to perform an aggregated analysis considering all the tests (18 in total).
For all the experimental plots, we only registered noteworthy temperature response (>60ºC) at some thermocouples named as TC1 (5 cm apart from the ignition source, 15 cm depth) and at some TC2 and TC3 (both 10 cm apart from the ignition source, 5 cm depth). Table 3 summarizes the main findings obtained after processing temperature vs time evolution curves of all the active thermocouples used in our two blocks. In 67% of the cases, at least TC1 showed some significant temperature increase, achieving values above 60ºC, which is roughly the mean value corresponding to protein degradation and at which water loss starts (Cerda & Robichaud, 2009; Swezy & Agee, 1991). The time needed for these thermocouples to reach this threshold oscillated from 8h to 16h after ignition depending on the plot, which is well after the time needed for almost complete (98%) charcoal consumption. Slightly less than half of these thermocouples reached 80 ºC (threshold for many soil microbes death, (Cerda & Robichaud, 2009), with only 3 from 18 sensors peaking values above 100ºC at which water vaporizes and carbon volatizes (Swezy & Agee, 1991). We had only one case from 18 tests, at which typical ground fire front temperatures were registered (Rein *et al*., 2008), with a peak temperature above 400 ºC. Concerning TC2 and TC3 readings, temperatures above 60ºC were achieved in 3 cases and only in one of these, peak temperature reached 80ºC.
These results show that under our experimental conditions, there are only 6% chances for a weak ground fire ignition (i.e. a ground fire that may propagate less than 10 cm from the ignition point tending to self-extinguish). Furthermore, there are 17% chances for the formation of a heat front of around 60ºC which may travel less than 15 cm and finally, 6% chances that the same front may reach the temperature needed for killing most of the microbes present at the soil.

Table 3. Temperature response occurrence of the ground fire experiments.

Peak Temperature	Number of tests	Occurrence
TC1 at T > 60 ºC	12/18	67%
TC1 at T > 80 ºC	5/18	28%
TC1 at T > 100 ºC	3/18	17%
TC1 at T > 400 ºC	1/18	6%
TC2/TC3 at T > 60 ºC	3/18	17%
TC2/TC3 at T > 80 ºC	1/18	6%

Temperature vs time profile of some selected TC1 thermocouples readings are plotted in Figure 4. TC1 of W1B1 plot is the one showing successful ignition. Soil at TC1 vicinity was 5 hours above 400 ºC, it reached a maximum temperature of 463ºC 15 hours after ignition, and it was more than 16 hours at temperatures exceeding 200°C (threshold for N volatilization (Raison, Woods, Jakobsen, & Bary, 1986)). Considering the instant of maximum temperature as the smouldering front characteristic arrival time, we can affirm that the mean spread rate of the ground fire was 3 $mm \cdot h^{-1}$. This value corresponds to a self-extinguishing ground fire front and is below the typical ranges for smouldering fronts of 10-30 $mm \cdot h^{-1}$ (Rein, 2009).
W2A3, W1D1 and W2D4 TC1 profiles show temperature evolution of failed ignition tests. However, it is worth mentioning some interesting patterns of these three sensors: TC1 in W1D1 had a clear drop around 12 hours after ignition which would correspond to the 100% consumption of the ignition source; W2A3 TC1 had one of the longest residence time (14 h) above 60ºC, surpassing in this case any ignition effect. Finally, W2D4 was more than 45 h above this latter threshold, exhibiting plateaus at 80ºC -100ºC corresponding to the evaporation of the moisture in the soil.

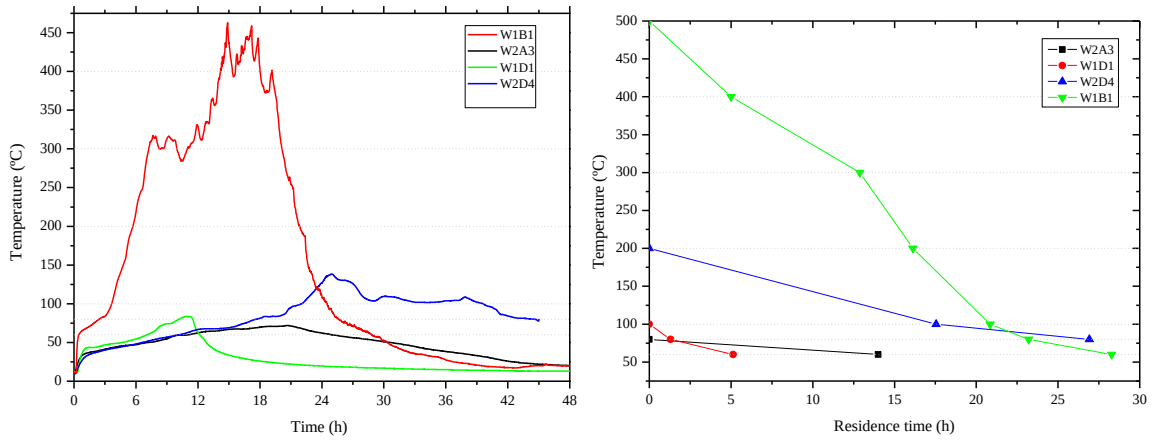

Figure 4. Left) Temperature evolution of four selected TC1 thermocouples; right) thermal severity registered by the same TC1 thermocouples

Grassfires results

The experimental program comprised a set of seven and six experimental fires in the 3-years-old puna and the 7-year-old puna, respectively performed during 4 burning days (July 5th, 6th, 9th and 10th 2012). Figure 5 shows the evolution of the relative humidity (RH) with time for the four days together with the exact time when the experiments were undertaken. Taking into account the expected unfavourable climatology of the area despite being at the dry season (70% of daily raining probabilities were registered during June-July 2011 by the Pumataki weather station), a RH range of around 50 points

could be picked during the four burning days, taking advantage of the daily fluctuation of this variable to perform several tests within the same day.

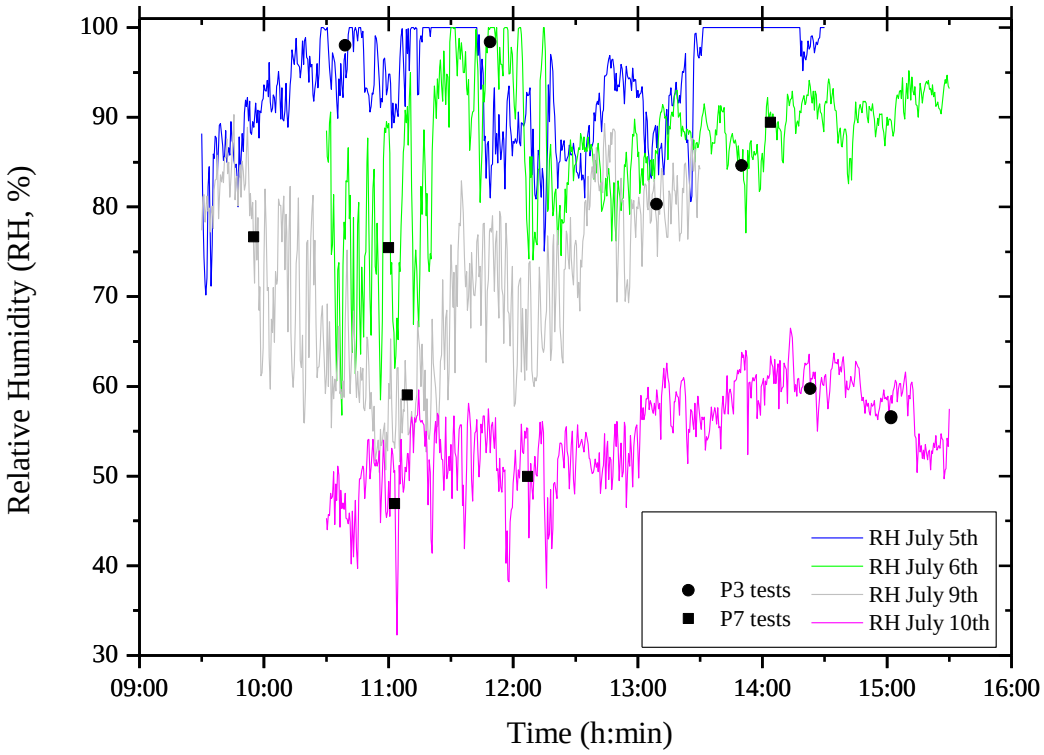

Figure 5. Relative humidity time evolution for the four burning days (5th, 6th, 9th, 10th July 2012)

Environmental parameters (i.e. fuel characteristics and fire weather) changed from one test to another. Table 4 provides the experimental range of these, partitioned by fuel type. Statistical differences between both types of fuels were explored for each variable. 3-year and 7-year old puna differed in terms of dead fuel load, degree of curing and fuel cover, whereas no statistically significant differences were found for FMC, respectively. Air temperature, RH and wind speed varied roughly within the same order of magnitude for both plots, being the latter reasonably well aligned with the slope (leeward side of the plots north/north-westerly oriented).

Table 4. Range in environmental parameters associated with the grassland fires

Group	Variable	3-year puna	7-year puna	Statistical test (p-value)
Fuel	Dead fuel load ($kg \cdot m^{-2}$)	0.2 – 0.5	0.8 – 1.4	Mann-Whitney (p< 0.005)
	Degree of curing (%)	70 – 76	78 – 87	ANOVA (p<0.005)
	Fuel cover (%)	47.5 – 80	75 – 99	ANOVA (p=0.005)
	Dead fuel moisture content, FMC (%)	8.2 – 30.6	7.2 – 23.3	ANOVA (p=0.651)
Fire weather	Air temperature (ºC)	7.8 – 10.6	7.8 – 11.7	ANOVA (p=0.163)
	Relative humidity (%)	57 – 98	47 – 89	ANOVA (p=0.131)
	2-m wind speed ($km \cdot h^{-1}$)	5.4 – 12.9	5.8 – 12.6	ANOVA (p=0.526)
	2-m wind direction (º)	98 – 107	80.8 – 98.1	ANOVA (p<0.005)

We counted 3 go-fires from 7 ignitions in 3-year old puna and 4 go-fires from 6 ignitions in the elder puna. We explored differences between parameters for go and no-go fires (analyzing both P3 and P7

tests together). Figure 6 suggests fire sustainability could be explained by means of dead fuel load and dead fuel moisture content. These results are in agreement with other fire sustainability studies (Cruz & Gould, 2010). Our preliminary results show there could be a FMC threshold between 17-23% which could avoid fire propagation in our experimental set as well as a dead fuel load threshold around 0.2 $kg \cdot m^{-2}$ below which there might be not available fuel for a sustained fire spread. This idea is supported by the fact that FMC differences between go and no-go fires were found to be statistically significant (ANOVA p=0.042). However, we could not find any statistical bases related to DFL, probably because P3 mean dead fuel load is already marginal for sustained fire spread and we do not have any test with DFL significantly lower than this in our dataset.

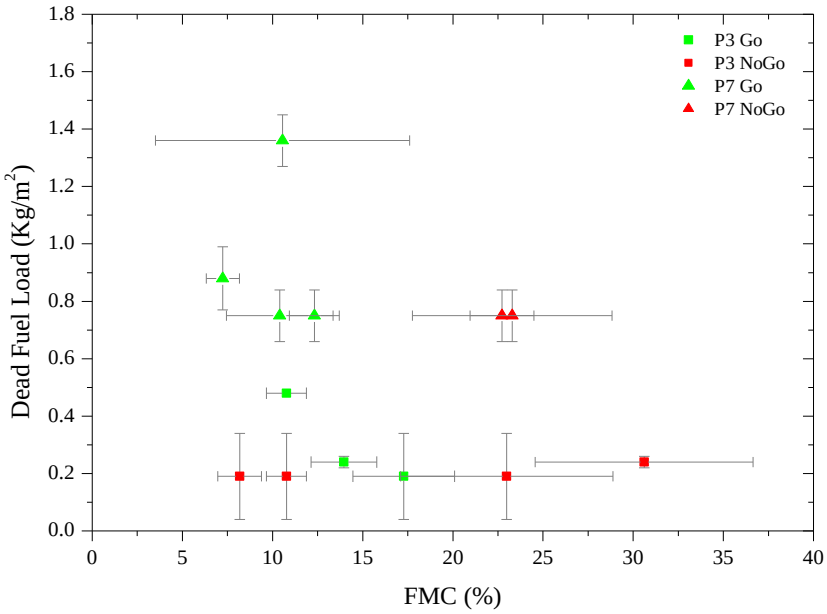

Figure 6. Go/no-Go matrix for P3 and P7 fires

Rate of spread was analysed for P3 and P7 self-sustained fires. There was a convergence to a pseudo-stationary rate of spread for all P3 (a) and all P7 (c) go-fires (Figure 7). Analysing ROS averages at 2-minutes intervals, it can be observed how steady state was achieved after 10 minutes in P3 fires with a mean stationary propagation of 0.37 m/min (s.d. 0.038), and after 8 minutes in P7 fires, at 0.56 m/min (s.d. 0.095). A 2-Sample t-test between all P3 ROS observations and all P7 ones, denoted dissimilarity between groups ($p<0.005$). This difference can be explained in terms of relative humidity (ANOVA p=0.02), curing degree (ANOVA p=0.013) and dead fuel load (ANOVA p=0.02). The latter result highlights the important role of the amount of available fuel on fire behaviour in this type of ecosystem.

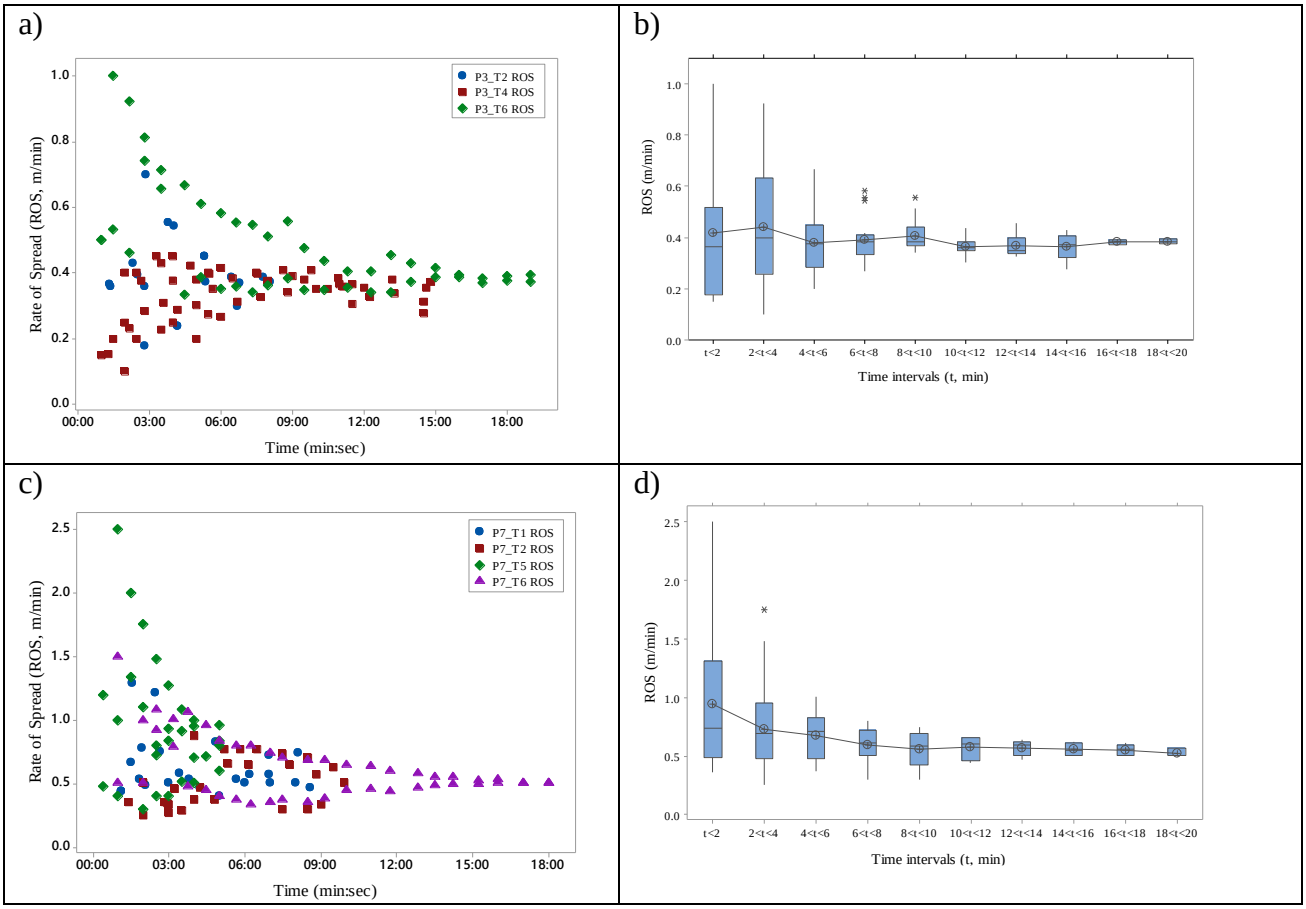

Figure 7. ROS evolution for P3 tests and P7 tests; left) Scatterplots of all fire observations sorted by tests at a) P3 and c) P7; right) evolution of 2-min interval mean ROS value for all b) P3 and d) P7 dataset.

Byram's fireline intensity, flame length of the leading edge and flame angle (defined as the inclination of the leading edge from the vertical) are presented in Table 5. According to these, experimental tests are in agreement with low intensity back-fire regime figures (Andrews, Heinsch, & Schelvan, 2011). The lowest mean fire intensity computed corresponds to test 6 of 3-year puna, and equals to 18.9 $kW \cdot m^{-1}$ (s.d. 4.5) which can be considered the threshold for backfire spread by flaming combustion in the study area. It is to be highlighted that this threshold almost doubles the headfire spread minimum intensity limit set at 10 $kW \cdot m^{-1}$ (Alexander, 2000) which reveals the existing differences between head and backfire propagation mechanisms.

Table 5. Mean values of fireline intensity and flame geometry characteristics

	Fireline Intensity ($kW \cdot m^{-1}$)	Flame angle (º)	Flame length (m)
P3	39.5 (s.d. 27.6)	45.8º (s.d. 12.9)	0.34 (s.d. 0.23)
P7	180.1 (s.d. 82.9)	46.0º (s.d.13.6)	0.94 (s.d. 0.57)

Concluding remarks

A twofold experimental program was performed to study critical conditions that favour fire spread in the puna-TMCFs interface, providing understanding of the threshold environment and fuel conditions allowing sustainable ground smouldering fires and back-propagation grassfires. These results will

allow a more accurate estimation of the magnitude of the fire impact into the TMCFs ecosystems and will help envisaging primary fire management policies.

A novel methodology for in-situ ground fire tests has been developed and found successful, being our experimental dataset the first of these characteristics, far beyond the controlled conditions of laboratories set-ups. Conditions tested have been found marginal for self-sustained propagation (SMC between 91-131%, IC 18% and BD 830 $kg \cdot m^{-3}$). However, in one particular case, a smouldering front has been observed advancing 5 cm in 15 h, with typical temperature ranges above 400ºC. In 67% of the tests, temperatures for biological molecules denaturation have been reached with residence times up to 14h but the water evaporation threshold has been only surpassed in 3 tests, which confirms that given the physical properties of the soil, moisture content has been the factor preventing self-sustained smouldering fires in our dataset. Despite the front propagation has been in all plots weaker than in many of the lab-scale tests reported in the literature, residence times found in our experimentation are substantially larger and not dependent on the ignition source used.

Sustainability of back fires at the puna grasses sitting above the TMCFs is a key aspect when studying fire occurrence and its environmental implications at the forest-puna treeline. A complete understanding of this phenomenon is needed for fire managing purposes, in particular for debriefing indigenous communities about the correct use of fire. Our grassfire behaviour and sustainability experiments have proved that fire sustainability at the Andean puna can be explained by key fuel parameters. Fuel moisture content has a preponderant role and dead fuel load appears to be also important. For dry season, we suggest initial thresholds of 20% and 0.2 $kg \cdot m^{-2}$, respectively, to be used in our study area. However, our dataset would have to be enlarged with more experimental campaigns to precise these figures. Due to the difficulty and cost of this type of experimentation, physical or quasi-physical simulation appears to be the most feasible alternative to burning campaigns. With a complete experimental design, a simulation-based probabilistic model for fire sustainability could be obtained, which should be of great help for management purposes in the zone of influence of our study area and in other Andean emerging fire-prone grasslands, provided the selected fire simulation tool is validated with the already available experimental dataset.

Steady state fire spread at puna of different ages has been achieved in the go-fires of our experimental campaign. Relative humidity, curing degree and dead fuel load are the key parameters that have major influence on the rate of spread in our experimental dataset. The limit for sustained back-fire spread has been found at around 20 $kW \cdot m^{-1}$. This is the minimum power needed for the flame front to overcome grass clumps discontinuities. Rate of spread, fireline intensity and flame dimensions have been accurately quantified for 3-year and 7-year puna grasses. These are the main variables arisen from the heat transfer processes between the fireline and the surrounding environment. This information can be of great help when evaluating different aspects of fire impact and the ecosystem response to it. In particular, this data with such a degree of accuracy shall be useful to improve carbon losses estimations.

Fine fuel particle heating during experimental laboratory fires

Jack D. Cohen, Mark A. Finney

Abstract
Fuel particle temperature measurements were related to measurements of particle irradiance and impinging gas temperatures during seven fire spread experiments at the U.S. Forest Service Fire Sciences Laboratory, Missoula, Montana. Fine particle temperature increases corresponded to pulses of impinging hot gases and thus suggested convection as the primary heat transfer mechanism responsible for particle ignition. An analysis using the flux-time product correlation (FTP) indicated that flame radiation was insufficient to pilot ignite fuels for fire spread. A numerical modeling examination of fine particle heating indicated flame radiation was insufficient for particle ignition and convection heat transfer from flame contact was the primary heating mechanism leading to particle ignition.

Keywords*: Fuel heating, Fire spread, Ignition processes*

Introduction

Since the 1940's wildfire spread has been described as a step-wise process of ignition by heat transfer from the burning zone to adjacent fine fuel particles (Fons 1946). Observations and experiments have identified fine live and dead vegetation (e.g. conifer needles and twigs < 3 mm diameter) as the burning fuels primarily responsible for the intensity of the propagating flame zone and thus wildfire spread (Fons 1946; Rothermel 1972; Pagni and Peterson 1973; Call and Albini 1997; Stocks *et al*. 2004). For example, after fire spreads through shrub and tree canopies the branches larger than 6 mm commonly remain unconsumed after a high intensity wildfire has burned the area. Thus, understanding fire spread requires an understanding of ignition processes at spatial and temporal scales of fine fuels.
Sufficient understanding of wildland fire spread processes does not exist for reliable *ex ante* physical modeling. An indicator of this insufficient understanding is the inconsistency between fire spread models that attempt physical descriptions of radiation and convection (Sullivan 2009). Model developers have largely assumed fuel particle ignition processes without an experimental basis (Finney *et al*. 2013a). For example, radiation heat transfer has been commonly assumed to govern fire spread. However, experimental evidence suggests radiation heat transfer is insufficient for igniting fine fuel particles (Fang and Steward 1969; Baines 1990; Finney *et al*. 2013a). And prior experimental evidence (Rothermel and Anderson 1966; Fang and Steward 1969) and laboratory fire observations (Baines 1990; Fang and Steward 1969) indicated that most fuel particle heating to ignition occurred within the last 0.025 m during fire spread. Given that burning fine fuels are primarily responsible for wildland fire spread, if radiation is insufficient for fine fuel ignition then convection must be the heat transfer mechanism governing fire spread. The convective heating would occur from flame impingement on fuels adjacent to the flaming front, and recent experiments have shown how this occurs (related paper[1]). The following discussion describes measured fuel particle temperatures related to measured incident radiation heat fluxes (irradiance) and gas temperatures during experimental surface fires and how that relates to heat transfer mechanisms governing fire spread.

[1] Finney et al. 2014. Experimental evidence of buoyancy controlled flame spread in wildland fires; VII ICFFR.

Methods

We are experimentally examining wildfire ignition processes to provide a basis for physically modeling fire spread. The following discussion describes fuel particle heating experiments with measurements made at fine fuel particle spatial and temporal scales. The experiments relate measured fine fuel particle temperatures with measured irradiance and impinging gas temperatures during the approach of spreading flame zones. In conjunction with the experiments, heat transfer processes are examined using modeling.

Experiments

Special wood fuel particles were instrumented with thermocouples along with measurements of incident radiation (irradiance) and gas temperatures adjacent to the particles. Machined wood (*Liriodendron tulipiferia*) particles with 1 mm and 12 mm square cross-sections, both 120 mm long were instrumented with fine thermocouples (K Type, 0.05 mm). The 1 mm fuel particles had thermocouples embedded at the center of the front (facing the approaching flames) and back vertical surfaces; the 12 mm particles had thermocouples embedded at the center of each vertical and horizontal surface (front, top, back and bottom) (Figure 1). The fuel particles were horizontally attached to the top of precisely constructed cardboard "comb" fuel beds. The particles were located 130 mm to one side of the center line of the 2.44 m wide fuel bed in the U.S. Forest Service experimental wind tunnel burning facility in Missoula, Montana.

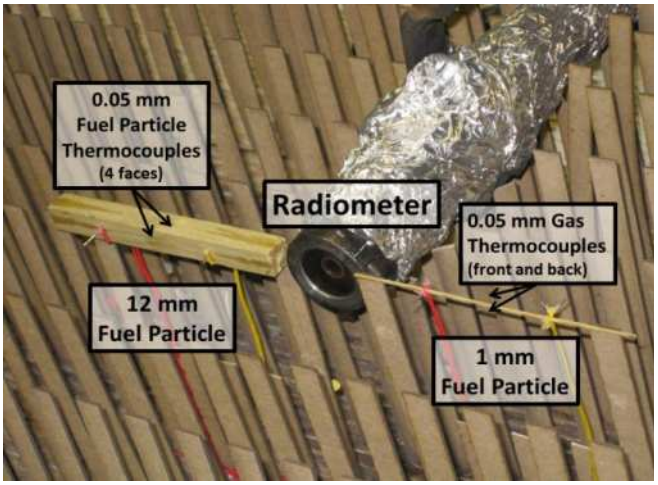

Figure 1 - 1 mm and 12 mm fuel particles were instrumented with 0.05 mm thermocouples. The 1 mm particle had thermocouples embedded in the centers of front and back faces only; the 12 mm particle had thermocouples centered in four faces (ends are neglected). The particles were attached to the top of a "fuel comb" in the cardboard fuel bed. The comb fuel bed shown had tines 152 mm tall and 12.4 mm wide and spaced 46 mm between rows. A water cooled radiometer at fuel particle height estimated particle irradiance and suspended 0.05 mm thermocouples estimated gas temperatures.

Fuel particle irradiance and temperatures of impinging gases were measured as the fire spread to the particles. Fuel particle irradiance was estimated using a water-cooled radiometer placed even with the fuel particles. Temperatures of gases flowing around the fuel particles were estimated using fine thermocouples (K Type, 0.05 mm) suspended approximately 5 mm from the particle's front and back vertical faces (Figure 1). To reliably measure the flame radiation we calibrated the radiometer using a black body cavity having temperatures in the range of a spreading flame front (1000 K – 1400 K). All measurements were taken at a sampling rate of 500 per second (500 Hz). At this rate, the sampling time interval (.002 sec) is less than one-half the time constant (.04 sec) of the fastest responding sensor (thermocouple) and meets Nyquist frequency aliasing criteria (Fritschen and Gay 1979). Measurements began before fuel bed ignition and continued through fine particle ignition and burning.

The "comb" fuel beds were engineered using 1.25 mm thick cardboard (Finney *et al*. 2013b). Each comb was laser cut from a 1.2 m long sheet to specified tine heights and widths (Figure 1). Fuel particles were mounted on combs having tine widths of 2.31 mm, 6.20 and 12.4 mm and comb heights ranging from 102 mm to 203 mm. To change flame zone characteristics fuel beds were constructed with combs at various spacing widths between rows and combinations of combs with different tine

heights and widths. For fuel beds with comb size combinations, fuel particles were mounted on the combs with the highest tines.

Modeling

We used a two-dimensional numerical model of fuel particle heat transfer to further examine particle heating during the fire experiments. The numerical model calculates fuel particle temperatures across the particle mid-section and these temperatures reasonably represent temperatures for most of the particle. This assumes that end effects are negligible and the particle exchanges energy uniformly along its length (120 mm) such that no significant lengthwise temperature gradients occur through most of the particle. The numerical model used a finite difference, explicit method with a grid increment of 2.5×10^{-5} meters between computational nodes and a time increment of 5.0×10^{-4} seconds. We verified that the computational results were stable and independent of spatial and temporal increments. The irradiance and gas temperature measurements from the experiments were used as inputs to the 1 mm particle model.

The initial conditions and boundary conditions were determined by a combination of measured values and assumed values. We assumed the fuel particle initially had uniform temperature corresponding to the measured front face temperature before heating from the flame front. It was assumed the particle was in equilibrium with its surroundings just prior to the first model computation. Radiation boundary conditions were estimated by the measured irradiance for the front face and the designated constant blackbody temperature of the surroundings for the other three faces of the particle. The convection boundary conditions were estimated by a computed convection heat transfer coefficient and the measured gas temperature adjacent to the fuel particle front face. For the lack of a convection coefficient correlation that matched the particle heating context, the Hilpert average correlation for non-circular forms (Incopera and DeWitt 2002) was used. The flow velocities were assumed based on the measured gas temperature. At gas temperatures below 500 C the flow velocity was designated to be the wind tunnel flow speed. For gas temperatures equal to and greater than 500 C, the gas flow velocity was increased to seven times the ambient flow based on observations of higher flow circulations associated with flames. Although the convection coefficient and air properties were determined for the entire particle based on the average film temperature for the front face, the heat transfer was calculated at each computational node. At every time increment, the physical properties of the wood particle were determined by the temperature at each computational node.

The model only accounted for heat exchange and did not include chemical kinetics and mass transfer related to moisture vaporization and pyrolysis. Although particles were not oven-dried prior to the experiments, the 1 mm particles had moisture contents less than six percent and assumed negligible for modeling. Pyrolysis was assumed negligible at particle temperatures below 275 C. The model was considered unreliable at temperatures above 275 C and thus modeling ended prior to particle ignition. The purpose of the modeling was to examine heat transfer processes leading to particle ignition during fire spread. There was no intent to develop a predictive tool with this effort. Thus, model parameters were set without benefit of prior comparisons between model and experimental results and model parameters were not adjusted after comparisons to improve estimates of measured particle temperatures.

Results

Seven fire spread experiments were conducted with instrumented fuel particles. To describe the context of the particle heating experiments related to fire conditions, Table 1 provides the wind speed, fire spread rate, flame length, flame zone depth and particle irradiance for each burn. After ignition the experimental fires spread with a nearly straight flame front across the 2.44 meter wide fuel bed. The flame lengths from Table 1 suggest fire characteristics similar to those burning actual fuel beds composed of short grasses or surface forest litter under dry conditions and low wind speeds. The factors contributing to the variety of spread rates and flame lengths such as fuel bed characteristics are beyond the scope of this discussion and not included in the Table 1.

Table 1. Laboratory Fire Spread Conditions. Wind speed was a constant wind tunnel setting. Rate of spread and flame length were estimated after the influence of the ignition line became negligible. Flaming depth was the estimated distance from the forward edge of the propagating flame front to the rear where coherent flaming ceases due to fuel consumption. The fuel particle irradiance range is from the last four seconds before the 1 mm particle ignition.

Fire Exp.	Wind Speed (m/s)	Rate of Spread (m/s)	Flame Length (m)	Flaming Depth (m)	Irradiance [4 s to ign.] (kW/m^2)
a	0.34	0.028	1.0	0.54	20 - 29
b	0.34	0.024	1.2	0.41	20 - 30
c	0.22	0.016	1.4	0.57	22 - 40
d	0.56	0.032	1.2	0.68	17 - 34
e	0.34	0.031	1.3	0.56	25 - 44
f	0.67	0.034	1.5	0.60	13 - 22
g	0.34	0.031	0.6	0.28	10 - 22

Every experiment produced the same general results regarding the fuel particle thermal response to transient conditions and ignition. The 1 mm particles responded quickly to changing thermal conditions compared to the 12 mm particles (Figure 2). Within the last four seconds of the approaching flame front the 1 mm particle temperatures rapidly increased resulting in sustained ignition while the 12 mm particle had not yet ignited before flame front arrival (Figure 2). Particle ignition was determined by fuel particle and gas temperatures and confirmed with video recordings. In all seven experiments the 1 mm particles ignited before the 12 mm particles.

None of the experiments produced measured fuel particle irradiance capable of piloted ignition. Using a validated irradiance based ignition correlation (Cohen 2004) the flux-time product (FTP) was computed from the measured fuel particle irradiances. The resulting FTP values for all the fuel particle experiments were well below the criteria for ignition. For example, the maximum measured irradiance of the fuel particle experiments was 44 kW/m^2 (Table 1, experiment "e") and the FTP value when the 1 mm particle sustainably ignited was 1313. The minimum value for piloted ignition is 11501, nearly an order of magnitude greater (Figure 3). Thus, radiation heat transfer was insufficient for particle ignition during all the fire spread experiments.

We take a closer examination of fine fuel heating during an approaching flame front. Because the general response characteristics of all fuel particle heating experiments were similar, we use measurements from fire experiment "d" (Table 1) to show the 1 mm particle response related to the irradiance and gas temperatures.

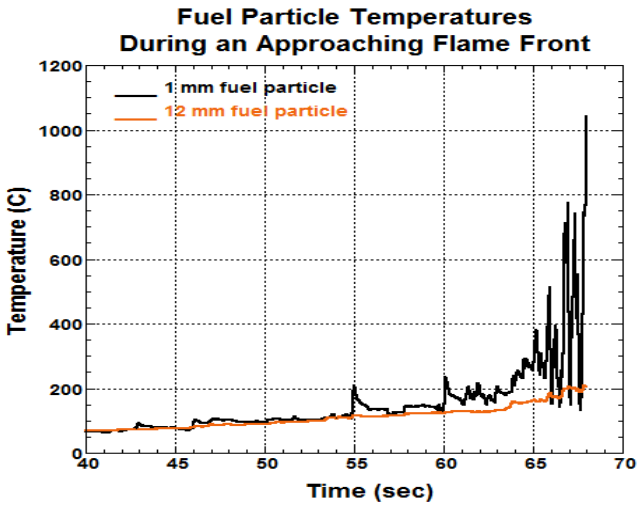

Figure 2 - For the same thermal conditions, the 1 mm particle (black) has a large temperature variation compared to the 12 mm particle (orange). In the last second of data the 1mm particle ignited while the 12 mm particle had not yet reached a temperature corresponding to a pyrolysis rate that could result in piloted ignition (example from

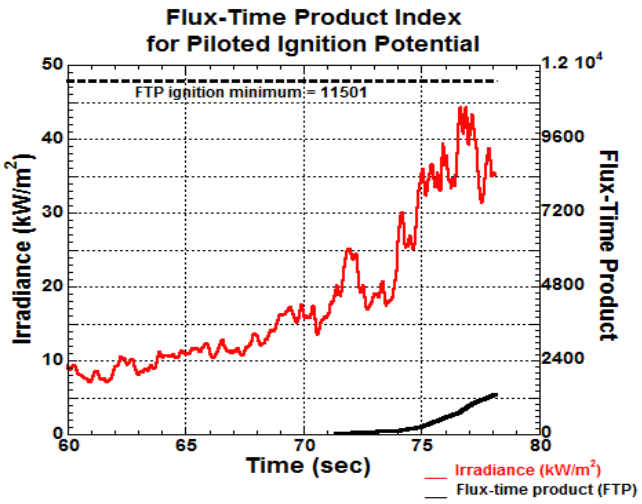

Figure 3 - The FTP (solid black) is calculated based on the measured irradiance (red, from experiment "e"). If the minimum FTP for ignition (broken black) is met and

Examination of the 1 mm particle response uses measurements of the irradiance, gas temperatures adjacent to and in front of the fuel particle and front face surface particle temperature ("front" refers to the side facing the fire). The 1 mm particle temperature graph (Figure 4) starts before significant thermal exposure from the flame front and ends just prior to the 1 mm particle ignition. Gas temperatures (blue) less than the particle temperature (black) indicate convective cooling; gas temperatures higher indicate convective heating. The gas temperature chronology shows intermittent high temperature spikes for approximately 20 seconds prior to ignition whereas radiant flux increases more steadily. Radiation energy absorbed by the particle is indicated by particle temperatures remaining higher than gas temperatures with noticeable particle temperature responses to gas temperature. Pulses of higher gas temperatures result in particle temperature increases. The higher the gas temperature and longer the pulse duration the greater the particle temperature increase. For example, the particle remains at 100 C – 120 C in the 50 – 55 second time interval (Figure 4). Small temperature increases occur only during pulses of gas temperatures above the particle temperature. The significant particle temperature increases occur during impinging pulses of hot gasses such as those that occur at 55, 60 and 64 seconds (Figure 4). In the last 1.5 seconds of the heating sequence the particle temperature increases from below 200 C and approaches 300 C (with subsequent ignition) only after gas temperatures remain above and several hundred degrees Celsius higher than particle temperatures (Figure 4).

Importantly, the pulsing higher gas temperatures result from the spreading flame front; the wind tunnel air flow is temperature controlled. The pulsing occurred in all fire experiments and produced particle heating downwind of the flame front. In Figure 4 pulses greater than 100 C began at about 20 seconds before particle ignition. Using the average rate of spread for experiment "d" from Table 1 (0.032 m/s) and neglecting the pulse advection time, the flame front was about 0.64 meters (0.032 m/s x 20 s) from the fuel particle when this convective particle heating occurred. The high temperature gas pulses at 55 seconds and 60 seconds (graph times; Figure 4) were greater than 600 C and within the range of visible flame temperatures. These pulses could have been observed as lateral extensions of the non-steady flaming front contacting the fuel particle across distances of 0.35 meters and 0.19 meters, respectively.

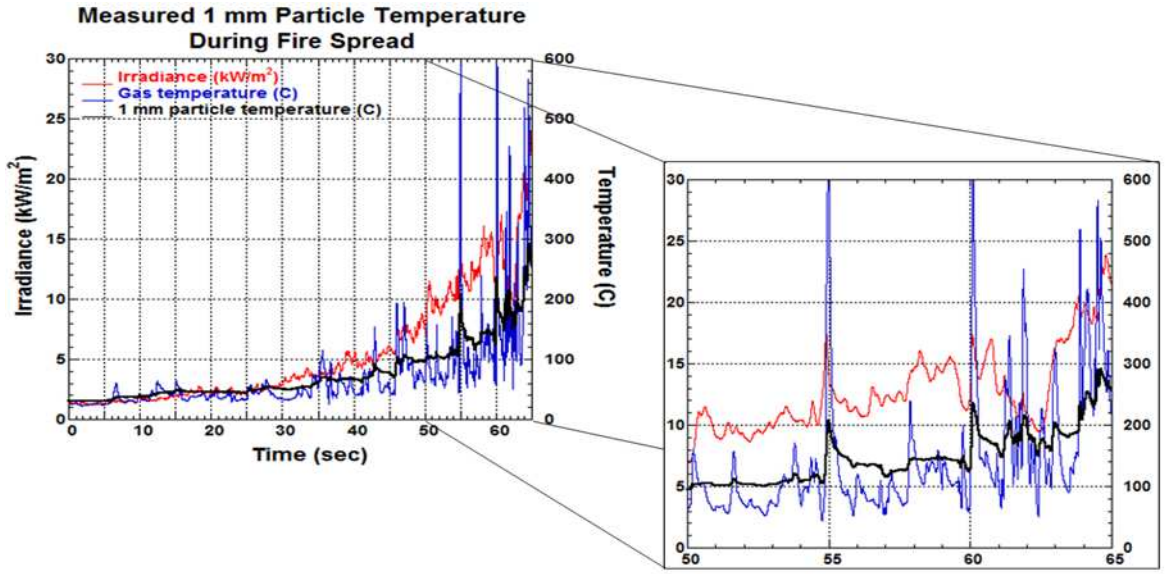

Figure 4. The left graph shows the measured front surface 1 mm fuel particle temperature with the corresponding measured irradiance and front face gas temperature as the fire spread to the particle. The graph ends just prior to particle ignition. The right graph is an enlargement of the last 15 seconds. The right graph shows particle temperatures responding (heating and cooling) to the variations in gas temperature and heating primarily during the pulses of high gas temperatures. (Data from experiment "d" of Table 1.)

The fuel particle heat transfer model computes fuel particle temperatures similar to the measured particle temperatures (Figure 5). Inspection of Figure 5 indicates the model captures the convective heating, both the response time and the magnitude during the high temperature gas pulses at 55 seconds, 60 seconds, and in the last second of the graph. However, the model did not simulate the thermal sensitivity revealed in the measured particle temperatures.

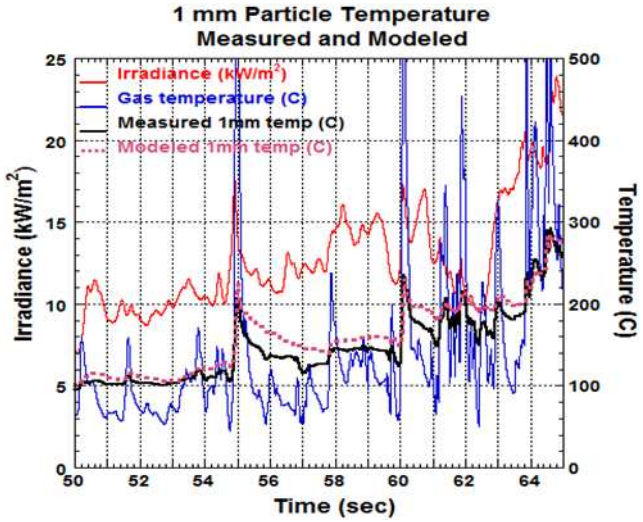

Figure 5. The same measured irradiance and gas temperatures as in Figure 4 are used as inputs for computing the 1 mm particle face temperature (purple). The measured 1 mm face temperature (black) is presented for comparison with the modeled temperature (the last 15 seconds as in the right graph of Figure 4).

In particular, the model does not cool as much as the particle as indicated by the modeled temperature (purple) largely remaining above the particle temperature. It is not clear what factors are causing the

difference but it could be the use of an average particle convection coefficient, higher absorbed radiation than actual and/or measurement errors.

Discussion and Analysis

The fuel particle heat transfer experiments have shown the importance of convection heat transfer. As seen in Figure 2 fine fuel particles convectively exchange heat at a higher rate than coarser particles. Thus, at cooler gas temperatures fine fuel particles will more effectively reduce radiation heating but at high gas temperatures fine particles will more effectively heat to ignition. Initially convective cooling was indicated by the particle temperatures largely staying above the gas temperatures (0 – 35 seconds, Figure 4). As the flame front approached (after 35 seconds), fuel particle temperatures increased primarily in response to convection heat exchange and this was particularly evident in the last 1.5 seconds of the graph (Figure 4). A separate analysis using the flux-time product (FTP) correlation based on the measured irradiance indicated insufficient flame irradiance for piloted ignition and thus the necessity of convective particle heating seen in Figure 4. However, even with fine scale sampling during the particle heating experiments it is difficult to differentiate the radiation and convection heat transfer mechanisms during fire spread. A heuristic examination using computational modeling has the potential to overcome practical limits of experimentation and explore questions such as "What if we stopped the flame radiation without affecting flame convection at the particle and vice versa?".
We used the model to examine the specific contributions of flame radiation and flame convection on fuel particle temperature by eliminating one and then the other.
No flame radiation: The measured irradiance was replaced by the constant irradiance of 300 K (27 C) blackbody surroundings. The measured gas temperatures were used as previously modeled. Inspection of Figure 6 indicates the modeled particle temperature responds to gas temperatures similar to the measured particle.

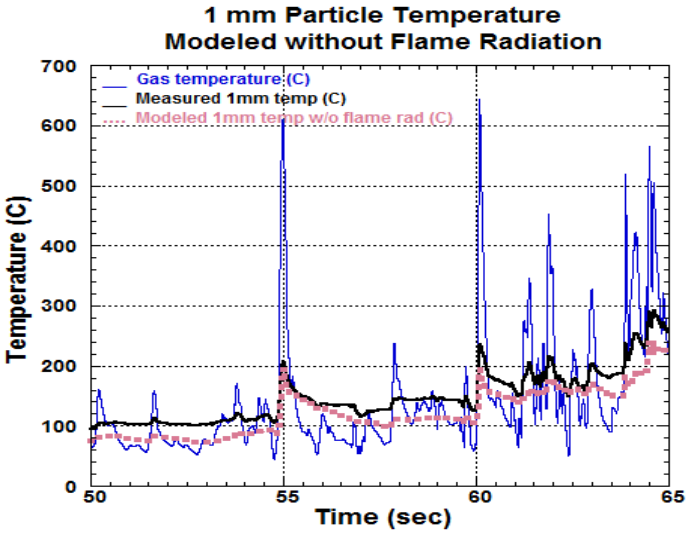

Figure 6. A constant irradiance of 300 K surroundings was substituted for the measured flame irradiance. The measured gas temperatures (blue) were used to compute convection heat transfer as before. The last 15 seconds of the computed particle temperature (purple) was compared to the measured particle temperature (black).

However, without flame radiation the modeled particle temperature remains below the measured temperature and below the modeled temperature in Figure 5. *No flame convection*: The measured gas temperatures were replaced by the constant wind tunnel flow speed of 0.56 meters/second at a constant temperature of 300 K (27 C). The measured irradiance was used as previously modeled. Inspection of

Figure 6 indicates a dramatic change in the modeled particle response characteristics compared to the measured particle.
The rapid increases in measured particle temperatures corresponding to 55 seconds and 60 seconds (Figure 7 graph time) did not occur with the modeled particle. At 63 seconds the modeled particle temperature drops corresponding to the measured irradiance but the measured particle temperature increased.

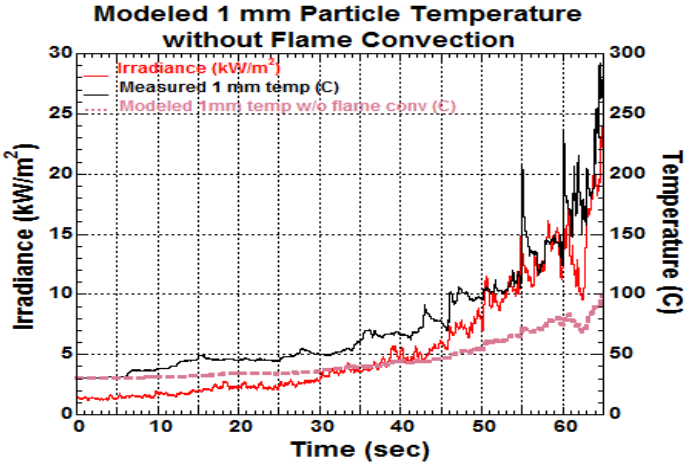

Figure 7. A constant 300 K gas flow was substituted for the flame gases. The measured flame irradiance was used as before. The 65 second sequence shows how the measured particle temperature (black) diverges from the computed temperature (purple) without hot flame gases.

Notably, just prior to ignition the final modeled particle temperature was about 100 C while the measured particle temperature was approaching 300 C. This result is consistent with the FTP analysis indicating that the irradiance was nearly an order of magnitude less than necessary for piloted ignition.

Conclusion

Fuel particle heat exchange experiments and heuristic modeling have demonstrated convection heat transfer as the principal mechanism governing fire spread during experimental laboratory fires. Temperature measurements have shown that fine fuel particles thermally respond at the time scales of significant convective pulses. As the flame front approaches, fine particles primarily heat convectively with increasing gas temperatures and pulse frequencies. In agreement with prior research, our experiments showed that the primary heating to ignition of the fine particles occurred within 0.05 meters of the approaching flame front during our laboratory fires. Measured temperatures along with modeling indicate convection heat transfer from flame contact was the primary mechanism responsible for the rapid particle temperature increases prior to particle ignition.

Abstract

Prescribed burns are widespread in many countries, becoming a management practice in different types of vegetation. In addition to practice pasture renewal and land clearing, prescribed burns also represent a means of preventing forest fires, because through this practice, the fuel load can be reduced significantly. To be used safely and effectively, it is crucial understand the aspects of the fire behavior from the vegetation to be burned. The Grass-Woody Steppe (Natural Fields) consists of the phytogeographic regions of the state of Paraná, covering an area of approximately 20,000 km^2 of east-central region of the state. The vegetation consists mainly of grasses and shrubs, with a large concentration of fine fuels (≤ 0.7 cm), representing a high danger of forest fires. For many years, the region of Grass-Woody of Paraná was used as pasture for the intensive rearing of cattle and sheep, activity that lost momentum in recent years due to the advancement of agriculture and forestry. Many farms, however, still keep areas of fields that are management by the fire. Although the burning of vegetation is still a common practice in the region, there are not however, information about the behavior of fire in this vegetation type. The objective of this research was to characterize the behavior of fire in steppe vegetation of the state of Paraná, through prescribed burns. The results aim to support studies of effects of fire on survival and regeneration of plant species in this environment, considering the hypothesis that controlled burning is a viable and safe activity for pasture management. The survey was conducted in the period preceding the winter in an area with more than eight years without human interference, located in Palmeira county, Paraná state. For the experiment, 10 plots of 3 x 20 m were prepared and burned by backfire and head fire techniques. On the day of burning, the weather conditions were: average wind speed of 2.20 $km.h^{-1}$, average relative humidity of air 60.31% and average temperature of 21.83 °C. The surface fuel load was estimated at 2.53 $kg.m^{-2}$, with an average moisture content of 79.77%. The results obtained in the backfire and headfire burnings were: rate of spread - 0.0536 and 0.0150 $m.s^{-1}$, height of flames - 1.39 and 0.68 m, fire intensity - 119, 11 and 51.96 $kcal.m^{-1}.s^{-1}$ and heat per unit area - 2218.84 and 4259.32 $kcal.m^{-2}$. It concluded with the achievement of the experiment, that the prescribed burns conducted at vegetation of Steppe within the established criteria and burning plans, are feasible and safe from the point of view of fire hazard.

Keywords*: fuel loading; fire intensity; fire danger.*

Introduction

Fire is the result of the rapid combination of oxygen and a combustible substance, releasing large amounts of energy. Although it may cause serious environmental damage, the fire is not only a agent that can cause damage to nature, but can also bring benefits to certain ecosystems, when used in a controlled manner, ie, through burnings that provide management vegetation without compromising the processes of natural regeneration (Soares, 1985).

Prescribed burnings, widespread in many countries, are a practice of manegement of different types of vegetation (Soares, 1995). Basically, consists in using the fire confined to a selected area and in appropriate climatic conditions, so that the rate of spread, the intensity of the fire and the heat released, reach management objectives intended in any vegetation. The use of prescribed burning has, among

other objectives, to reduce the surface fuel load that can generate the most destructive fires in most critical periods, manegement the vegetation of pastures, control of pests and diseases and to promote the clearing of land for agricultural crops and forest (Soares; Batista, 2007).
For conducting prescribed burns properly, it is essential, however, know how fire behaves in relation to vegetation that will be managed. The knowledge of fire behavior allows understanding the factors that have an important role in the onset and spread of fire. This knowledge is thus so important for the management, as being for planning to fight forest fires operations (Souza *et al*., 2003).
Basically, the variables that describe fire behavior are: rate of spread, fire intensity, heat per unit area and residence time (Soares; Batista, 2007). These variables serve to quantify and characterize the behavior of the fire, as well as, to control the difficulty of extinguishing any fire (Vega, 1996). Other variables such as the maximum temperatures reaching in the areas of combustion and the height of the flames, in addition to describing aspects of fire behavior, can establish associations about the effects produced on the various elements of the forest ecosystem (De Ronde *et al*., 1990).
In Brazil, the use of fire in many regions to vegetation management is still a common practice. Although all biomes are subject to burning a greater or lesser extent, the Savanna (Cerrado) and the Steppes (Southern Fields) are handled more frequently by fire (Pivello, 2011). This is the case of natural fields present in the state of Paraná, which are covered by grasses and shrubs and calling of "Estepe Gramineo-Lenhosa". The "Estepe Gramineo-Lenhosa" of Paraná state covers approximately 20,000 km^2, composing a phytogeographic zone with vegetation of grasslands adapted to relatively dry environments (Maack, 1981).
Although the burning of vegetation in the region is still a common management practice, there is, however, information about the behavior of fire in this vegetation type. Therefore, the aim of this research was to characterize the behavior of fire in steppe vegetation of the state of Paraná through prescribed burning in order to generate knowledge related to the effects of fire on the survival and regeneration of vegetation.

Methods

2.1. Study area

The study was conducted in the Private Natural Heritage Reserve "Caminho das Tropas". (Figure 1), coordinates 620334 E and 7196739 S, located in Palmeira county, state of Paraná. Created by decree nº 188/08 of the Environmental Institute of Paraná (Instituto Ambiental do Paraná, 2013), the Reserve with an area of 189.70 hectares, is one of the few private protected areas that conserves "Estepe Gramineo-Lenhosa" vegetation in the region.
The climate of the study area, according to the Köppen classification, is the Cfb, present in the higher portions of Paraná highlands. The summers, are usually fresh, with average temperature of 22 °C, while in the winters the average temperatures are below 18 °C. Severe frosts are frequent, occurring on average of 10 to 25 days annually. Rainfall is evenly distributed throughout the year, however, with higher intensity during the summer. The wind blows constantly, in the prevailing direction northeast (Instituto Agronômico do Paraná, 2013).

***Figure 1. Study area** – Private Natural Heritage Reserve "Caminho das Tropas".*

The experiment

For the realization of the experiment, 10 plots with dimensions of 3 m x 20 m (60 m^2) were bounded with the use of tractor, arranged in the predominant wind direction in the region (Figure 2). The burnings were held in the 5th July (autumn) between 02:00 pm and 6:30 pm, period of the day when weather conditions were more favourable to burn and with less risk of loss of control of the fire. To evaluate the fire behavior, two techniques (treatment) of burning were employed: backfire and headfire.

*Figure 2. **Delimitation of plots to the experiment***

The last rains before of the experiment ocurred on 29 and 30 June with 12.8 and 37.4 mm rainfall respectively (Fundação ABC, 2013). Thus, the burnings occurred 5 days after the last rainfall, covering a period considered relatively safe for burning (within 10 days since the last rain), when the degree of fire danger has not yet reached critical levels (Soares; Batista, 2007).

Fuel characterization

To characterize the fuel, informations about the type, quantity, moisture content and thickness formed by the deposition of material on the ground were obtained (Figure 3). To do so, it were allocated randomly in each plot three samples of 400 cm^2 (20 cm x 20 cm), where fuel was collected and separately in four categories: material with diameter between 0 and 0.7 cm, material with diameters between 0.71 and 2.5 cm and material whith diameter between 2.51 and 7.6 cm. This fuel was oven dried at 75 °C of constant temperature for determination of dry weight.

After drying, it was determined the fuel moisture using the formula U% = [(Mu - Ms) / Ms] .100 (Batista, 1990), where: **U**% is the fuel moisture content (%); **Mu** is the mass of the fuel during the collection (in grams) and **Ms** the mass of fuel after drying (in grams).

Figure 3. Collection and fuel characterization

2.4. Monitoring of weather conditions

During the period in which the burns were done, the weather conditions were monitored. In all plots were recorded the variables: wind speed ($m.s^{-1}$), air temperature (°C) and air relative humidity (%). For the measurement of meteorological variables, an automatic station Kestrel 6000 Station was used, positioned a height of 1.20 meters above the ground.
Data regarding rainfall of days prior the burnings were obtained from de weather station of the locality of Rosario from the city of Ponta Grossa, whose results are available for viewing on the ABC Foundation website (Fundação ABC, 2013).

2.5. Fire behavior variables

While the burning was occurring in each plot, observations about the following fire behavior variables were made, according to standard procedures adopted internationally and recommended by several authors (Ribeiro *et al*., 2006; Garnica *et al*., 2006; Kuçuk *et al*., 2008; McDonald; McPherson, 2011):

- Rate of spread - obtained visually by determining the time required to the fire line cover distances of 2 m, previously demarcated in each plot, along its length (20 m);
- Flame height - visual estimate of the average height reached by the flames in each 2 m at the advancing of line fire, with the aid of comparators (scales) of known dimensions;
- Intensity of the fire - estimated by the equation proposed by Byram (1959):

$I = H. w. r$

Where:
I = intensity of fire in $kcal.m^{-2}.s^{-1}$
H = calorific value in $kcal.kg^{-1}$
w = weight of fuel available in $kg.m^{-2}$
r = rate of spread of fire in $m.s^{-1}$

For the calorific value was used 3875 kcal.kg^{-1}, proposed by Griffin and Friedel (1984) for the grasslands and savannas vegetation.

Figure 4 present the plots before, during and after the prescribed burning.

Figure 4. ***Sequence of operations in the burning plots***

2.6. Processing and analyzing the data

From the collection and processing of data was possible to construct a matrix, composite of environmental (fuel and weather conditions) and fire behavior variables (Table 1). The data, relating to the environment (fuel and weather conditions) and fire behavior, were processed and analyzed with software STATGRAPHICS Centurion XV. The statistical test used for analysis and comparison of data was the "t" test.

Table 1. Environmental and fire behavior variables

Variable	Description	Unit
WCf	Fuel load (average of 3 samples per plot) before burning	kg.m^{-2}
WCc	Residual (average of 3 samples per plot) after burning	kg.m^{-2}
Hch	Flame height during burns (average of 10 observations per plot)	m
T	Air temperature at the beginning of the burning portion	°C
UR	Relative humidity at the beginning of the burning of plot	%
r	Rate of spread (average of 10 observations per plot)	m.s^{-1}
Vv	Wind speed at the beginning of the burning of plot	km.h^{-1}
I	Fire intensity (average of 10 observations per plot)	kcal.m^{-1}.s^{-1}
H_a	Heat per unit area	kcal.m^{-2}

Results

3.1. Weather conditions

The prescribed burnings must be conducted in accordance with established the previous requirements for the weather and fire behavior conditions (Fernandes *et al.*, 2002; Soares; Batista, 2007; Fernandes; Loureiro, 2010). For grasslands, the appropriate recommendations to carry out the burns and achieve the objectives with less risk of fire control losing are shown in table 2.

Table 2. Prescription for burning grassland vegetation

Weather conditions	Optimun	Minimum	Maximum
- Number of days without rain	3 - 7	1	10
- Air temperature (°C)	8 - 20	5	25
- Air Relative humidity (%)	30 - 70	20	85
- Wind speed ($km.h^{-1}$)	5 - 5	1	20
Fire behaviour			
- Rate of spread ($m.s^{-1}$)	0,03 - 0,08	< 0,03	0,13
- Flame height (m)	1 - 4	< 1	5,5

Note: adapted from Fernandes et al. (2002).

Weather conditions recorded at the day of the experiment are presented in table 3

Table 3. Weather conditions

Meteorological variables	Backing fire burning			Head fire burning		
	Mean	Minimum	Maximum	Mean	Minimum	Maximum
Air temperature (°C)	$22,32_a$	20,00	24,00	$21,34_b$	18,50	23,50
Relative humidity (%)	$58,40_a$	54,00	63,00	$62,20_b$	55,50	69,00
Wind speed ($km.h^{-1}$)	$1,36_a$	1,00	1,80	$3,08_b$	2,20	4,00

Note: Results in the same line followed by different letters are statistically different, by "t" test ($p < 0,01$).

It is observed by table 3, as well as verified for the precipitation, that the experiment was accomplished within condition acceptable of weather and fire behaviour for the achievement of the prescribed burn safely, according to the parameters listed in table 2.

The results in table 3 indicate that there were differences in weather conditions for the burnings techniques utilized. These distinct weather conditions demonstrate the difficulties that are often encountered when performing burning experiments outdoors. Despite the variations in the weather, the values of weather variables remained very close to the limits recommended for safely performing burnings as shown in table 2.

3.2. Fuel caracteristics

The fuel, as one of the components of the fire triangle is basic and essential for the occurrence and spread of fire. The amount of fuel in an area and their characteristics define whether there will be ignition and how will be the spread of fire. Therefore, the characterization of the remaining fuel is a decisive factor in plans to prevent and fight fires, especially in prescribed burnings programs (Soares; Batista, 2007).

The characteristics of the fuel in the area of the two burn treatments are shown in table 4.

Table 4. Fuel characteristics

Fuel variables	Backing fire burning			Headfire burning		
	Mean	Minimum	Maximum	Mean	Minimum	Maximum
Fuel load ($kg.m^{-2}$)	$2,72_a$	1,23	4,48	$2,35_a$	1,59	4,18
Fuel moisture (%)	$74,60_a$	52,00	92,19	$86,46_b$	60,61	115,83
Fuel consumed ($kg.m^{-2}$)	$2,09_a$	0,85	3,12	$1,19_b$	0,78	1,81
Fuel consumed (%)	$76,25_a$	69,11	90,98	$56,60_b$	30,12	77,19

Note: Means in the same line followed by different letters are different, by "t" test ($p < 0,01$).

There is not statistical difference in fuel load of the two areas of burns, reflecting the homogeneity of the surface fuels in this type of vegetation.

The fuel moisture was statistically different between the two burning techniques. This variable has great influence on the ignition and the efficiency of combustion, and can vary greatly depending on weather conditions observed on the day or pre-burn period, as well as the season of the year. The fuel moisture found for the 20 plots was approximately 80%, being 74.60% (with a range of 52.00 and 92.19%) in the backfire burning and 86.46% (variations of 60.61 and 115.83%) in headfire burning.The most of the fuel (approximately 70%) was dead and was composed primarily of fine material (≤ 0.7), sorted by Soares (1985) as a hazardous fuel. Although the most of the vegetation was dead, even so, the fuel moisture was high, probably due the amount of rainfall that occurred five days prior to the experiment and due to the overcast sky that prevailed in the following days. However, even with the high fuel moisture, the fire has spread normally, being influenced by the amount of dead fuel, its thickness and also because of the fuel arrangement. Experiments by other authors in grassland vegetation showed that the fuel moisture vary greatly depending on the season and the region. Fidelis *et al*. (2010) reported values between 37.80 and 44.49% for the fine fuels in an experiment conducted with burning of grassland near the Porto Alegre county, south region of Brazil. Miranda *et al*. (1996) found values between 8 and 23% of moisture in fine dead fuel (≤ 0.7 cm) and 113-163% in live fuels in the Savannas near Brasília city. Pivello and Coutinho (1992) reported content of 21-44% moisture of the vegetation of Savannas in the São Paulo State.

Regarding the "burning efficiency" variable that comes to the amount of fuel consumed (in percentage) in relation to fuel load, differences were also recorded. The results of 56.60% for the treatment of headfire burnings and 76.25% for the backfire burnings are significantly different. The burning efficiency of herbaceous vegetation in fields and grasslands may vary from 65 to 95%, according Levine (1996). For savannas of Brazil, Pivello and Coutinho (1992) found values of 63 and 77%, while Miranda *et al*. (1996) determined values between 81 and 94% for the same vegetation. In vegetation of Steppe, Fidelis *et al*. (2010) reported values of 93% in an area with about two years without burning and 95% in an area with six years without fire.

In general, two conditions acting directly for the efficiency of burning: the first related to vegetation type and its characteristics (thickness, arrangement, fuel moisture, etc.), and the second, the meteorological factors during burning (Soares; Batista, 2007).

The differences for the two techniques burning of the experiment can be explained mainly by the physiological state of the fuel load. The moisture checked for fuel from the plots of backfire burnings was greater than moisture of the burned plots of headfire burnings. Other factors, such as, the weather conditions shown in table 3 during the burning may also have influenced the results.

3.3. Fire behavior

It is understood by fire behavior, the result of the interaction between weather, fuel caracteristics, topography, burning technique and form of ignition. The results of the fire behavior variables are represented in table 5.

Table 5. Fire behavior variables of the burning treatments

Fire behavior	Backing fire burning			Headfire burning		
	Average	Minimum	Maximum	Average	Minimum	Maximum
Rate of spread ($m.s^{-1}$)	$0,0150_a$	0,0100	0,0239	$0,0536_b$	0,0391	0,0841
Flame height (m)	$0,68_a$	0,47	0,86	$1,39_b$	1,20	1,75
Fire intensity ($kcal.m^{-1}.s^{-1}$)	$51,96_a$	35,83	73,95	$119,11_b$	65,40	205,08
Heat released ($kcal.m^{-2}$)	$4259,32_a$	1498,85	5754,20	$2218,84_b$	1167,64	2802,29

Note: Means in the same line followed by different letters are different, by "t" test ($p < 0,01$).

The table 5 shows that all variables that characterize the fire behavior are significantly different for the two treatments.

The mean rate of spread of the backing fire burning was 0.0150 $m.s^{-1}$, with a range of 0.0100 and 0.0239 $m.s^{-1}$, classified as slow according to Soares and Batista (2007). At the head fire burning, the rate of fire ranged between 0.0391 and 0.0841 $m.s^{-1}$, with mean of 0.0536 $m.s^{-1}$, classified as medium by the cited authors.

In a research on fire behavior in prescribed burning in grasslands in the Oklahoma State, United States, Bidwell and Engle (1991) obtained values of 0.20 and 0.02 $m.s^{-1}$ for the rate of spread in the headfire and backing fire burnings, respectively.

Fidelis *et al*. (2010) recorded average rate of spread of 0.015 $m.s^{-1}$ in burnings in an area with one year without burning, and 0.013 $m.s^{-1}$ in an area with six years without burning, in the both cases with headfire. Miranda *et al*. (1996) has found values of rate of spread of burnings in brazilian savannas of 0.13 to 0.64 $m.s^{-1}$ (mean of 0.385 $m.s^{-1}$). Brown and Davis (1973) observed in several experiments of burning in the United States of America, a rate of spread of backing fire burnings with variations of 0.009 to 0.018 $m.s^{-1}$, values very similar to those observed in this experiment.

Statistical analysis detected a significant difference between the mean flame height between the two burning techniques, which were of 0.68 and 1.39 m respectively. These values are within the recommended limits to conduce the fire safely (Fernandes *et al*., 2002).

The fire intensity also varied significantly between the two forms of burnings. In the backing fire burnings, the values were lower, mean of 51.96 $kcal.m^{-1}.s^{-1}$, ranging between 35.83 and 73.95 $kcal.m^{-1}.s^{-1}$. In the backing fire burnings performed in prairies by Engle and Bidwell (1991), the mean of intensity observed were 23.18 $kcal.m^{-1}.s^{-1}$, ranging from 7.41 to 34.89 $kcal.m^{-1}.s^{-1}$. In the headfire burnings, the variation was from 65.40 to 205.08 $kcal.m^{-1}.s^{-1}$ (mean of 119.11 $kcal.m^{-1}.s^{-1}$). In the literature very different values of the fire intensity of prescribed burning on grassland vegetation are found. Fidelis *et al*. (2010) determined a mean of 22.35 $kcal.m^{-1}.s^{-1}$for an area with frequent burning and 42.79 $kcal.m^{-1}.s^{-1}$ to an area with more than five years without burning, both headfire burnings. In the study by Miranda *et al*. (1996), values between 299.99 and 3405.95 $kcal.m^{-1}.s^{-1}$ were recorded and an average of 995.33 $kcal.m^{-1}.s^{-1}$. Fidelis *et al.* (2010) cited the following values obtained by various researchers: 6.68 to 4276.53 $kcal.m^{-1}.s^{-1}$ for the African savannah; 36.06 to 2200.72 $kcal.m^{-1}.s^{-1}$ for the Australian savannas; from 23.64 to 273.95 $kcal.m^{-1}.s^{-1}$ for the grasslands of Australia; 7.40 to 2813.12 $kcal.m^{-1}.s^{-1}$ for the prairies of the United States; from 10.27 to 265.59 $kcal.m^{-1}.s^{-1}$ for the heaths (wetlands) of Scotland; from 95.06 to 112.73 $kcal.m^{-1}.s^{-1}$ for the low savannas of Venezuela; from 46.09 to 538.11 $kcal.m^{-1}.s^{-1}$ for the high Venezuelan savannas and 678.80 to 3916.59 $kcal.m^{-1}.s^{-1}$for the Brazilian savannas.

The fire intensity, calculated by the equation of Byram (1959), has proven to be a very useful parameter in the description of fire behavior, and serve as a benchmark to visualize and compare the rates of energy released by different types of burnings or forest fires (Soares; Batista, 2007).

Regarding the heat released per unit area, values of 4259.32 $kcal.m^{-1}.s^{-1}$ at the backing fire burn (ranging from 1498.85 and 5754.20 $kcal.m^{-1}.s^{-1}$), and 2218.84 $kcal.m^{-1}.s^{-1}$ were obtained in the headfire

burnings (range of 1167.64 and 2802.29 kcal.m^{-1}.s^{-1}). Miranda *et al.* (1996) found values from 1999.85 to 3405.94 kcal.m^{-1}.s^{-1} in a experiment with headfire burnings in Brazilian savanna, considered very close to the values determined for the African savannas. This variable of fire behavior is an important parameter to evaluate the effects of fire on soil and on the emission of particles in the atmosphere. Generally, as higher is the rate of spread, the lower the amount of energy directed to the inner layers of the soil. In contrast, as slower is the spread of fire, the greater is the amount of energy concentrated there. The highest values of observed heat per unit area in backing fire burning when compared with the headfire burning, are due to the lower rate of spread in this kind of burning.

Conclusions

Considering that the controlled burns were conducted within the limits of environmental conditions recommended by the guidelines for fire management adopted internationally**,** it can be concluded that**:**

- The prescribed burns in vegetation of Steppe carried out within the criteria set out at burns plans are feasible and safe from the point of view of fire hazard;
- The parameters of fire intensity, the rate of spread, the heat released per unit area and flame height could be quantified easily and accurately, allowing adequate description of fire behavior;
- The values of fire behavior observed in this study are compatible with most results recorded in similar surveys conducted in other regions and are fundamental to evaluate the effects of fire on the dynamics of post-fire period in steppe vegetation of Paraná state.

Abstract
The size of a fuel break in a top of the ridge with several different configurations of slope is studied on this work.
Laboratorial tests were performed to simulate the same geometric conditions of a fire occurred in centre of Portugal and that was extinguished by itself due to the special configurations of slope and geometric barrier to fire spread that correspond to a fire break. Based on this fire other configurations were tested to measured their impact on the probability of the fire crossing the geometric barrier of a gap.

Introduction

It is observed that in some instances a fire spreading upslope, without wind and in the absence of spotting, stops when it reaches the ridge even with a relatively narrow fire break at the ridge top. Referring to fire fighter safety in Green (1977) it is assumed that a fire spreading along a slope of 35º, in heavy brush fuel, with low humidity, and heavy winds, flames with 15 m long flames a fuel break with 60 m is efficient. But if a sharp ridge marked the centre of a fuel break, protection from radiation would be afforded by crouching in the lee of the ridge top, and somewhat less than 60 m would be needed. Indeed a forest road or a maintained right-of-way such as a power or telephone line often serves as a firebreak (Brown and Davis 1973). In Butler & Cohen (1998) a general rule in wich a safety zone radius must be equal or greater than four times the maximum flame height is proposed. This situation was observed for example at fires in Segade (Coimbra) in 2001 and in Sardinia in 2010. In order to analyse this phenomenon and to assess the effectiveness of fire breaks placed at the ridge tops in general the present research was performed.

Experimental Study

Physical problem

We consider a ridge formed by two planar slopes making an angle α_A in face ***A*** and α_B in face ***B*** and assume that there is a fuel break with a width equal to *c* at the ridge top (Figure 1). A fire spreading upslope on face ***A*** in the absence of wind will reach its top with a ROS R_1, a flame length L_1 and will either spread across the fuel break or not.

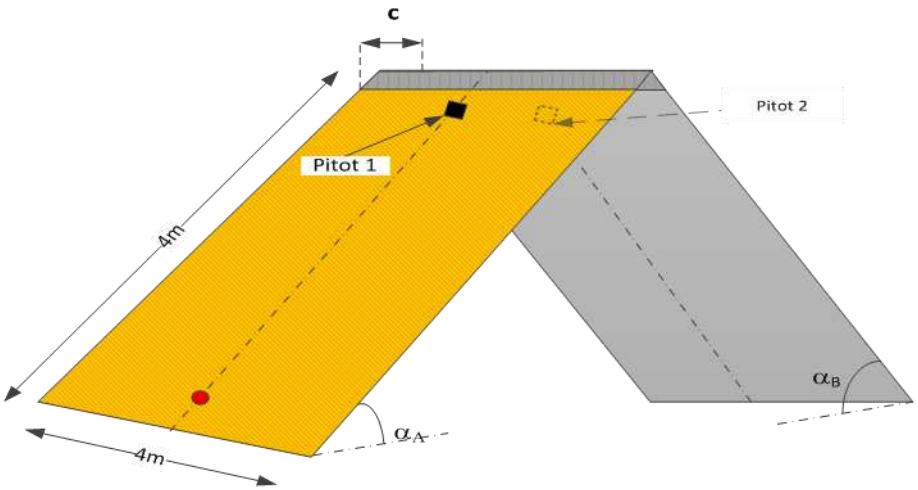

Figure 1. Schematic view of the ridge and the fuel break.

Laboratory Experiments

In the present study an experimental research was carried out at the Forest Fire Research Laboratory of the University of Coimbra on the Dihedral Table that has two faces of 4x4m^2 each that can be inclined independently between -45º and +45º in relation to the horizontal reference (figure 2a).

b)

Figure 2. Picture of the test SE11 with parameters: α_A=40º, α_B= -20º, c=0.30m. a) Front view, b) Side view with detail of the ridge and fuel break.

The fuel bed was made with straw with a fuel load of 0.6 kg/m^2 (dry basis) and the fire was ignited at a point in the centre line of face A 0.25m above its lower edge. The fuel covered the entire face A and only 1.6x4 m^2 on face B. The ROS of the head fire was measured using strings of cotton placed across the fuel bed with a gap of 20cm between them. A pair of S Type pitot tubes equipped with thermocouples was placed near the ridge top to measure flow velocity even inside the flames at the positions indicated in figure 2a). A video camera was used to record and analyse the flame front near the ridge top to capture a side vew of the fire front when it approached the ridge line (figure 2b)). Several tests were performed with various combinations of slope angles αA and αB with fuel break widths in the range of 0 to 0.3m. The main parameters of the tests are given in Table 1.

Results and Discussion

4.1. Probability of fire crossing

In figure 3 a plot of the cases in which the fire went or did not go across the fuel break as a function of c/L_1 is presented. The value one in this graph indicates that the fire passed the fuel break while the value zero indicates the contrary. Only for cases in which the slope angle α_B was positive we had passage of the fire. The terrain configuration in such cases is not really a ridge. As can be seen in this figure a relatively small value of c/L_1 of the order of 0.2 seems to be sufficient to stop the fire which is much smaller than the value of c/L_1 =4 presented in Green, (1977) for the case described above.

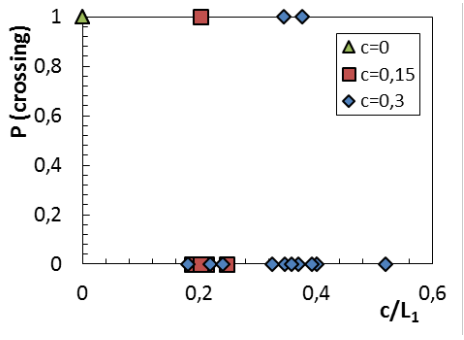

Figure 3. Probability of fire crossing as a function of c/L_1 for all tests.

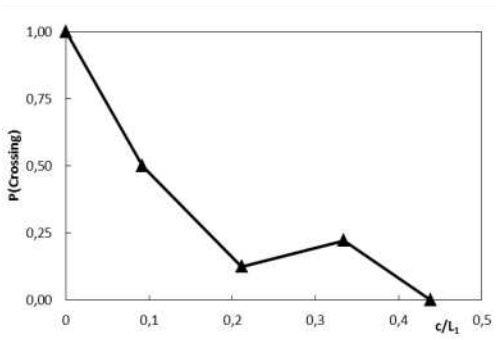

Figure 4. Average probability of fire crossing as a function of c/L_1 for classes with a step of 0.13 between them.

In figure 4 the average probability of crossing for different classes of values of c/L_1 is presented. The range of values were split in groups of values of c/L_1 with a length of 0.13 between them and the correspondent value of the probability for each class of c/L_1 was plotted. In agreement with the previous data a sharp decrease of the probability of the fire crossing with the increase of relation c/L_1 is clear. For c/L_1 >0.2 the probability of crossing becomes constant with a small increase for c/L_1 close to 0.36. Comparing figure 3 with the data of the figure 4 it is possible to relate this small increase with the occurrence of two crossings of the fire to the face B. After this occurrence no more crossings were registered with the increase of c/L_1 making the value of the probability of crossing to decrease to zero for c/L_1=0.4.

Radiation

Using a simple model based on principles of radiation presented in Wong (2003) was estimate the radiation flux from a vertical flame with constant height to an infinitesimal element of area, with an area of 0,05x0,05m^2, placed on face B at the centreline at a distance c from the base of the fire (figure 5) the results were plotted in figure 5 were obtained.

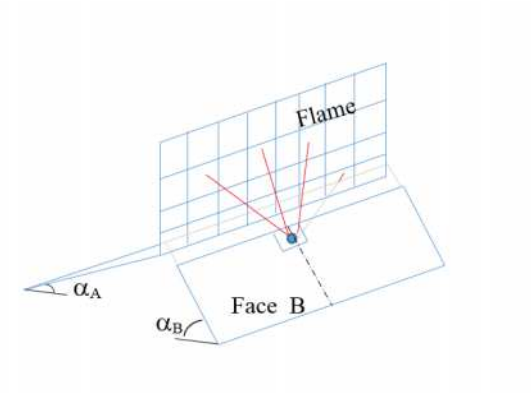

Figure 5. Skecth of the radiation flux from the vertical flame in the side A for the target in face B.

The properties of the flame and the slope of face B were established according to the average values obtained in the tests for the points plotted in figure 4, a table with the values is presented below.

Table 2. Set of data for the computation of the radiant flux.

α_{Bavg}	g/L_1	$q(kW/m^2)$
-40	0,00	94,47
-15	0,09	83,30
-20	0,21	65,12
-15	0,33	52,00
-10	0,44	40,17

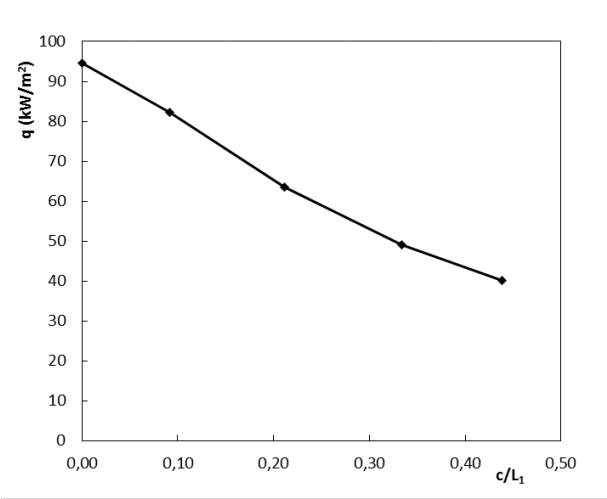

Figure 6. Computation of the net rate at which an infinitesimal element face B gains radiation due to the interaction of the flame in the side a for several values of c/L_1.

By the analysis of the data is possible understand as was expected that the rate of radiation that arrives to the face B is greatly affected by the distance between the two surfaces. It is possible to see that the trend shown in figure 4 for the variation of the average probability of fire crossing as a function of c/L_1 is very similar to the decrease of the radiation flux on the surface element that is shown in figure 5 putting in evidence the role of flame radiation in this process.

4.2. NDROS (R') and Induced Flows

In figures 6 to 8 results from NDROS (R') on face ***A*** and of flow velocity are shown as a function of time. In these tests the fire did not cross the fuel break. The coloured lines indicate the times of the end of spreading of fire for each test. The flow velocity U_1 measured at P1 is shown in figure 7 and the flow velocity U_2 measured at P2 is shown in figure 8.

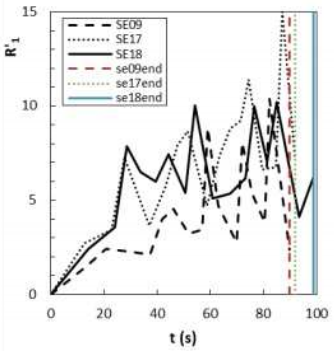

Figure 6 –ROS values as a function of time for tests: SE 09, SE 17and SE 18

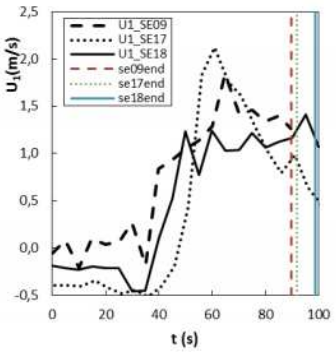

Figure 7. Flow velocity at positions P_1 as a function of time for tests: SE 09, SE 17 and SE 18

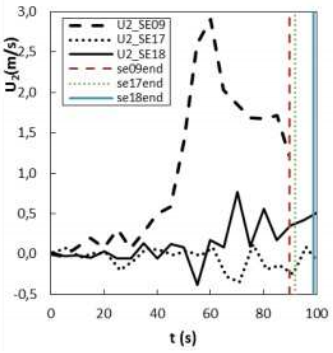

Figure 8. Flow velocity at positions P_2 function of time for tests: SE 09, SE 17 and SE 18

In the case of SE 09, dashed line, with configuration α_B=0º, the increment of the NDROS with a maximum of 10 is visible in figure 5 plotted with dashed line, coincident with this increment is the increment of the flow in both pitot tubes. The presence of a positive flow meaning that the flow is in same direction of the rate of spread was observed. The maximum flow was registered at P_2 (face B), figure 7, with the value of 3m/s. It was noticed at least in U_1 flow (figure 6) some negative periods that could correspond to the indraft of air towards the fire front as the slope of side B is not a barrier to the income of air this type of flow is allowed.

In the case of SE 17 α_B=20º, dotted line, an increment of the NDROS with the course of time until the end of side A, with a peak of 11m/s and then appears the maximum of 15m/s, was also observed.
In figure 6 it is detected that the flow measured at P_1 starts with a decreasing to negative values of -0.5m/s and then have a sharp increase until a maximum of 2.1 m/s. The value of the flow registered at P_2 was mainly negative or close of zero the reason of this behaviour could lie on the fact of the second slope works as a barrier to the feeding air for the fire front and only when the fire front is very close of P_2 it was observed some positive flow.
In the last experiment, plotted with a bold black line, that is the test SE18 with α_B=30º, was registered an increasing of NDROS very sharp and with several fluctuations the maximum value recorded was of 10 the difference in relation with the others is that in all the experiment several times was recorded high values of the NDROS.
The flow velocity U_1 also was high and constant, only at the beginning a negative flow of -0,5 m/s was recorded and then the flow shifted to positive and more or less stable at the values of 8-9 m/s. As in previous case the presence of the second slope of the face B could cause some interference on the free progress of the flow and for that the P_2 in the major part of the test present a negative flow that is against the fire spread direction and only in the very end an increase of the flow velocity to values of less than one 0.5 m/s but favourable to fire spread was registered.

Conclusion

Our results show that with a ridge shape like the one tested by us in the absence of wind the flow induced by the fire does not cause an inclination of the flame front towards the unburned fuel (figure 2b)) and consequently the fire does not spread across the fire break.
The probability of the fire crossing the fuel break decreases with the increase of the parameter c/L_1 and therefore it indicates that radiation is the dominant heat transfer mechanism in this process. The explanation of this lies on the fact that even for small values of the gap between the fire front and the unburned fuel bed on face B the radiation flux is relatively small and consequently the fire does not spread across the fire break.

Abstract
Most of the operational tools of fire propagation in natural environment are based on statistical or semi-empirical approaches. However, under conditions that deviate from the database used to construct these models, extrapolation may be completely random and, therefore, not very reliable. Subsequently, other models have been developed, taking into account the various interactions occurring between the vegetation and the surrounding fluid medium. This approach is based on a very detailed modeling of the physicochemical phenomena involved in a fire that are quite complex (turbulence, combustion, radiation, interaction between the fluid and vegetation ...). The 3D model developed in this work (referred to as "FireStar3D") is part of the latter class of models, and consists in solving the conservation equations of the coupled system consisting of the vegetation and the surrounding gaseous medium. The model takes into account the phenomena of vegetation degradation (drying, pyrolysis, combustion), the interaction between an atmospheric boundary layer and a canopy (aerodynamic drag, heat transfer by convection and radiation, and mass transfer), and the transport within the fluid phase (convection, turbulence, gas-phase combustion). This paper presents the validation of this 3D model that was conducted for a fire in confined environment, by reproducing experiments of fuelbed fire in a wind tunnel carried out by Catchpole *et al*. in 1998. The comparison between the simulations and the experimental data is mainly based on the rate of spread of fire or ROS (velocity of the fire front). A good agreement is obtained for most of the simulations that were conducted, and a study of the dependence of the rate of spread on the wind speed and on the fuel bed characteristics, particularly the fuel moisture content, is carried out.

Keywords*: Forest fires, turbulent reactive flows, modelling and numerical simulation, high performance computing.*

Introduction

As evidenced by the literature, most of the operational tools of fire propagation in natural environment are based on statistical or semi-empirical approaches [1]. However, under conditions that deviate from the database used to construct these models, extrapolation may be completely random and, therefore, not very reliable. Subsequently, other models have been developed; in these models, the study of the spread of a fire and its behavior are addressed through its physicochemical aspects, taking into account the various interactions occurring between the vegetation and the surrounding fluid medium [2]. This multiphase approach is indeed based on a very detailed modeling of the physicochemical phenomena involved in a fire that are quite complex (turbulence, combustion, radiation, interaction between the fluid and vegetation, ...). To better understand the phenomenon of the spread of fire in natural environment, the model developed in this work is part of the latter class of models, and consists in solving the conservation equations of the coupled system consisting of the vegetation and the surrounding gaseous medium [3]. This model is already operational in a 2D approximation [4] and

consists in solving the multi-physical model in a vertical plane defined by the direction of fire propagation. The 3D extension of the existing model enables to render the 3D effects observed in real fires and to represent the real heterogeneous structure of the vegetation. The objective of this paper is to evaluate the potential of this 3D model (referred to as "FireStar3D") that has been mainly developed within the context of the European integrated project "FireParadox". This leading evaluation was conducted for a fire in confined environment by reproducing experiments of fuelbed fire in a wind tunnel (the so-called Rothermel configuration), carried out by Catchpole *et al*. in 1998 [5].

Modelling and Numerical Method

The present multiphase formulation, detailed in [3, 4, 6, 7], is based on the description of the behaviour of the coupled system formed by the vegetation and the surrounding atmosphere. The model consists of two parts: one part devoted to the calculation of the turbulent-reactive fluid flow resulting from the mixture of the pyrolysis and combustion products and the ambient air, and a second part devoted to the evolution of the state of the solid vegetation subjected to the intense heat flux coming from the flaming zone. Each solid fuel particle is assimilated as a mixture of water, dry foliage (or dry wood), char, and residual ashes. During fire propagation, the degradation of the vegetation is represented using a three steps temperature-dependent mechanism (drying, pyrolysis, and char oxidation), where the constants (activation energy and pre-exponential factor) are evaluated empirically from thermo-gravimetry Analysis (TGA), performed for solid fuel samples [6]. It is assumed that the pyrolysis process can be activated only if the dehydration was completed, and that the surface oxidation can begin only if the pyrolysis was completed. The gas flow around the fire is considered to be fully unsteady and turbulent. To extract a coherent behaviour, the balance equations (mass, momentum, energy, and chemical species) governing the time evolution of the fluid phase are filtered using a weighted average RANS (Favre) formulation [8]. The interaction between the ambient atmosphere and the vegetation is taken into account through additional terms in the equations (gas production due to pyrolysis reaction, drag force, heat transfer by convection and radiation exchange with solid phase, …). The closure of these equations is done using an eddy viscosity concept [9], evaluated from the turbulent kinetic energy and its dissipation rate. An adapted statistical two-equations (k-Epsilon)-RNG version turbulence model in a high Reynolds number formulation is employed [10,11]. The Eddy Dissipation Concept (EDC) combustion model [9,12] is used to evaluate the combustion rate in the gaseous phase, where it is assumed that the reaction is mainly limited by the mixing rate between the pyrolysis and the oxygen of the ambient air. Convection and radiation heat transfers between the hot gazes, the flame, and the unburned solid fuel are taken into account as follows: the convection heat transfer coefficient is modelled using empirical correlations [13] and the radiation heat transfer is obtained by solving the radiation transfer equation (RTE) [14] in which the contribution of the flames (soot particles) and the embers is included [3]. The fluid enthalpy-temperature dependence is treated using the CHEMKIN thermodynamic database [15]. Finally, the soot volume fraction field is obtained by solving a transport equation [16,17] including a thermo-phoretic convective contribution [3] and a soot oxidation term [18].

The fluid flow conservation and transport equations are solved numerically by a fully implicit finite volume method in a segregated formulation [19]. "FireStar3D" predicts turbulent reacting flows in rectangular domains on a structured but non-uniform staggered mesh. The time discretization relies on a third order Euler scheme with variable time step. To ensure the numerical stability, the space discretization is based on second order schemes with flux limiters (Quadratic Upstream Interpolation scheme [20] and ULTRA-SHARP [21]) for convection terms while diffusion terms are approached by central difference approximation with deferred corrections [22] to maintain accuracy. The Radiative Transport Equation (RTE) is solved using a Discrete Ordinate Method (DOM), consisting in the decomposition of the radiation intensity in a finite number of directions. This set of discrete contributions is integrated using a numerical Gaussian quadrature rule (a S8 method is used) for the

calculation of the total irradiance [23]. The set of ordinary differential equations describing the evolution of solid fuel are solved separately using a fourth order Runge-Kutta method. From implementation point of view, the code is parallelized [24] and optimized [25] using the APIs OpenMP and HMPP directives (suitable for shared memory platforms and accelerators) and is operational on a high-performance computing machines consisting of a SMP node using modern processors with INTEL Xeon Phi co-processors and NVIDIA graphic cards. Finally, the hydrodynamic module of the code has been extensively validated on several benchmarks of laminar and turbulent natural convection, forced convection and neutrally stratified flow within and above a sparse forest canopy [26-31].

Rothermel configuration

As mentioned in introduction, in the framework of validating "FireStar3D", several experiments of fuelbed fire carried out by Catchpole *et al*. in a wind tunnel are reproduced numerically. Figure 1 shows a perspective view of the flow computation domain; all the simulations were carried out using the same geometric parameters and the depth of the fuel bed δ was fixed at 20.3 cm. The fuel bed is divided into two zones that have the same characteristics, however only zone (2) is thermally degradable. Zone (1) was added to account for the wire mesh spoiler used in the experiment that was placed on the floor of the wind tunnel from wall to wall, 2 m upwind the fuel trail, and was adjusted to have the same height as the fuel depth; as mentioned by Catchpole *et al*., this wire mesh was placed in order to simulate a longer reach of the fuel and its resulting turbulent boundary layer. Also, vertical strips of metal sheeting (25 cm high) were placed in the experiments along each side of the tray to mimic a wider fire front by preventing indrafts into the combustion zone. These strips were accounted for numerically by placing vertical baffles along each side of the fuelbed (see Figure 1); the velocity component normal to the baffles (y component) is set to zero, while a drag coefficient $C_D = 1.0$ (based on the baffles exposed surface) was introduced in the momentum equations of the velocity components tangential to the baffles (x and z components). The value of the drag coefficient $C_D = 1.0$ resulted in a quasi-uniform fire-front, as observed experimentally.

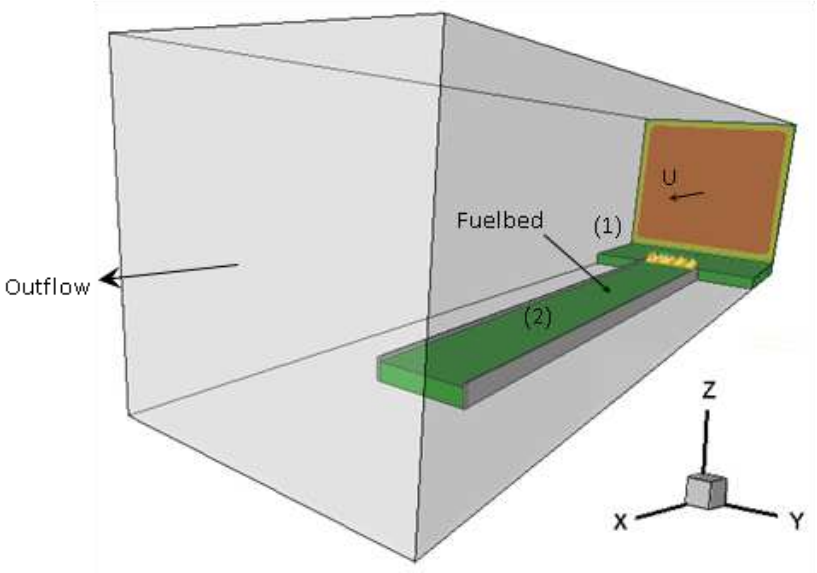

Figure 1. Perspective view of the computation domain corresponding to Catchpole et al. experiment. The flow domain dimensions are $12\times3\times3$ m3 and those of the fuel bed are $10\times1\times\delta$ m3 (δ = 20.3 cm). The fuel bed is divided into two zones, only zone (2) ($2m < x < 10m$) is thermally degradable, vertical baffles (25 cm high) are placed along both sides of zone (2) and fire is set at its entrance.

Before ignition, simulations were run long enough using Neumann conditions at the open boundaries while maintaining a negative pressure gradient in the x-direction that was adjusted in order to reach a turbulent steady state with the desired mean wind speed that was imposed in the experiment; 5 seconds were sufficient for this phase. Then, the turbulent velocity profile, obtained at channel inlet at the end of this phase, is applied (as a Dirichlet condition) at the inlet of the domain during the remaining time

of simulations. At t = 5 s, fire is set at the entrance of zone (2) by injecting carbon dioxide at 1600 K from the bottom of the computation domain for another 5 s. The injection surface lies between x = 2 m and x = 2.16 m, and along the entire width of zone (2). At t = 5 s, the average injection velocity is at its maximum (V_j = 10 cm/s), then it decreases linearly with the burned mass of dry material (m_b) according to the equation (1) in order to avoid destabilizing the fire-front by suddenly ceasing the injection.

$$V_j(cm/s) = 10 \times \left(1 - \frac{m_b}{m_{b0}}\right) \quad (1)$$

where m_{b0} is the initial mass of dry material located above the burner (i.e. the mass of dry material inside the volume $V_{b0} = 0.16 \times 1 \times \delta$ m^3). Eq. (1) is used between t = 5 s and t = 10 s as long as V_j remains positive, injection of carbon dioxide is ceased if V_j reaches zero during this time interval.
Several simulations were conducted for different wind speeds and for different moister contents of the fuelbed. The simulations correspond to experiments EXMC 23, 24, 28, 36, 48, and 69 carried out by Catchpole *et al*., in which regular excelsior is considered; the main physical data of the simulations are shown in Tab. 1. A wall-refined mesh of 300×80×62 grid points was used for the fluid domain, while a uniform mesh was used for the solid domain with a grid size (Δx, Δy, Δz) = (2 cm, 1.25 cm, 1.69 cm). Since a high-Reynolds turbulence model is used in the simulations, the fluid domain mesh was carefully chosen to be fine enough for an accurate description of the solution, while respecting the condition $11.5 < y^+ < 500$ during the entire simulations time. The results were obtained using an adaptive time-step strategy based on a local truncation error approach, with time steps in the range of 0.001 to 0.01 seconds. At each time step, the conservation and transport equations were solved with an accuracy of 10^{-4} in normalized form.

Table 1. Rothermel configuration experiments chosen to show the effect of wind speed and moister content on fire spread dynamics. δ - fuelbed depth, U - wind speed, α - packing ratio, σ - surface area to volume ratio, M - moister content. Regular excelsior (particles density ρ_P = 398 Kg/m^3) is considered in all experiments.

Results

Figure 2 shows the temperature field obtained at t = 15 s (i.e. after 10 s of burning) in the simulation corresponding to experiment EXMC23 in Tab. 1 (U = 2.68 m/s and M = 5.5%); figure 2 shows the development of the flame and the expected propagation of fire. Figure 3 shows the corresponding distributions of temperature and dry material fraction at fuelbed-surface; figure 3 shows clearly the quasi-uniform fire-front obtained experimentally as mentioned in the previous section, and we notice also that the fuelbed upstream the ignition line (at x = 2 m) remains intact during the entire simulation time.

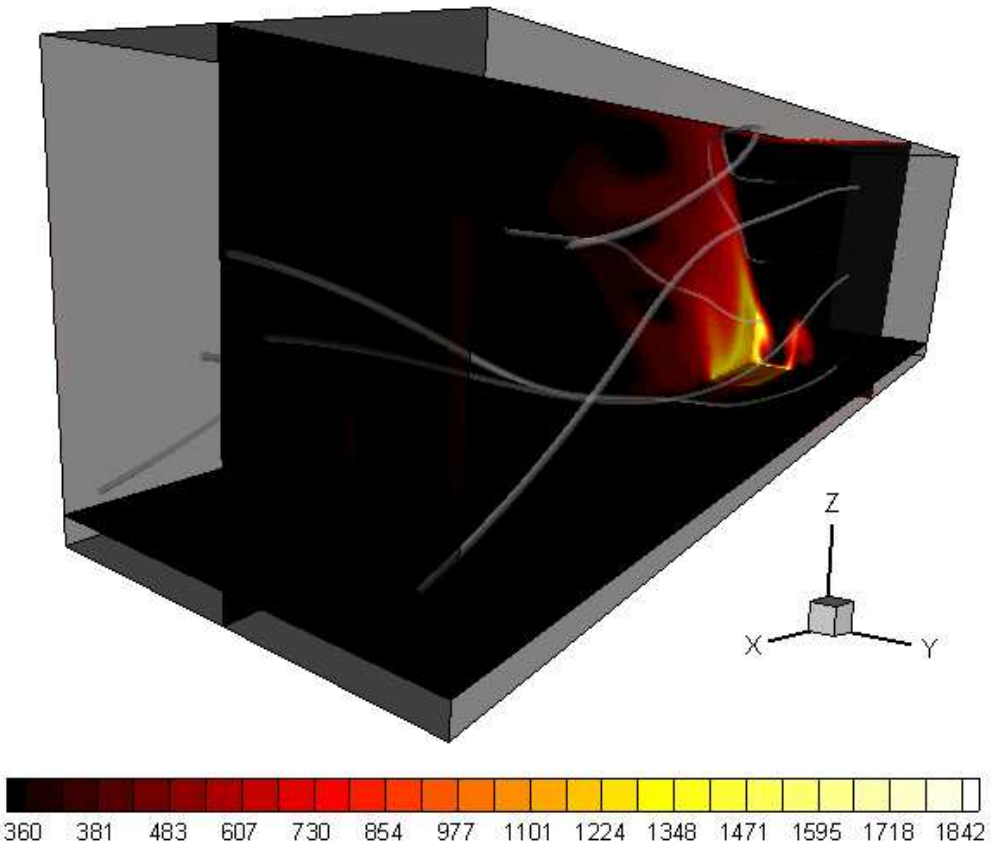

Figure 2. Temperature field and some streamlines obtained at t = 15 s, corresponding to experiment EXMC23 of Catchpole et al. (regular excelsior, wind speed of U = 2.68 m/s, moister content 5.5%, see Tab. 1 for more details).

The comparison between the simulations and the experimental data is based on the rate of spread of fire or ROS (i.e. the average velocity of the fire front). For this purpose, fuelbed characteristics were monitored at several positions along the line (y = 1.5 m, z = 0.203 m) as shown in Figure 4, by analogy to the photocell tubes positioned at 0.5 m intervals in Catchpole *et al*. experiments. Figure 5 shows the time evolution of the fuelbed temperature at duly chosen points of Figure 4; we clearly notice the phases of pyrolysis and char combustion. Indeed, according to the solid-fuel combustion model implemented in "FireStar3D", pyrolysis of dry material takes place between 400 K and 500 K, while char combustion starts once all dry material at a given location has been consumed. The ROS could be easily estimated from Figure 5 by measuring the average time required for the pyrolysis front (isotherm 500 K) to move from a monitoring point to another (covering each time the distance of 0.5 m). However, a simpler and more accurate method for estimating the rate of fire spread consisted in finding at each time step of simulation the average position of the pyrolysis front at the fuelbed surface. This was done by determining the average positions of the furthest points downstream the ignition line where the dry material fraction is equal to zero. In Figure 3(a), we clearly distinguish the pyrolysis front, it corresponds to the white-black interface located at about x = 5 m. Figure 6 shows the time evolution of the fire-front positions for duly chosen simulations; the ROS was obtained by evaluating the average slopes of the curves in Figure 6 after t = 10 s (end of ignition time). We notice, as expected, that increasing the wind speed or decreasing the fuelbed moisture-content increases the rate of fire spread.

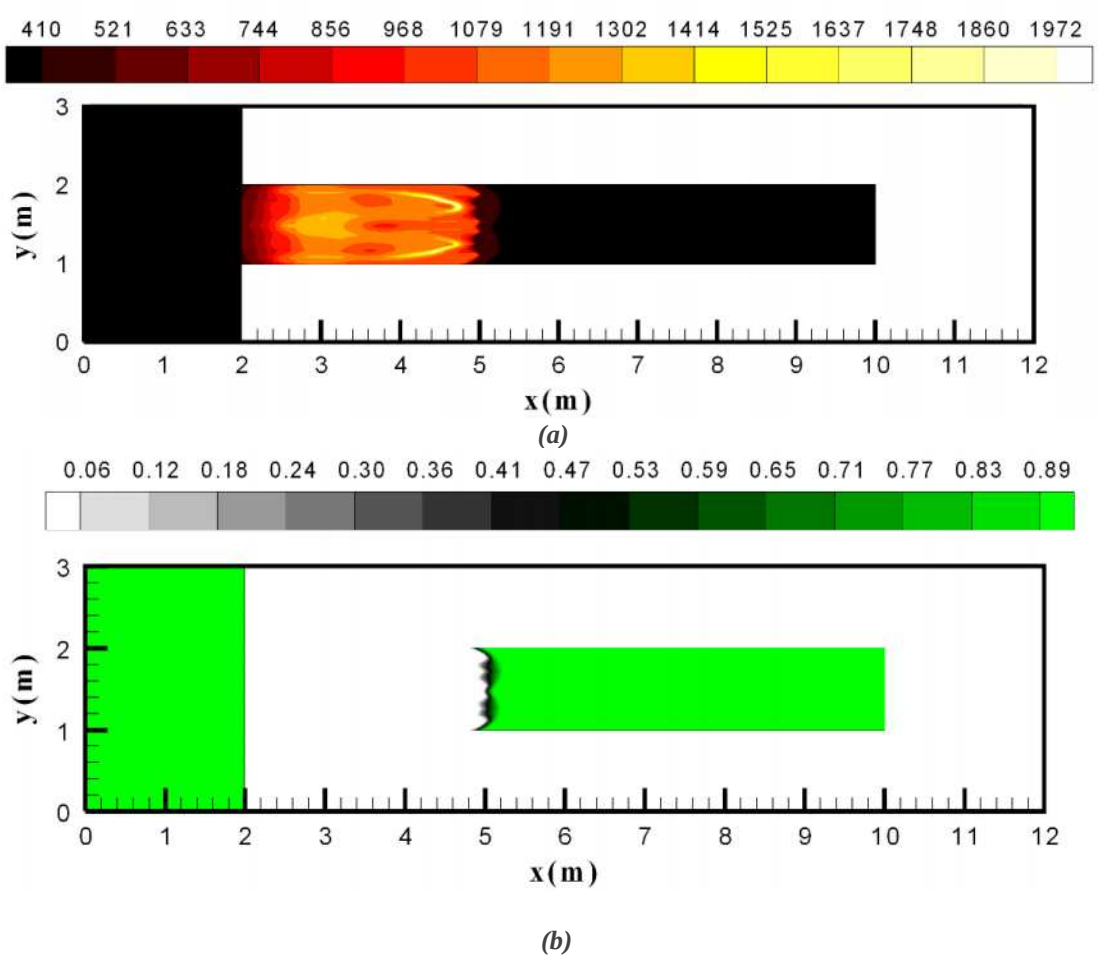

Figure 3. Temperature (a) and dry material fraction (b) distributions at fuelbed-surface (z = 0.203 m) obtained at t = 15 s, corresponding to experiment EXMC23 of Catchpole et al. (regular excelsior, wind speed of U = 2.68 m/s, moister content 5.5%, see Tab. 1 for more details).

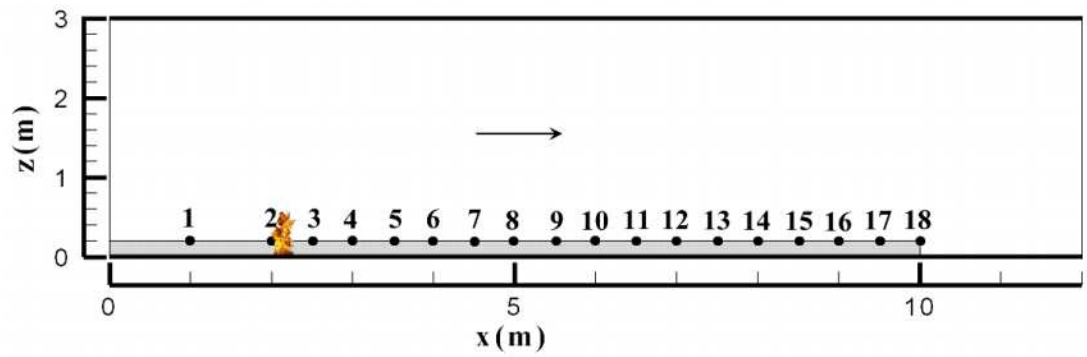

Figure 4. Positions in the vertical median plan of the computation domain (at y = 1.5 m) where fuelbed characteristics are monitored during simulation.

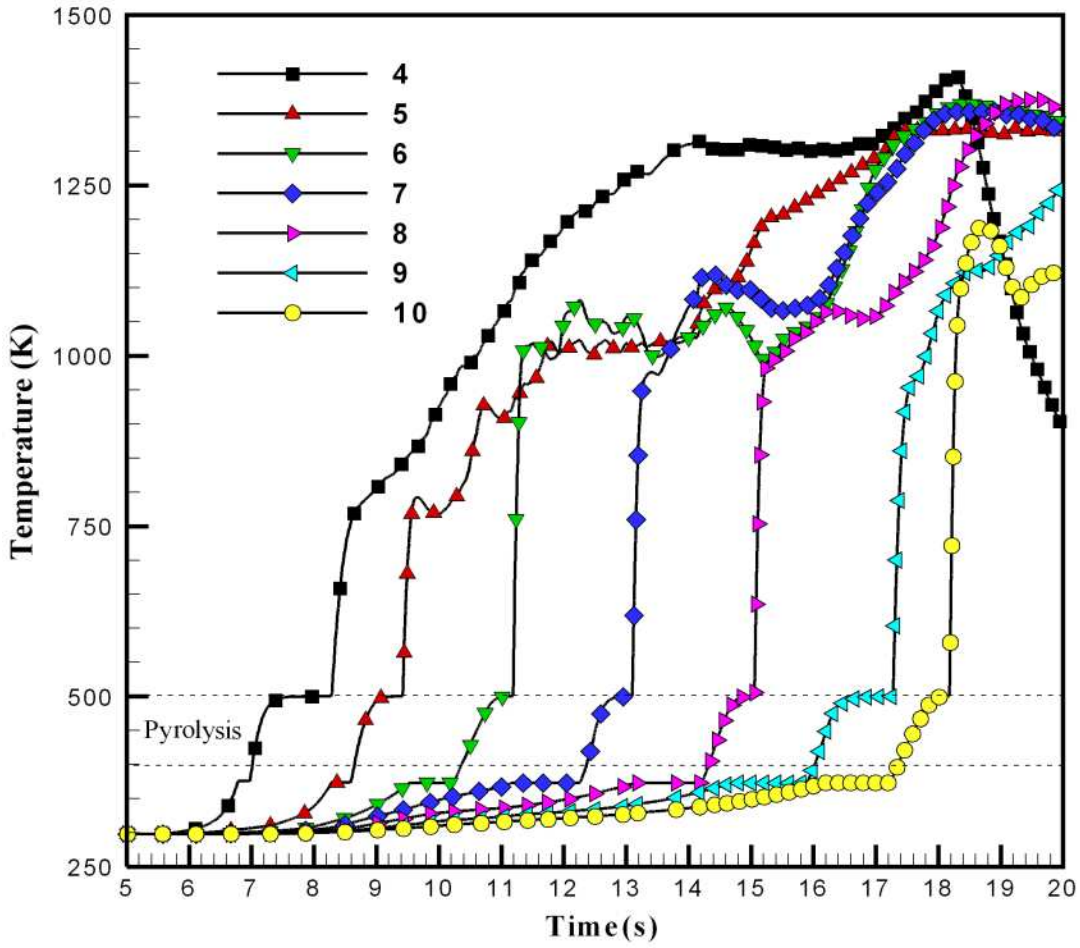

Figure 5. Time-evolution of the fuelbed temperature at positions 4 to 10 of Figure 4, corresponding to experiment EXMC23 of Catchpole et al. (regular excelsior, wind speed of U = 2.68 m/s, moister content of 5.5%, see Tab. 1 for more details).

The rates of fire spread were evaluated for the different simulations that had been conducted and are shown in Tab. 2, compared to those obtained experimentally. Table 2 shows also ROS values obtained using the correlation given by eq. (2) that was established by Catchpole *et al*. for different fuel types and properties using 357 experimental fires.

$$ROS = \frac{\left(I + mU^{n}\right)e^{-347/\sigma}\alpha^{-0.499}e^{-kM}}{\rho_{P}\left(Q_{P} + MQ_{W}\right)} \qquad (2)$$

Where I = 495.5, m = 1934, n = 0.91, and k = – 0.73 are model constants, and Q_P = 711 KJ/Kg and Q_W = 2250 KJ/Kg are the pyrolysis heat and water latent heat respectively.

We notice first that "FireStar3D" predicts the correct order of magnitude of the rate of fire spread (which is not easy to obtain for confined fires) and its correct dependence on the wind speed and on the fuelbed moisture-content. We notice also that, even though FireStrar3D seems to overestimate the rate of fire spread in the case of Rothermel configuration, especially for low wind speeds (EXMC24), the predicted ROS values are comparable to those obtained experimentally or estimated using different analytical models.

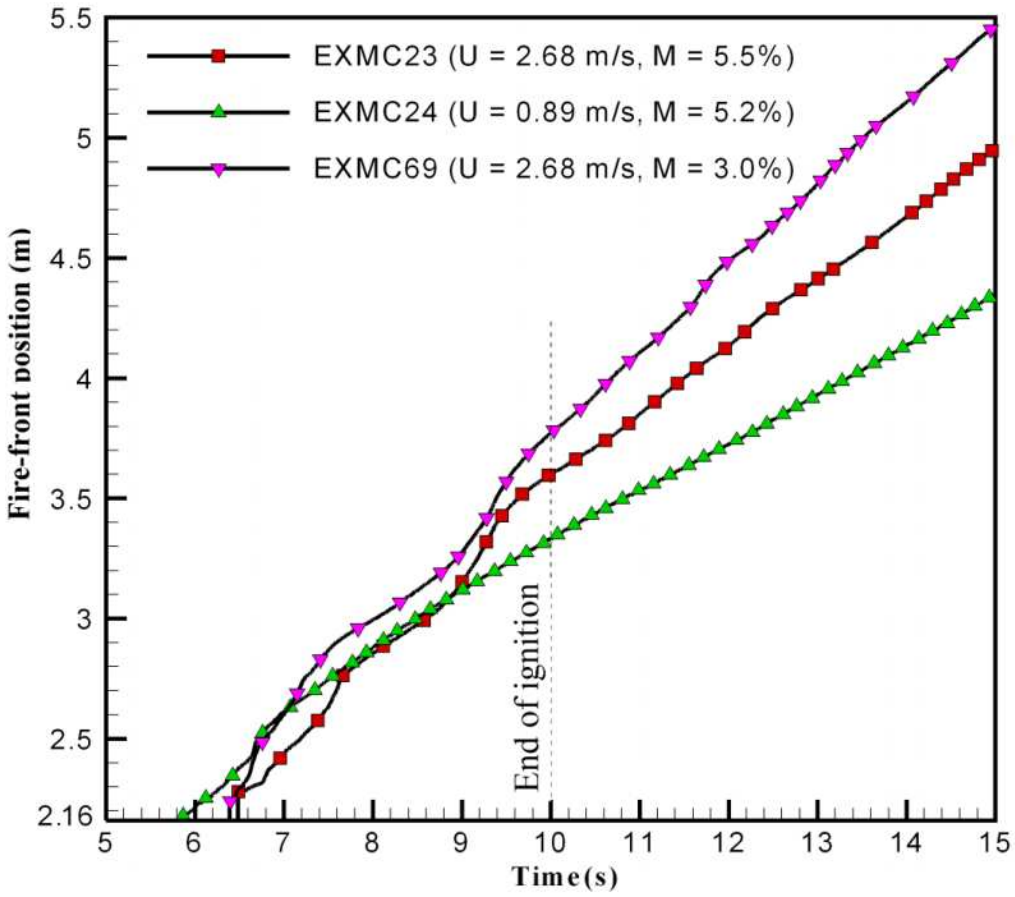

Figure 6. Time-evolution of the average position of the pyrolysis front, corresponding to experiment EXMC23, EXMC24, and EXMC69 of Catchpole et al., showing the effect of wind speed and moisture content on the rate of fire spread. The ROS is the average slope of the curve after t = 10 s (end of ignition time).

Table 2. Comparison of the rates of spread (in m/s) obtained numerically using FireStar3D, experimentally, and using the correlation established in Catchpole et al. (eq. 2) for the different experiments shown in Tab. 1.

	EXMC23	EXMC24	EXMC28	EXMC36	EXMC48	EXMC69
Simulation	0.285	0.201	0.241	0.230	0.199	0.345
Experiment	0.252	0.105	0.129	0.156	0.175	0.242
Correlation	0.221	0.094	0.159	0.203	0.181	0.232

Conclusions

A fully-physical wildfire model was used to simulate a confined fire in a wind tunnel. A preliminary study was carried out in the case of a homogeneous fuel bed to evaluate the potential of the model to predict fire behaviour. The obtained result were analysed in terms of fire front rate of spread (ROS) and shape, for different wind velocities and fuel moisture content values and compared with experimental data from the literature (measurements and empirical correlations). Globally, the obtained results compare well enough to experimental data, despite the relative difficulty of the considered configuration (confinement effects) and a consistent monotonicity is observed numerically

when varying the control parameters (wind speed and moisture content) accordingly to the realistic physical expectations. The next step will be to extend the investigation to other set of parameters (influence of particle size, other fuel types, …) and also to consider heterogeneous fuelbeds in this confined configuration for which correlations also exist. Finally and beyond the scope of this work, prospective numerical simulations for grassland fires were also carried out for different values of wind velocities; the leading results are in good agreement with some previous numerical studies and experimental data from literature.

Abstract
Local dynamic or thermodynamic variables that are the primary time and space dependent variables predicted by the FIRETEC physics-based model of fire behaviour, including gas velocity and gas temperature, have not been tested against experimental measurements to date. In the present study, we attempt to reproduce the FireFlux experiment with the FIRETEC model and we compare the predicted time evolution of wind velocity components and temperatures above the fire to data measured on a tower up to 43 meters above ground level. Given the complex and somewhat uncertain wind and ignition scenario that cannot be exactly reproduced by the model simulation, FIRETEC captured well the timing and magnitude of downdrafts, updrafts and temperature variations observed during the experiment when the fire plume crossed the measurement tower. The drawbacks of the experimental measurements and the influence of ambient wind fluctuations that cannot all be captured by the model do not allow conclusive comparisons regarding turbulent statistics and fluxes during the fire period.

***Keywords**: grassland, fire plume, temperature, velocity, model testing*

Introduction

FIRETEC is a three-dimensional coupled fire-atmosphere model that allows the simulation of fire spread in natural conditions at a high spatial resolution (one meter) over areas typically 10 to 100 ha. Earlier fire behaviour simulation studies of the physics-based FIRETEC model have provided reasonable results with respect to qualitative and some quantitative observations of global aspects of wildfire behaviour in the field. Previous evaluations considered fire spread in grasslands (Linn and Cunningham 2005), interactions between two fires (Dupuy *et al*. 2011), crown fire behaviour (Linn *et al*. 2012), fuel moisture effect on the rate of spread (Marino *et al*. 2012), or fire shapes as influenced by the combination of wind and terrain slope (Pimont *et al*. 2012). However, local dynamic or thermodynamic variables that are the primary time and space dependent variables predicted by FIRETEC, including gas velocity and gas temperature, have not been tested against experimental data. In fact, only turbulent wind profiles over tree canopies in absence of a fire have specifically been tested to date (Pimont *et al*. 2009).
The FireFlux experiment has already been used to assess the performance of coupled fire-atmosphere models (Fillipi *et al*. 2013, Kochanski *et al*. 2013). The above models are essentially designed to address lower spatial resolution and larger domains than FIRETEC and fire-atmosphere coupling refers to coupling between the atmospheric flow and a fire spread equation, whereas FIRETEC couples the atmosphere with a combustion model. In the present study, we attempt to reproduce the FireFlux experiment (Clements *et al*. 2007, 2008, Clements 2010) with the FIRETEC model. The reader may refer to earlier papers (e.g. Dupuy *et al*. 2011, Pimont *et al*. 2012) for a description of the model.

In the present study, we compare the predicted time evolution of wind velocity components and temperatures above the fire to data measured on a tower up to 43 meters above ground level (AGL). We quickly address the comparison of turbulent statistics and fluxes during the fire period.

The FireFlux experiment

The FireFlux experiment was conducted on 23 February 2006 and is described in detail by Clements *et al*. (2007). The atmosphere was neutral except in the first tens of meter. The experimental burn was conducted in a tall grass over a plot approximately 800 m long in the south direction (x-axis) and 400 m wide in the east direction (y-axis). The plot was surrounded by blocks of forested areas dominated by Chinese tallow trees of a maximum height 12-13 m. The experiment was designed to measure the winds and temperatures over the vertical direction as the plume and the fire passed two instrumented towers. A 43 m height instrumented tower (main tower, MT) and a 10 m height tower (short tower, ST) located 300 m downwind of the MT were equipped with three-dimensional sonic anemometers and thermocouple probes. In the current paper, we will focus on measurements at the MT. ST data have only been used together with MT data for adjustment of the wind scenario. The three-components of velocity were measured by the sonic anemometers at 2, 10, 28 and 43 m above ground level (AGL) at MT and 2 and 10 m AGL at ST. These data were recorded at 20 Hz and post-processed to produce valid data files (1 Hz) in earlier analysis. Temperatures were measured by a set of fine-wire thermocouple probes at 1 Hz from 2 to 43 m AGL, we will use only those probes that are located at 2, 10, 28 and 43 m AGL. The sonic anemometers measure virtual temperature, but they could not measure temperatures above 50°C. Temperature recordings readily show that these sensors underestimated the temperatures measured by thermocouple probes, especially at the lowest levels. On the other hand, thermocouple probes were not at the same position as sonic anemometers except at 2 m AGL level. That prevents their use for computation of turbulent correlation between temperature and velocity components (time shift in signals) at all levels.
Fire was ignited by two teams walking respectively to the west (actually 280°) and to the east (100°) direction from a point located in the central part of the plot, at approximately 120 m north of the MT. The timing of fire ignition was recorded for the eastern branch of the ignition line thanks to a GPS located with the ignition crew member. We used these data to build the simulation scenario of the ignition by FIRETEC. It was assumed that the western part was ignited at the same speed as the eastern branch. The exact MT position was known, the position of the ignition point was known within +/- 10 m. Fire spread and fire line shape were difficult to observe and were not well documented. According to temperature data recorded at lowest levels, fire reached the MT at 12:46:40, and according to photographs ignition started at 12:43:36 (+/-6 s) in the data logger clock time. From videos and photographs, the spread of the fire head was about 1.2 m/s when fire approached the tower.
Wind measured at the MT since 12:00 prior to fire ignition indicate that the mean wind speed was about 6 m/s and the mean wind direction was 11°. Wind data also show that wind speed decreased to 3.5 m/s and wind direction changed to North-East (45°) just before the ignition time. These values were observed for 30-40 s after ignition and then wind speed increased again and wind direction changed to the North roughly after about 1 min from ignition time. Later on, the ambient wind at the MT was modified by the fire and the plume, and thus is basically unknown.

Simulation setup

The simulation domain was 1200 m long (x-axis), 600 m wide (y-axis) and 615 m high. The actual position of the MT in this domain was (x=636 m, y= 330 m). The computational mesh is orthogonal and stretched over the vertical direction. Cell size was 2 x 2 x 1.5 m at ground level. Figure 1 shows a map of the vegetation types that was produced from an aerial image of the area. Tree canopy was represented by a homogeneous layer of 10 m height and a constant plant area density (note that those

deciduous trees were leafed out at the season of the burn). The rest of the area is covered by tall grass (fuel) and some areas of cut grass.

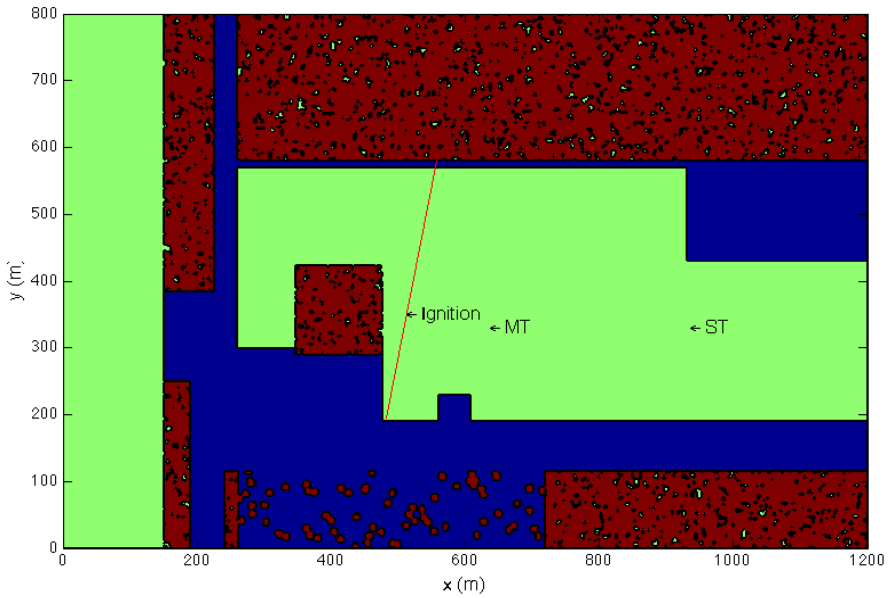

Figure 1. Simulation domain and vegetation map (Red : trees; Green : tall grass; Blue : cut grass)

A turbulent wind field was pre-computed using the same simulation domain dimensions, but the area was covered by a 600 x 600 m strip of tree canopy and two strips of tall grass upwind and downwind of the tree strip. This pre-computation used cyclic boundary conditions and a large-scale pressure gradient force method to allow the development of realistic turbulent structures due to vegetation roughness. In this method, a target wind is specified at some height where drag effects are minor (here 43 m AGL). Then the pre-computed wind field was used to set the initial and the boundary conditions for the computation of fire spread over the map shown in Figure 1. In this simulation, ignition started 300 s after run start to allow the wind field to adjust to the drag effects of the actual map of vegetation. In particular, the block of trees located just upwind of the ignition line influenced the wind field in the area of interest (between ignition line and MT). We adjusted the initial wind of the pre-computation and the (unknown) plant area index (PAI) of the tree blocks to get mean wind speed values closed to the observed ones at 10 m AGL at both the MT and the ST (respectively 4.9 and 5.7 m/s). That led us to use a 7 m/s wind speed and 11° wind direction at 43 AGL in the pre-computation and a PAI of 0.2 for the tree canopy with a drag coefficient set to 0.15. Fuel parameters were set following estimates reported in Clements *et al*. (2007) and ignition reproduced the process described in section 2. Fuel and ignition parameters are reported in Table 1.

Because fuel was removed 5 m around the tower base, we ran two fire simulations, one with no fuel clearing and one with fuel clearing (residual fuel load: 0.05 kg/m^2) in a square of 14 m side centred on the tower location. In fact, fuel clearing in the simulation was not operated at the actual tower location, but at two locations among points that were reached by the head fire within the observed timing. This is explained in the next section.

Table 1. Fuel (tall grass and live shrubs) and ignition parameters of the simulation

Fuel height (m)	1.5	Length of ignition western branch (m)	155
Fuel load (kg/m^2)	1.08	Duration of ignition western branch (s)	138
Dead fuel (% load and cover)	96	Length of ignition eastern branch (m)	237
Dead fuel moisture content (%)	9	Duration of ignition eastern branch (s)	205
Live fuel moisture content (%)	200	x, y position of ignition start (m)	513, 350

Results and discussion

4.1. Ambient wind adjustment

The experimental wind profile at MT, determined from recordings prior to fire ignition, was not perfectly predicted by the model at that location. To get the observed value at 10 m AGL, the mean predicted wind speed was close to 7 m/s at 43 m AGL at MT (the same as in the pre-computation), whereas the observed value was 6 m/s. We suspect that the model overestimates the influence of trees on the mean wind profile downwind of tree canopy since we got a profile close to the measured wind profile some tens of meters downwind of the MT.

4.2. Fire spread

Figure 2 shows the simulated fire front 60 s, 120 s and 190 s after ignition start. According to temperatures predicted at 2 m height, fire reached the x-position of the MT (636 m) within 185 and 195 s after ignition for points located between 340 and 370 m in y-direction, thus exactly the experimental timing. The actual y-position of the MT (330 m) was reached with ~ 10 s delay in the simulation. Owing to the uncertainty on the actual position and timing of the ignition line building, we did not expect a better result. In fact we must consider that within a few tens of seconds, this timing was obtained just by chance. The strong change in wind speed and direction during the initial development of the fire line cannot be rendered by the model simulation and certainly affected the fire line spread and shape and when plume and fire reached the MT just 2-3 minutes later. This change is likely due to large-scale atmospheric structures that cannot be captured with the current technique used to compute the ambient wind.

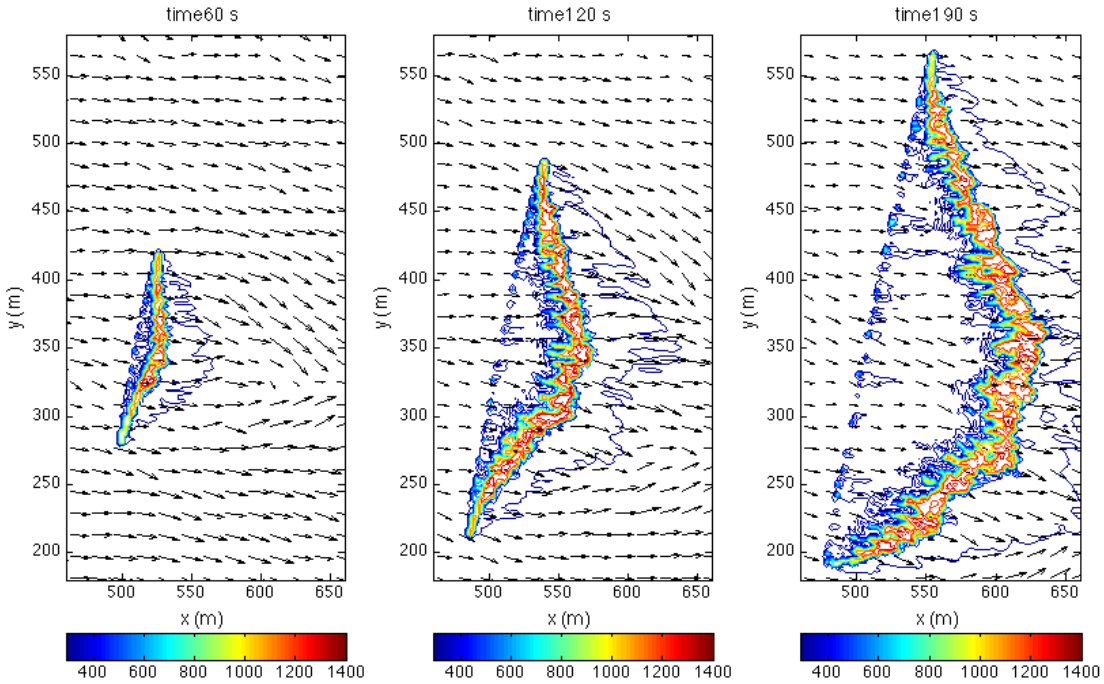

Figure 2. Fields of gas temperature (0.75 m AGL) and horizontal wind (10 m AGL) simulated with FIRETEC, 60 s, 120 s and 190 s (arrival of fire head at x=636 m) after the ignition

In the following, we will focus on those points comprised between y=340 m and y=370 m where fire arrived at x-position of the MT (636 m) in a timing close to the experimental one. In all time series plots of the variables, time zero corresponds to the ignition start time and fire reached the MT at ~ 190 s. Predicted time series are all shown together with the experimental one.

4.3. Horizontal velocity

We will only report results for the u-component of velocity (x-axis), which is the major component of horizontal wind speed (mean angle with North is only 11°) and drives the plume along the x-axis. Figure 3 shows 1 Hz time series of the u-component of velocity at y=340 m and y=370, and at 10, 28 and 43 m AGL. As expected (section 4.1), the mean wind speed is over-predicted at 43 m AGL and to a lesser extent at 28 m AGL, but also at 10 m AGL. In fact, variations in the measured wind are much higher than variations in the computed velocity. This was also observed prior to fire arrival (variance of predicted and measured velocities) and confirms we cannot capture all ambient wind fluctuations. The comparison between predicted and measured horizontal velocities is thus delicate since we cannot separate the largest variations due to the ambient wind flow structures (that cannot be rendered by the model) from the impact of the fire in the experimental data. At least a wind measurement not influenced by the fire should be used to do so. Nevertheless, experimental data exhibit two minimum values at all heights (approaching zero at 10 m AGL), prior to plume arrival, and then an increase of the wind when the plume crosses the MT. The model captures the increase in wind speed as the plume passes, but not the strong wind decay prior to plume arrival.

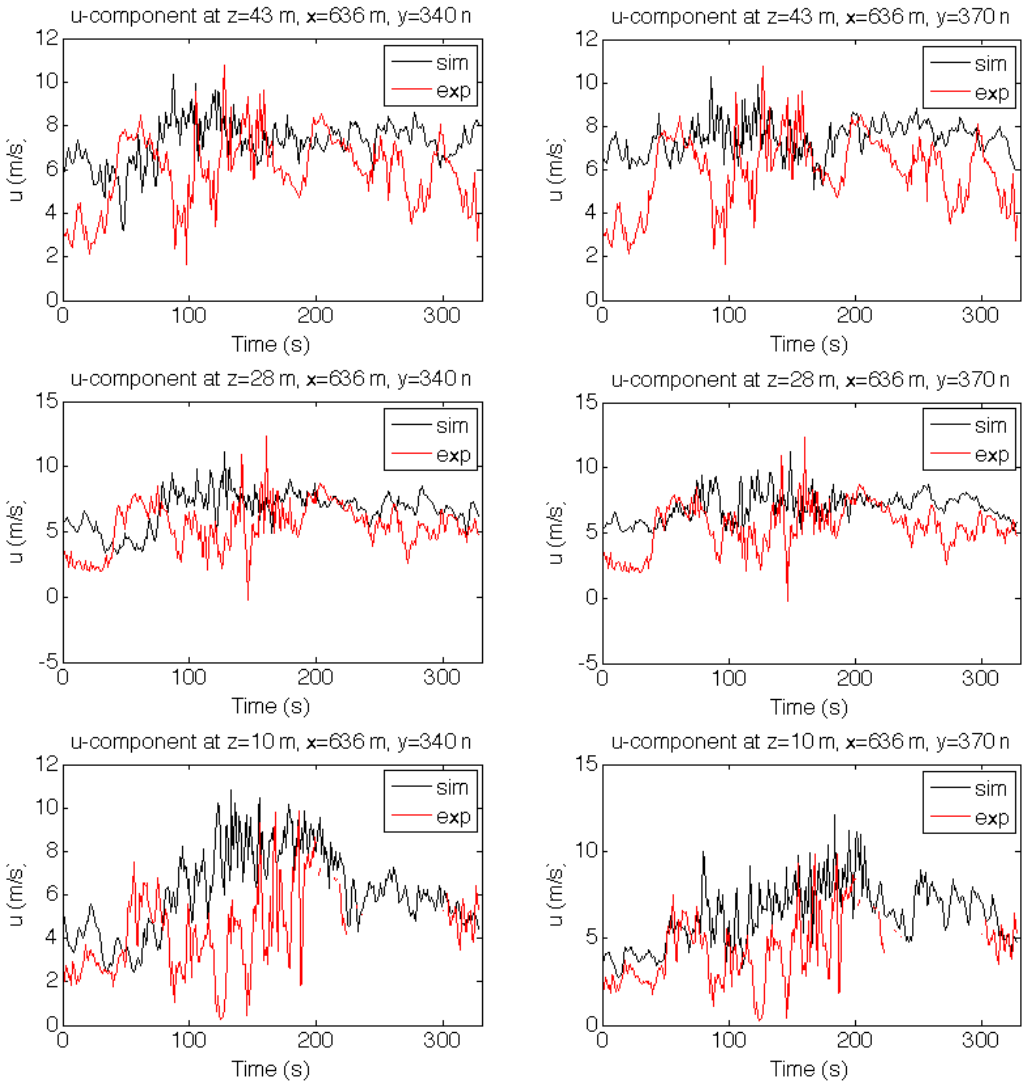

Figure 3. u-component of velocity versus time (1 Hz) at 10, 28, and 43 m AGL, at two points (sim) and at MT position (exp)

4.4. Vertical velocity

Over a flat terrain and in near neutral conditions, the ambient flow should have a small effect on vertical velocity as compared to the fire, which is a high source of buoyancy. In other words, comparisons of the model predictions to measured w-component of velocity should be meaningful for the model assessment. Figure 4 shows 1 Hz time series of the w-component of velocity (vertical velocity) at six points together with the experimental measurement, at 28 m AGL. The predicted and experimental patterns are very similar, in timing and in magnitude. In particular, the model renders the increase in vertical velocity peak values as the plume crosses the points and the downdraft observed just after the plume passed the tower location. Consistency between predicted and measured w-velocity patterns is confirmed at other heights (shown for two points in Figure 5). Figure 6 shows 10 s-averaged data at the six points between 340 and 370 m. It is easier to depict the magnitude of velocity and worth noting that variations among simulated points are important.

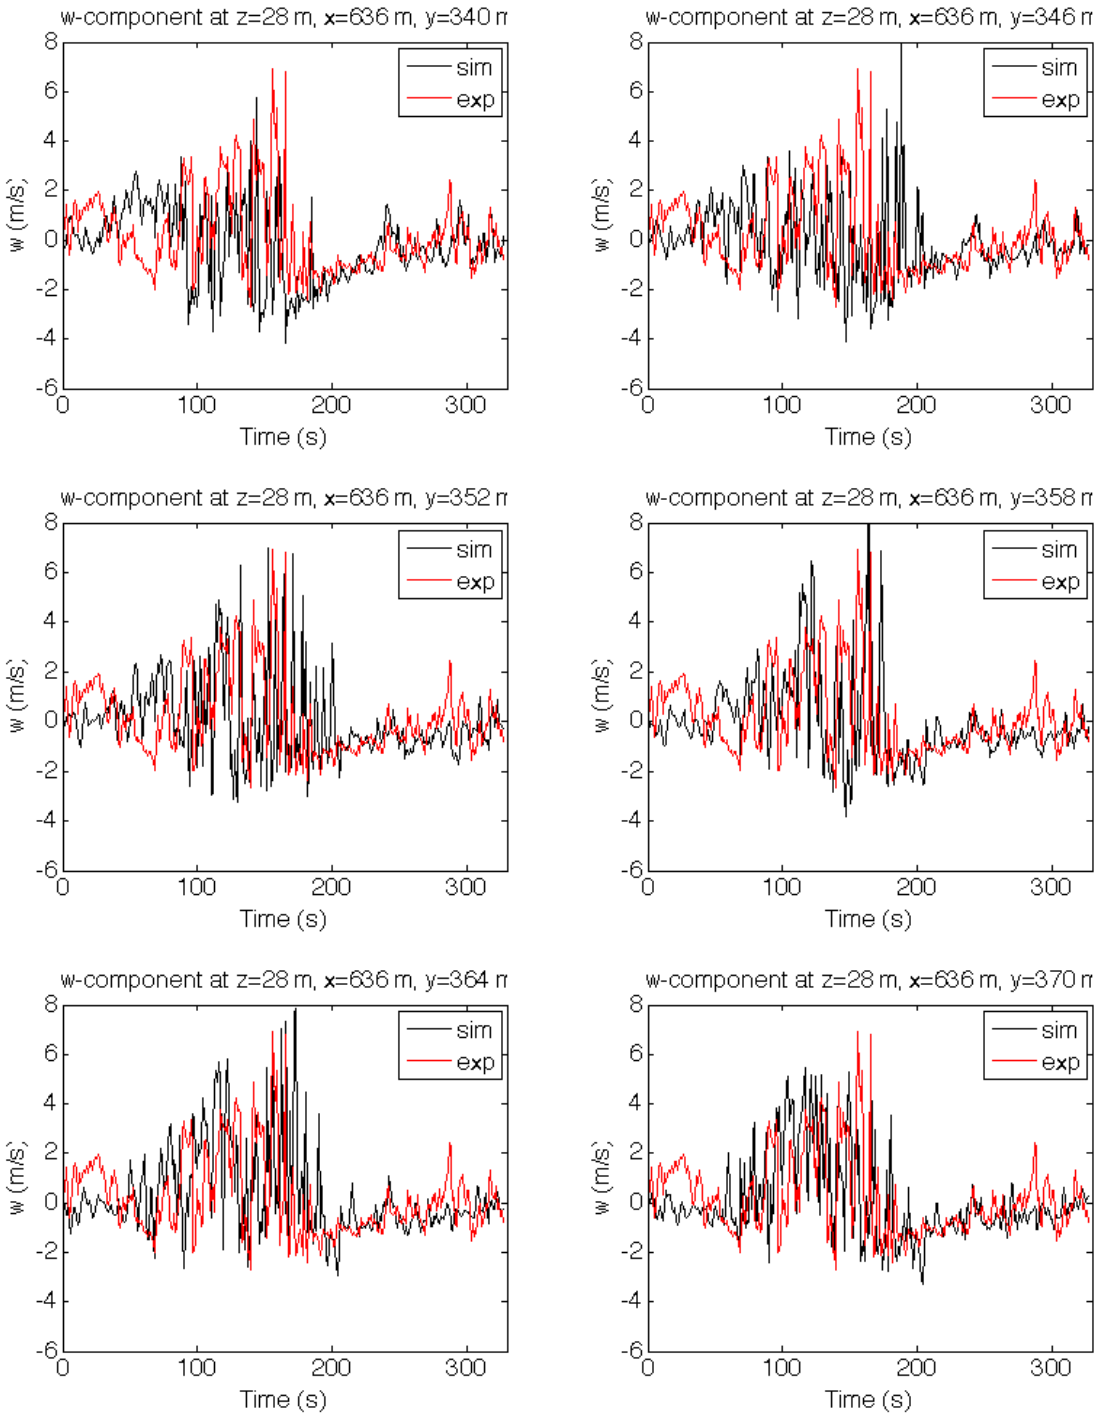

Figure 4. w-component of velocity versus time (1 Hz) at 28 m AGL, at six points (sim) and at MT (exp)

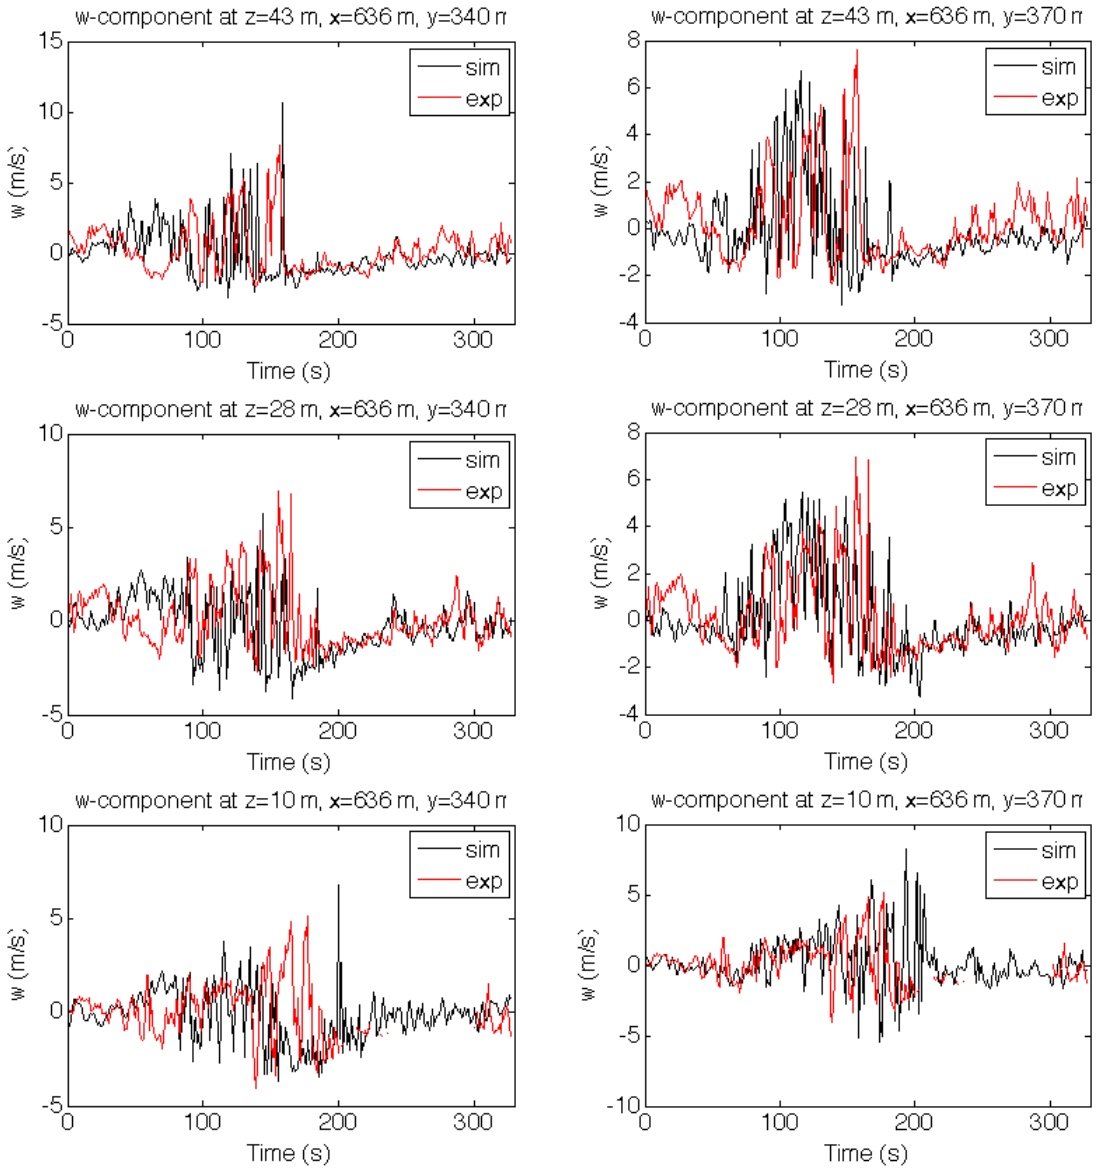

Figure 5. w-component of velocity versus time (1 Hz) at 10, 28, and 43 m AGL, at two points (sim) and at MT position (exp)

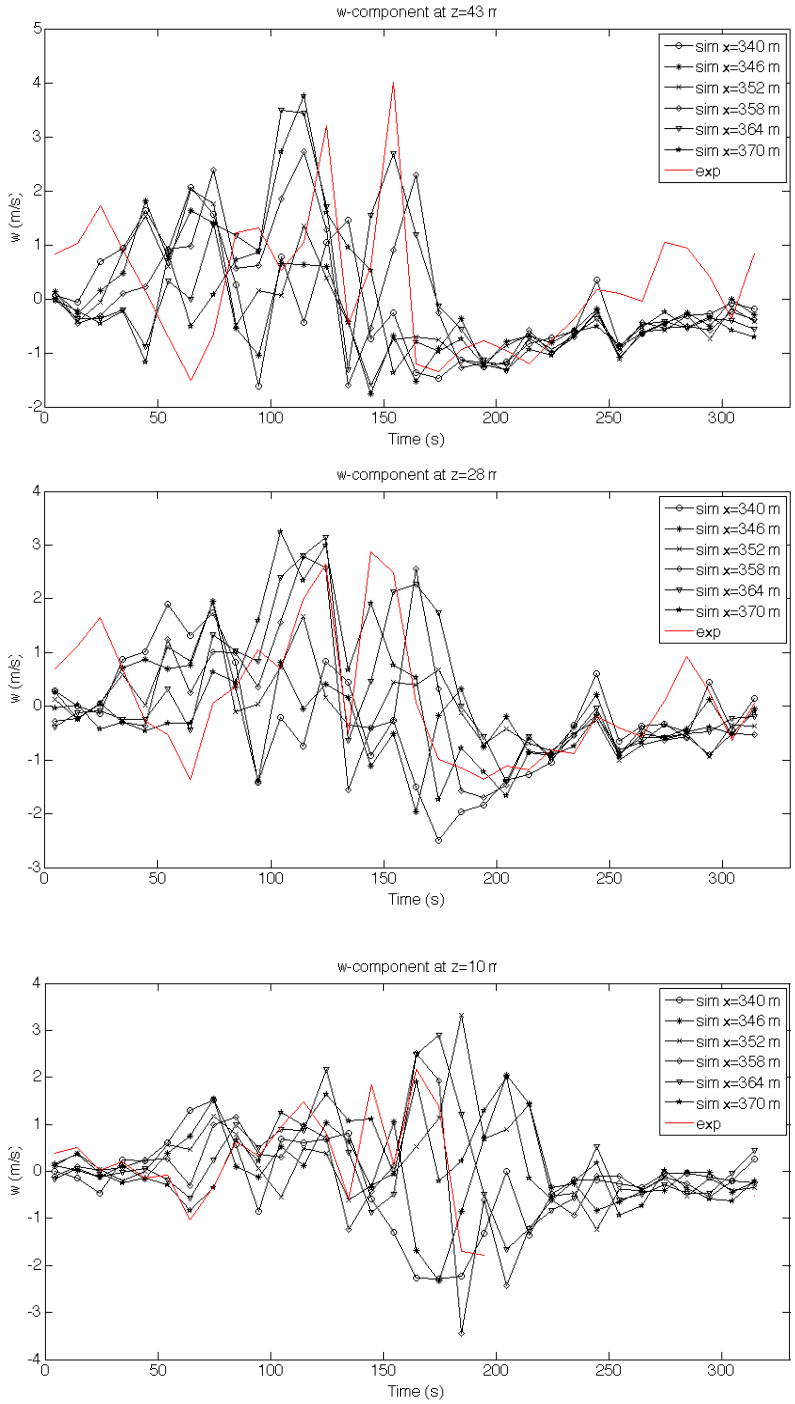

Figure 6. w-component of velocity versus time (10s-averaged data) at 10, 28, and 43 m AGL, at six points (sim) and at MT position (exp)

4.5. Temperatures

Plots of 1 Hz temperature time series at 10, 28 and 43 m AGL all show the same general pattern, but also important variations among points between y=340 and y=370 m (not shown). Figure 7 shows those time series of temperature at two points and three heights AGL (10, 28, 43 m). The plume impinges the upper levels of the tower earlier than in the experiment, typically 40-50 s earlier at 43 m AGL and 20-30 s earlier at 28 m AGL. This results in higher predicted temperatures than observed when the plume starts to cross the tower. That can be easily seen for the six points between 340 and

370 m on 10-s average plots of temperature (Figure 8). We assume that these differences are essentially due to differences in horizontal wind speed described above and to the initial wind change observed in the experiment. Higher wind speeds imply that heat is advected faster. The wind change in both speed and direction in the experiment is likely to have delayed plume impingement on the tower. It is worth noting from Figure 8 that the observed peak value of temperature at the three heights is in the range of predicted values, which however vary a lot among the different points.

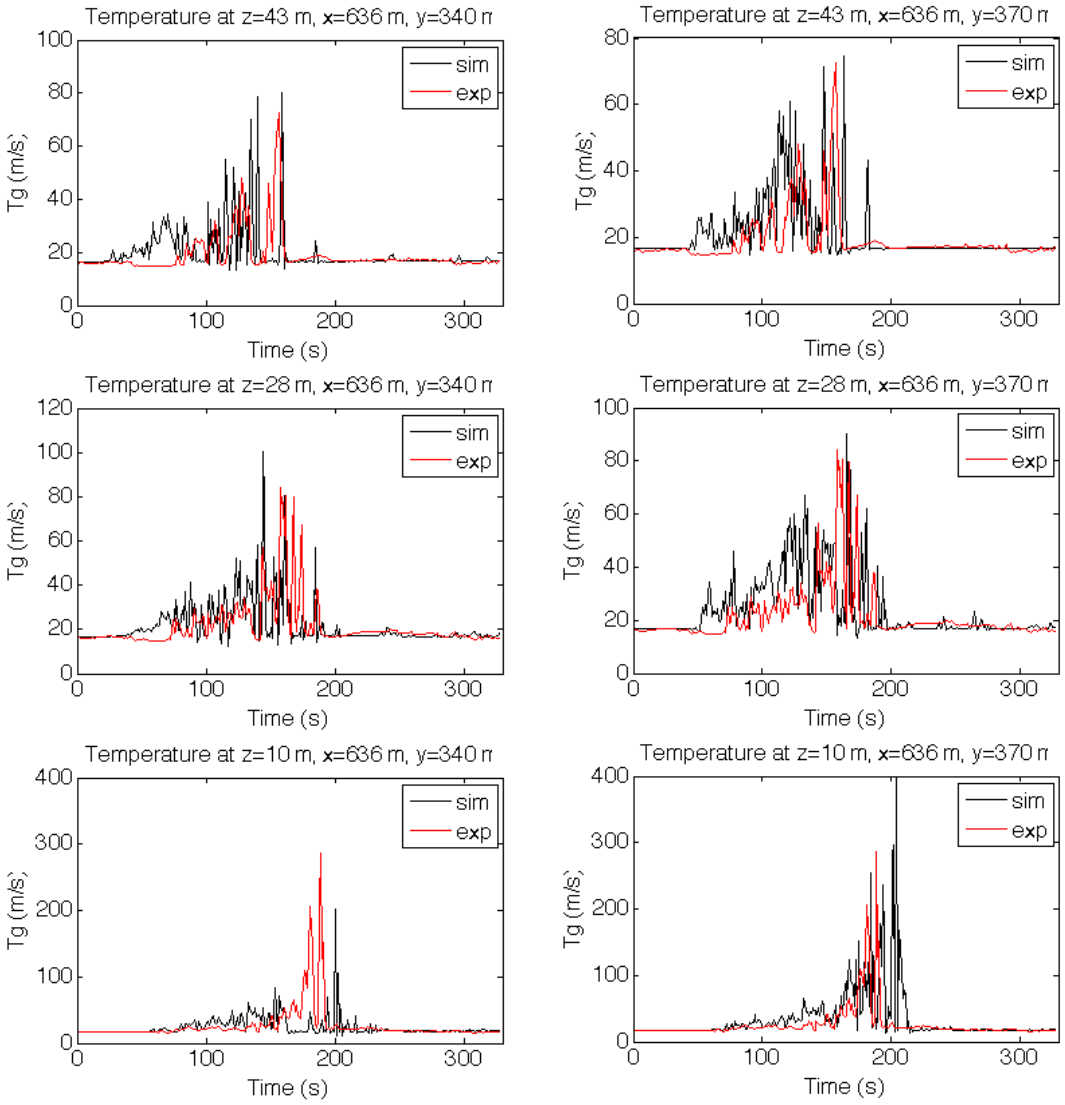

Figure 7. Temperature versus time (1 Hz) at 10, 28, and 43 m AGL, at two points (sim) and at MT position (exp)

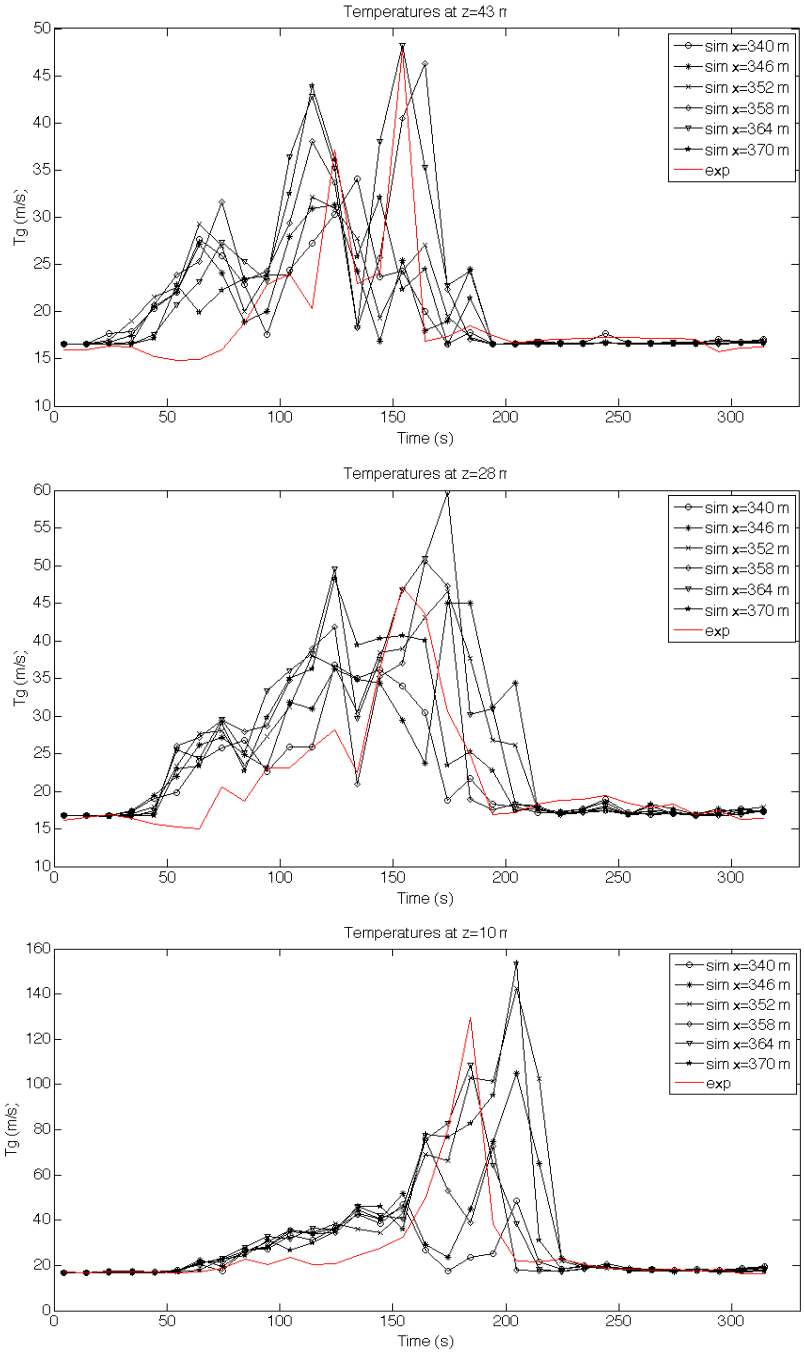

Figure 8. Temperature versus time (10s-averaged data) at 10, 28, and 43 m AGL, at six points (sim) and at MT position (exp)

4.6. **Influence of fuel clearing**

In a second simulation, fuel was cleared at y=340 m and y=370 m. Clearing had little effect on velocity and temperature patterns at the upper levels. We noticed some small changes in the temperature peaks at 10 m (not shown). This was expected since heat is advected faster in the horizontal than in the vertical direction (two times faster in order of magnitude in the simulation). In contrast, changes in temperature were very large at 2 m height. Figure 9 shows that peak temperatures were strongly reduced when clearing was applied and that predicted temperature levels with clearing match the observed values. Clearing also reduced the peak values of vertical velocity reached when the fire crosses the base of the tower (not shown).

4.7. **Turbulent statistics**

Turbulent statistics of atmospheric flows are meaningful when computed over time samples large enough to consider that variables are stationary. During the plume and fire passage, all variables measured at a fixed point are clearly unsteady. In addition, in the present experiment, measurements were taken at a position that was influenced by the initial development of the fire since the duration of ignition and the time to reach the MT were similar. Only point probes "attached" to a steady fire or more realistically 1D or 2D fields of data measurements, would be able to provide such statistics. This is of course a great challenge to perform such measurements.

Statistics may be computed over some reference time period with the purpose of model-experiment comparison only. Unfortunately, both the current technique of ambient flow modelling used by FIRETEC and the drawbacks of the temperature measurements strongly limited the possibility to perform such comparisons. As we mentioned, ambient wind variations are likely to influence the horizontal components of wind in the plume and as such, should influence their variance and co-variance.

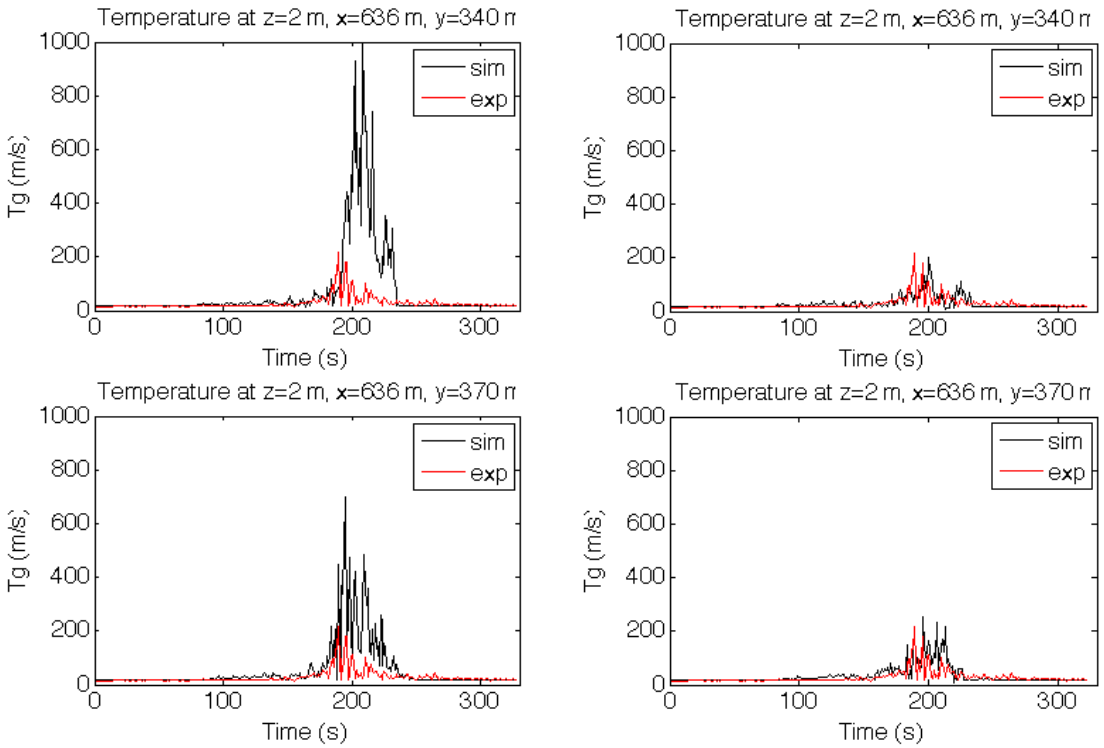

Figure 9. Temperature versus time (1 Hz) at 2 m AGL, at two points (sim) and at MT position (exp). Left : no fuel clearing; right : fuel clearing at point location

We readily found in the pre-fire period that the observed variances of u and v components of velocity were underestimated by the model, because we only capture those variations that are due to the vegetation roughness in the simulated domain we used. Besides, sonic temperatures were underestimated by the sonic anemometers, which compromises the calculation of the vertical sensible heat flux or the vertical buoyancy (e.g. basically the correlation of the vertical velocity and the temperature).

To support the above assertions, we computed one minute moving averages of velocity component variances and co-variances and the covariance of vertical velocity and temperature (w't') on 5 Hz data. We tracked the extrema of these statistics during the fire period (0 to 5 min after ignition). Those statistics were computed for the 16 points of the simulation located between y=340 and 370 m, and for

the experimental data, at 10, 28 and 43 m AGL. As expected, the model underestimated the observed peak variance of horizontal velocity (u'^2, v'^2) and the magnitude of the (negative) peak vertical momentum flux (u'w'). The variance of the vertical velocity (w'^2) from the observations was similar to the model. The experimental w't' correlations (or the sensible heat flux) were clearly below the model predictions and it decreased with decreasing height AGL, whereas it increased in the model predictions.

Conclusion

The current work is the first assessment of temperature and velocity predictions by FIRETEC against data measured in a plume developed from a spreading fire in natural conditions. The updrafts and downdrafts observed in vertical velocity measurements are particularly well captured. Temperature magnitude at different heights is also well captured. This is particularly important because these two variables are mostly determined by the fire and much less by the ambient wind flow. However the model predicts a faster plume impingement on the upper levels of the measurement tower, whereas the arrival of fire at the position of the tower in the simulations is the same as in the experiment. We assumed that it was due to the model not being able to reproduce the actual wind profile at the tower location downwind a block of trees resulting in a 15% overestimation of wind speed at the upper level. The model also cannot incorporate the change in wind speed and direction that was observed during the initial development of the fire in the experiment and was likely to delay this impingement. The current technique used to set up the ambient wind field in the simulations does not allow to take into account such changes in ambient wind speeds that are likely not due to the surrounding vegetation, but to larger atmospheric structures. This is in fact a good illustration of the challenge that represents such model-experiment comparisons. The fact that the ambient wind during the fire was not known (not measured at a point not influenced by the fire) did not help with understanding the differences between predicted and measured horizontal wind speed during the fire passage. It is worth noting also that the model showed a clear effect of clearing the fuel at the tower base on temperature and velocity, which is important for design of future experiments. Finally, the drawbacks of the experimental measurements and the influence of ambient wind fluctuations that cannot all be captured by the model do not allow conclusive comparisons regarding turbulent statistics during the fire period.
These results encourage us to continue the assessment of the model using more recent experiments such as FireFlux II that benefit from progress in fire instrumentation and to simulate a diversity of situations that would help design future experiments by testing the sensitivity to environmental conditions and ignition scenario or the relevance of measurement devices.

Abstract
Fore fire code has been developed to bridge the gap between research and operational code, it is open source, designed for large scale fire simulation, can be easily extended with any new model formulations and can take typical landscape data as input. The code is composed of a simulation engine that has been numerically tested with numerous bindings for different computer languages to be integrated into other scientific environments ranging from SciPy/Numpy to Fortran parallel coupled numerical weather forecast models. This paper presents the general software architecture and concepts, illustrated by examples and use cases in different context.

Keywords*: software, model, simulation, source code, open source, python, fire front, forecast*

Introduction

Fire front simulation tools have either been targeted with great success for research or for operations (Finney and Andrews 94). If most research oriented codes were designed to handle specific configuration with a complex and possibly time consuming set-up, operational tools are designed to handle almost readily available landscape data in order to provide simulation results relevant for real large scales fire. The ease of use of such software, and their relevance for large scale fire simulation has helped the field of forest fire operational research with application among which fire re-analysis, uncertainty estimation, land use, fuel management. Nevertheless, all these software are monolithic, they are not designed to be modular, extended or used in the context of multiple interactions with other scientific software (model coupling, data analysis, post-processing). An important aspect is also that unlike research purpose code operational software's are mostly closed source, available only as a compiled binary with little opportunity to add or change the numerical scheme or the formulation of the rate of spread of fire intensity.
Fore fire code has been developed to bridge the gap between research and operational code, it is open source, designed for large scale fire simulation, can be easily extended with any new model formulations and can take typical landscape data as input. The code is composed of a simulation engine that has been numerically tested (Filippi *et al*, 2009) with numerous bindings for different computer languages to be integrated into other scientific environments ranging from SciPy/Numpy to Fortran parallel numerical weather forecast models.
This paper will present first the general software architecture, illustrated in a second part by examples and use cases in different context. Finally the conclusion will also review the requirements and future code developments.

Time handling and numerical integration method

The forefire code is based on discrete events simulation, a complete description can be found in (Filippi et.al. 2009). Basically, each action (fire portion moving, wind change …) is performed by a component (fire portion, atmospheric data model) at a specific time. An action, from a component, is scheduled at this specific time by an event, these events are received and time-sorted in a global timetable. Events can be inserted by the user, and each component, when activated, can re-schedule events. Time is

continuous, meaning that there in no time step, and activation times are real numbers, simulation is run by activating the component with the most imminent event, scheduling its output events and moving to the next imminent event.
Discrete events time handling has several advantages, first it does not forbids the use of discrete time stepping methods (with evenly timed events), it is easily integrated in a scripted environment, can easily handle the introduction of heterogeneous components and most of all, can optimize computational time when components have very different characteristic time (such as a between a very slow moving backfire and a strong head-fire).
ForeFire software architecture is not tied to a specific numerical method to simulate fire front propagation, yet, only a Lagrangian front tracking method of markers is implemented.
In the front tracking method, the fire line is decomposed into a set of connected points, or markers. Each marker is a component that has a specific propagation direction and speed, such as shown in figure 1.
The speed at which the marker is traveling along its propagation vector is given by the rate of spread model with many available (isotropic, wind-aided, Balbi (2009), Rothermel (1972), other can be added with a single C++ file. The direction of propagation vector is usually (several methods available) taken as the bisector of the angle formed by the marker, and the location of the immediate left and right markers. Markers are redistributed along the front if separated by more than a resolution distance Δr and removed if separated by less than $\Delta r/4$. A fire line is defined as a full set of interconnected markers. If two points of different fire lines are separated by less than $\Delta r/4$ the two fronts are merging. The integration of a marker advance is performed in a discrete event fashion, with no global time step but specific activation time for markers. Each marker is advancing by the same distance Δq with an event time activation estimated as the time it will take to the parker to move by this distance given its local propagation.

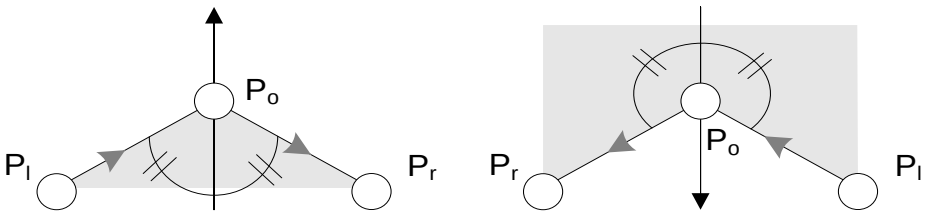

Figure 1. Front tracking and markers. Circles represent markers along the fire line. Arrows show the propagation vector (bisector of the local angle at the marker P0 between the point at left, Pl and point at right, Pr). Grey area represents the burned fuel.

The propagation velocity of the fire front given by the velocity model depends on the flame geometrical properties: tilt angle, curvature and front depth. The two firsts properties are assumed instantaneous in the model and may be observed from the front geometry or computed at a given time. On the contrary the front depth, thickness of the front where the flame is present, depends on front history and fuel properties (for how long and how fuel has been burning). When simulating the effect of a fire this history is also necessary to diagnose the location and intensity of different fire induces phenomenon (mass and heat fluxes for example, requiring user defined fluxed models). In the proposed method a high resolution matrix of arrival time is used to keep track of the fire history top perform instantaneous surface diagnostics. The matrix resolution is a key point and limitation of the method that requires to fix a physical lower limit, making the hypothesis of a minimal propagative front depth (if the front is thinner than this value the fire can't propagate and may go to extinction in non self-sustaining fire conditions). On large domains (tens of square kilometers) this two dimension matrix may contains millions of points at a typical resolution of one meter. Nevertheless, as in large Wildland

fires the active burning area is only a very small fraction of the total domain extension, arrival times is handled as a sparse matrix that may still be handled efficiently.

Software architecture

The general software architecture is presented in Figure 2. Basically, the software compiles in a shared library, that has optional bindings to different programming languages and data formats to use as input/outputs. In addition to these bindings, there is a binary interpreter with a ForeFire specific syntax and scripted commands that is compiled for standalone applications, parameterisation and text format data input/output.

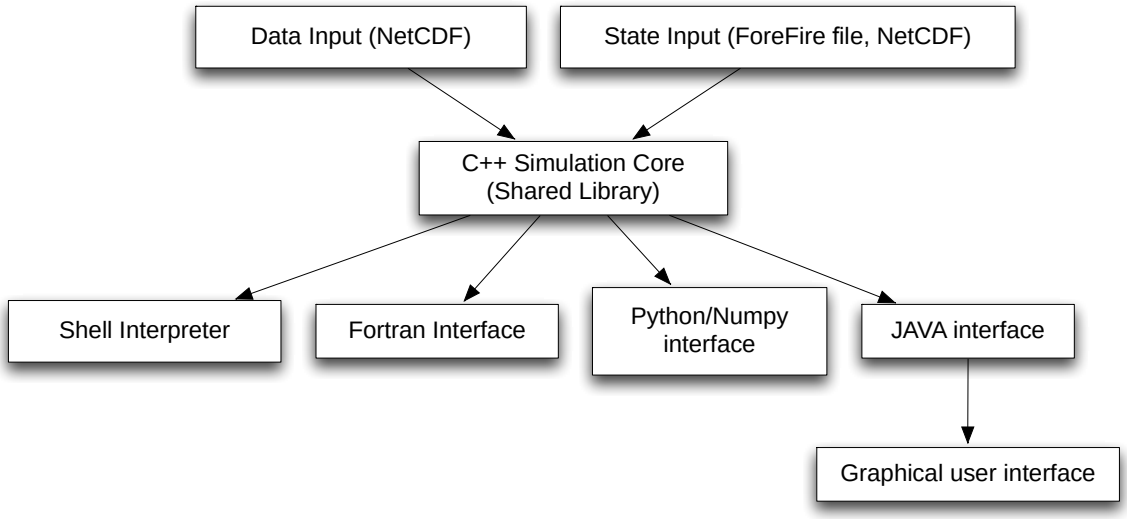

Figure 2. General software architecture and bindings

There are two different kind of input data, with sample format available from the software repository. The first is similar to Farsite's "Landscape" file but in the NetCDF file format, it defines, for a specific data domain a compilation of altitude, wind field, fuel distribution and optional diagnostic (fluxes) model distribution. Fuel state for each fuel classes is defined in a separated file and is highly dependent on the fire velocity model of use. The state input file is composed of the arrival time sparse matrix in NetCDF and ForeFire format for front input.

3.1. Command interaction

Interaction with the simulation is made with so-called commands, these can be either software calls (functions available in Fortran/Python/C++/Java interfaces) or command calls from the interpreter (a binary file launched from the command line). All commands are presented in Figure 3, all interaction with the simulation can be performed with this set of commands, with the exception of accessing the data arrays that cannot be made in text/console mode and can only be stored to files or accessed with programming interfaces.

```
FireDomain[date, location, extension] : creates a fire domain
FireFront[date] : creates a fire front with the following fire nodes
FireNode[location, velocity] : adds a fire node to the given location
step[duration] : advances the simulation for a user-defined amount of time
goTo[date] : advances the simulation till a user-defined time
setParameter[name=value] : sets a given parameter
setParameters[name=value;name=value] : sets a given list of parameters
getParameter[name] : return the parameter from a key
loadData[Netcdf File] : load a landscape file, define a domain
startFire[location, date] : start a triangular fire front
include[command file] : include commands from a file
print[output file(optional)] : prints the state of the simulation
save[NetCDF file] : saves the simulation state in NetCDF format
clear[] : resets the simulation
quit : quit and terminate
```

Figure 3. List of the scripted commands

Launching a simulation

If most of the commands are self-explanatory, some are notable, in particular the FireDomain, FireFront and FireNode commands that actually defines the fire mesh. A Node (marker) is container in a Front (interface) if it is defines just under it, with correct indentation. If it is only possible to define a single domain, it is possible in that way to define as many fronts with inner fronts as necessary. The propagation direction (contraction or dilatation) of the interface is given by the winding order. The Print command outputs the Domain/front/node structure in the same format, so it is directly readable with an Include command, Figure 4 is an example of the most simple isotropic front propagation.

```
1  setParameters[propagationModel=Iso;Iso.speed=1]
2  FireDomain[sw=(-10.,-10.,0.);ne=(10.,10.,0.);t=0.]
3      FireFront[t=0.]
4          FireNode[loc=(-3,-3,0.);vel=(-0.5,-0.3,0.);t=0.]
5          FireNode[loc=(0.,3,0.);vel=(0.2,1.2,0.);t=0.]
6          FireNode[loc=(3,0.,0.);vel=(0.7,0.1,0.);t=0.]
7  step[dt=10s]
8  print[sim1.ff]
9  clear[]
10 include[sim1.ff]
11 step[dt=5.2s]
12 quit[]
```

Figure 4. Simple simulation example

In this simulation, a domain is created between a southwest and a northwest point, and is added a front with three nodes (lines 3 to 7). The simulation is run for 10 seconds (line 8), then the structure is saved to a file, and reloaded (line 11), restarted for 5.2 more seconds then stopped. The “Iso” model is a simple isotropic model, taken as example for the simplicity of parameterisation here. More complex models are already available such as Balbi (Balbi *et al*, 2009) or Rothermel (1972), and the code design is such as it is very easily expandable with a minimum of coding, as one file is necessary (presented in Figure 5).

3.3. Adding new models

Adding a velocity model is simply done by adding a C++ file that define the “getSpeed” function, a name, and a constructor to specify the required parameters.

```
1  namespace libforefire {
2  /* model name */
3  const string ParametricROS::name = "WindSlope";
4  ParametricROS::ParametricROS(const int & mindex, DataBroker* db)
5          : PropagationModel(mindex, db) {
6      /* Locally interpolated values */
7      effectiveSlope = registerProperty("effectiveSlope");
8      normalWind = registerProperty("normalWind");
9      /* Global parameters */
10     windFactor = params->getDouble("WindAided.windFactor");
11     slopeFactor = params->getDouble("WindAided.slopeFactor");
12 }
13
14 /*  Velocity function */
15 double ParametricROS::getSpeed(double* localValue){
16     double speed = windFactor*localValue[normalWind]
17          + slopeFactor*(1.+localValue[effectiveSlope]);
18     if ( speed > 0. ) return speed;
19     return 0;
20 }
21 }
```

Figure 5. C++ fire velocity model

Once this file is added to the source list the model is available, callable by using the provided name (here “WindSlope”, line 3 of Figure 5). An important hidden object in ForeFire is the “DataBroker”, it is responsible to virtualize data access at the node location (here the “effectiveSlope” and the “normalWind”, both layers being a function applied on the elevation field and wind field given the node location). All data (fuel, wind, slope, flux, velocity) is in fact virtualizes as a Layer, that could be either data or a function, a Layer object has a name (eg. “effectiveSlope”) and can interpolate, compute or determine (index, table, vector, function, model) more layer types can be added and the reader is referred to the code for a complete description. The “getSpeed” function works by calling the DataBroker on each node at each activation, that will automatically compile the registered values interpolated at the node location (and with the node properties such as direction) from the different layers, in an array (“localValue”, line 15). Fluxes and diagnostic models can be added in a very similar fashion in the code.

Uses Cases

The originality of the code it its ability to be used in a variety of contexts, so the same developments (on a flux or velocity model, dataset, algorithm..) may be used to be tested in a pure analytic research mode, make its way to operations, and be compared easily with other approaches available from the same code. The open sourced code is essentially the simulation engine and bindings to other environments, there is no graphical user interface because it is intended to a research/developer community. Nevertheless, as a simulation engine, it is embedded in a system that does perform simulation for operational use, marking a clear separation between the simulation code and the user interface code. With this clear separation, any developments made in the research context can make its way to operational use in a very limited time.

Typical contexts of the code use are for research and testing purposes (using here scientific Python), operational use (used here with as a web-service) or even run in parallel embedded in a numerical

atmospheric model (Filippi et.al. 2013). Both scientific and operational use will be briefly presented here.

4.1. Simple simulation in a scientific python environment

The python interface is made with Numpy bindings, yet the interface is functional but minimalistic as it requires inputs from users to gain in usability. A sample script, performing a simulation is presented in Figure 6, only part of the code is shown to concentrate on the simulation aspects, with imports of the numpy and matplotlib libraries hidden.

```
1  ff = forefire.PLibForeFire()
2  ff.setString("propagationModel","Balbi")
3  ff.setString("fuelsTableFile","fuels.ff")
4  # Parameters for the global wind value
5  ff.setDouble("velU",0.)
6  ff.setDouble("velV",12.)
7  # Domain Definition
8  ff.execute("FireDomain[sw=(0.,0.,0.);ne=(300,300,0.);t=0.]")
9  # Adding layers
10 ff.addLayer("data","windU","velU")
11 ff.addLayer("data","windV","velV")
12 # Defining a specific fuel map
13 fuelmap = np.zeros((sizeX,sizeY,1), dtype=np.int32)
14 fuelmap[:,90:110,:] = 1
15 fuelmap[150:,90:110,:] = 3
16 ff.addIndexLayer("table","fuel",0 , 0, 0, sizeX, sizeY, 0, fuelmap)
17 ff.execute("    FireFront[t=0.]")
18 ff.execute("        FireNode[loc=(40,60,0.);vel=(-1.,-1.,0.);t=0.]")
19 ff.execute("        FireNode[loc=(40,65,0.);vel=(-1.,1.,0.);t=0.]")
20 ff.execute("        FireNode[loc=(260,65,0.);vel=(1.,1.,0.);t=0.]")
21 ff.execute("        FireNode[loc=(260,60,0.);vel=(1.,-1.,0.);t=0.]")
22 # Storing 20 fronts
23 for i in range(1,20):
24     ff.execute("goTo[t=%f]"%(i*20))
25     pathes += printToPathe( ff.execute("print[]"))
26 # Plotting the fuel map
27 CS = ax.imshow(ff.getDoubleArray("fuel"))
28 # Plotting the firelines
29 for path in pathes:
30     ax.add_patch(mpatches.PathPatch(path,edgecolor='red'))
31 plt.show()
```

Figure 6. ForeFire simulation in python

In this script a Forefire object is first created (line 1), it contains a simulation context, linked to one domain, parametrisations and data. In line 2 and 3 is defined the model and the comma separated array file that contains the fuel parameters that are relevant to the propagation model used.
The functions “addLayer” adds a parameter layer that will always return the value set in the corresponding parameter. A user defined indexLayer is then added as a numpy array (line 16). This layers contains the indices in the table (defined in the fuel file), so that all parameters linked to this indices may be passed to the velocity model, at the fire location. Finally, the simulation is initiated using the “execute” function, that calls the standards ForeFire commands, and simulation results are stored in an array (line 25).

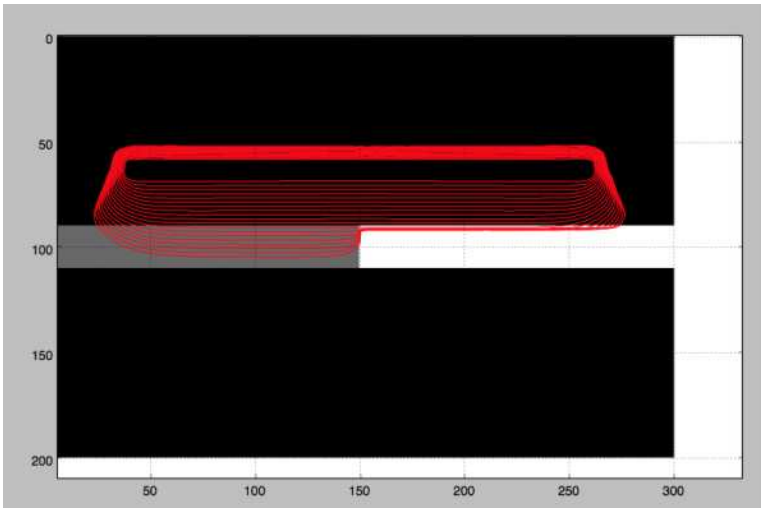

Figure 7. Output from the python script

Figure 7 presents the figure that is outputted from the script. Here MatPlotlib is used to visualize the front and fuel map using the "getLayer" function that return a numpy array.

4.2. Simulation in a operational context

Figure 8 presents a simulation results in a web application that provides a graphical user interface to easily launch simulations (available at http://forefire.univ-corse.fr/sim/dev/). This context is very different, user does not have to take time to prepare data, so everything is already available (a NetCDF file for each small region with all data layers) and the simulation is just run by using the "loadData", then "addFire", and "print" function in a loop on the server and sent back to the web browser.

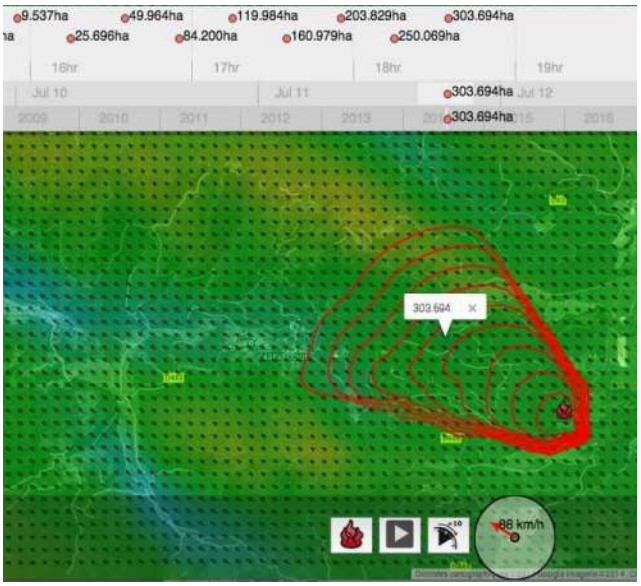

Figure 8. ForeFire in command line, launched on a server trough a web interface

Requirements and conclusion

Forefire library, python, java and command line interpreter is available on GitHub at address https://github.com/forefireAPI/firefront. The minimum requirement is to have NetCDF library

installed with legacy C++ interface. The SWIG (swig, 2014) build platform is used to automate the compilation. Target platform is a Unix compatible system with a C++ compiler available.
This paper presented the philosophy of the software as well as showing its usage in a scripted, command line and a coupled environment [Filippi *et al* 2013]. The same C++ compiled shared library is used here in a graphical user interface, a high performance computing environment and a scripted, scientific oriented environment (Python/Numpy).
The philosophy is typical of both scientific and operational software, with sources available, self compiling and expandable code but also having connections with data formats that allows to simulate real fire on existing data in a very limited time. Further work will be focused to enhance the python interface, optimize the code, add more components and interaction methods.

Forest fires effects on the atmosphere: 20 years of research in Portugal

Ana Miranda[a]; Amorim, JH[a]; Valente, J[a]; Monteiro, A[a]; Ferreira, J[a]; Borrego, C[a]

[a] *CESAM & Department of Environment and Planning, University of Aveiro, 3810-193, Aveiro, Portugal, miranda@ua.pt, amorim@ua.pt, joanavalente@ua.pt, alexandra.monteiro@ua.pt, jferreira@ua.pt; borrego@ua.pt*

Abstract
Forest fires are one of the most impressive forces of nature. Large amounts of gases and particles are emitted to the atmosphere, with significant impacts on operational safety, air quality, human health and climate change. In the European context, Portugal, together with other south European countries, has a dark record concerning forest fires, with alarming statistics, concerning occurrences, burnt areas, economic and ecological losses and human casualties.
Due to the frequency, magnitude and effects on the environment, health, economy and security, forest fires have increasingly become a major subject of concern for decision-makers, firefighters, scientists and citizens in general.
The GEMAC (Group of Emissions, Modelling and Climate Change) research team, at the University of Aveiro in Portugal, completed 20 years of experience in dealing with the effects of forest fires on the atmosphere, working on the monitoring and modelling of the impacts on the environment and human health, together with national and international teams, through the participation in numerous national and international projects. This research team has been involved in several experimental fires performed since 1998 in the GESTOSA experiments, at Serra da Lousã, Central Portugal. GEMAC has collected a large quantity of experimental data, used to support the development of new methods and models, aiming to estimate the effects of forest fires on the atmosphere. The work presented summarizes GEMAC's most relevant research in what respects the integrated and multi-scale analysis of the interrelations between forest fires and air quality, human safety and health, suppression and climate change.

Keywords*: fire emissions, air quality, smoke, health effects, visibility impairment, climate change, measurement and modelling*

Introduction

Forest fires are one of the most impressive forces of nature. A forest fire is a large-scale natural combustion process consuming various types of botanical specimen growing outdoors. Among their consequences, is the emission of various gases and solid particulate matter to the atmosphere with significant impacts on operational safety, air quality, human health and climate change.
In the European context, Portugal, together with other south European countries, has a dark record concerning forest fires, with alarming statistics, concerning occurrences, burnt areas, economic and ecological losses and human casualties.
The GEMAC (Group of Emissions, Modelling and Climate Change) research team, at the University of Aveiro in Portugal, completed 20 years of experience in dealing with the effects of forest fires on the atmosphere, working on the monitoring and modelling of the impacts on the environment and human health, together with national and international teams, through the participation in numerous national and international projects. The work here presented summarizes its most relevant research in what respects forest fires atmospheric emissions and its impact on air quality, human exposure and climate change.

Emissions

Smoke from forest fires includes important amounts of carbon dioxide (CO_2), carbon monoxide (CO), methane (CH_4), nitrogen oxides (NOx), ammonia, particulate matter (PM), non-methane hydrocarbon (NMHC) and other chemical compounds. These air pollutants can cause serious consequences to local and regional air quality. Therefore it is essential to understand and establish the relationship between emissions and air quality. The characterization of forest fire emissions is based on two different, but complimentary approaches: direct measurements and estimation of emissions based on emission factors. Miranda *et al.* (2005) measured, among other gases and particulate matter, volatile organic compounds (VOC) emissions in the flaming and smouldering phase of an experimental fire, verifying that despite the small size of the burning plots when compared to wildfires, the measured levels of pollutants were considerable, indicating the effect of these experiments on the local air quality and stressing the serious levels of air pollution that can be expected during wildfires. Moreover, emission measurements have been done in laboratory and during experimental field fires aiming to evaluate the impact of the use of fire retardants, concluding that in that specific case, though the production of smoke is increased by the application of retardants, the extension of the fire (both in area burned and in duration) is reduced, thus contributing to a decrease of the total smoke emissions (Amorim *et al.*, 2010).
Although there is an extensive body of literature on emission factors from forest fires, there are not many works that reflect the specificity of Southern European countries. Miranda (2004) performed and presented a selection of emission factors for South-European forest. This review and summarizing work was further updated and expanded, taking into account more recent works and additional pollutants (Ana I Miranda *et al.*, 2009). The GEMAC team has an extensive work on the estimation of pollutants emissions using emission factors (see e.g. Martins *et al.* 2012, **Erro! A origem da referência não foi encontrada.**1).

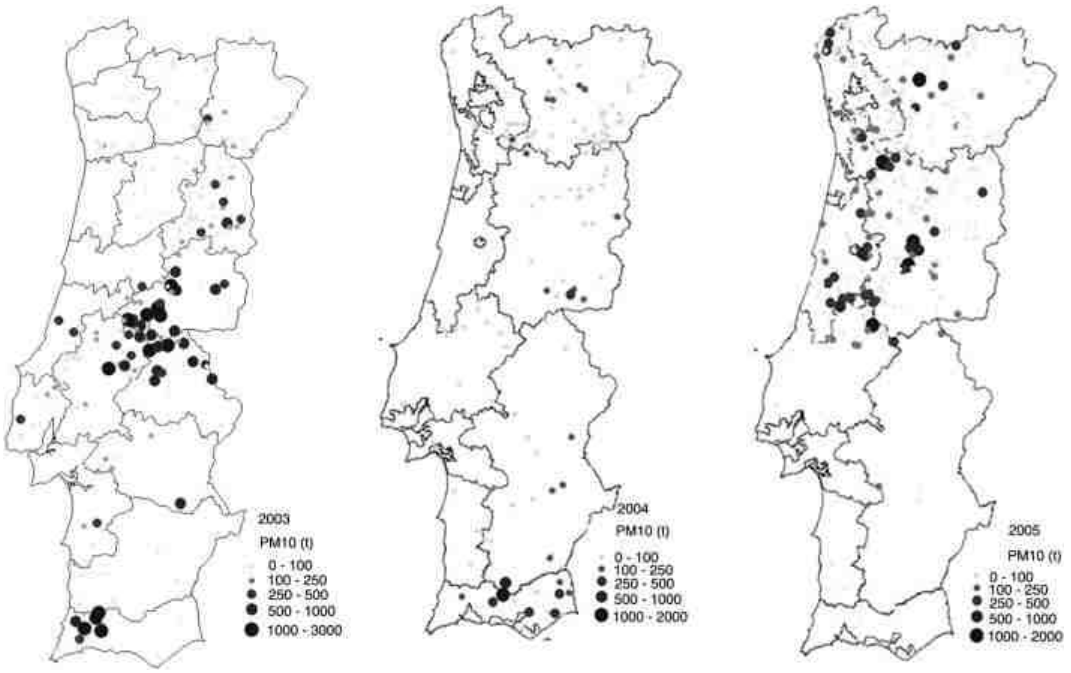

Figure 1. PM10 forest fire emissions spatial distribution for 2003–2005 fire seasons in Portugal (only large forest fires were considered (Martins et al., 2012).

Erro! A origem da referência não foi encontrada.1 shows the spatial distribution of forest fire PM10 emissions for 2003, 2004 and 2005 estimated for air quality modelling purposes. A comparison

between the estimated forest fire emission values and values reported by other available inventories is shown in Table 1, which presents the total forest fire emissions for Portugal (2003–2005) for CO_2, CO, CH_4, NMHC, PM2.5, PM10, total particulate matter (TPM) and NOx, based on three different inventories: the aforementioned Portuguese inventory, the Global Fire Emissions Database (GFED) inventory (Van Der Werf *et al*., 2010), and the European Forest Fire Information System (EFFIS) inventory (San-Miguel-Ayanz, J. Steinbrecher, 2009).

Table 1- Total forest fire emissions (t) in Portugal for 2003, 2004 and 2005 fire seasons based on different methodologies (Martins et al., 2012.).

Source	Forest fire emissions (t)							
Year	CO_2	CO	CH_4	NMHC	PM2.5	PM10	TPM	NO_x
2003								
Portuguese inventory	6,842,000	456,000	26,000	32,000	26,000	53,000	-	21,000
GFED	8,000,000	500,000	70,000	30,000	20,000	-	140,000	14,000
EFFIS	10,510,119	411,945	21,475	17,834	41,406	48,913	68,749	28,745
2004								
Portuguese inventory	2,096,000	137,000	8000	10,000	14,000	16,000	-	7000
GFED	3,000,000	200,000	20,000	10,000	10,000	-	50,000	5000
EFFIS	3,312,543	129,112	6735	5599	13,001	15,361	21,597	9013
2005								
Portuguese inventory	3,470,000	230,000	13,000	16,000	24,000	27,000	-	11,000
GFED	14,000,000	800,000	120,000	50,000	40,000	-	250,000	25,000
EFFIS	7,866,267	325,628	16,843	13,833	32,206	38,034	53,180	22,719

- Not available.

In general, the emission data presents the same order of magnitude, but in some cases it is possible to verify a larger difference, namely: for CH_4 in 2004 and 2005 in the GFED inventory; for NMHC in EFFIS inventory in 2004; for TPM for both GFED and EFFIS inventories. The differences were in some way expected because different methodologies were applied.

The GEAMC team is exploring new methodologies for the estimation of forest fire emissions, based on space borne data and on the fuelbed concept. Currently, large use is made of detailed space borne data to help reduce emissions estimation uncertainties, as shown by a recent comparison exercise at global scale (Jain, 2007; Stroppiana, Grégoire, & Pereira, 2003). In order to reduce these uncertainties, and because real-time information is now increasingly needed for operational use in rapid fire damage assessment, an operational fire emission model has been recently developed at regional/European scale in the European Forest Fire Information System (EFFIS) (San-Miguel-Ayanz, Schulte, Schmuck, & Camia, 2013). This system was applied and tested for a forest fire case study occurred in Portugal on 14th October 2011 (with a total of 4400 ha of burnt area), using detailed fuel maps and sequential mapping of the fire evolution on the basis of satellite imagery (Monteiro *et al*., 2014). In order to evaluate the relevance/importance of these forest fire emissions, they were compared with the anthropogenic emissions estimated for a typical week day over that area (Table 2). The anthropogenic emissions include all Selected Nomenclature for Air Pollution (SNAP) activities like industrial and residential combustion, production processes, solvents use, transports, waste treatment and agriculture, and were compiled using the national emission report developed on an annual basis by the Portuguese Agency for the Environment (Monteiro *et al*., 2007).

Table 2- Anthropogenic emissions (annually) estimated for the study area and the corresponding burnt area calculated by the EFFIS emission model to the study fire event (October 14, 2011) (Monteiro et al., 2014).

Emissions (ton)	CO	VOC	NH_3	NOx	PM10	SO_2
Anthropogenic (annual basis)	660	284	303	373	86	12
Forest fires (EFFIS model)	230000	15000	2000	15000	27000	2500
% anthropogenic/total	0.3	1.9	13.2	2.4	0.3	0.5

As observed from Table 2, the quantity of pollutants emitted by the forest fire event, corresponds to more than 90% of the total annual emissions over the study region. In the case of CO and PM10, forest

fire emissions are three orders of magnitude larger than the total annual emissions by all anthropogenic activities. These high values of forest fires emissions are, in part, explained by the rural characteristics of the study municipality. In this type of rural areas forest fire emissions can be the most important and relevant source of air pollution.
Although air pollutants released from forest fires depend on a number of factors (area burned, fuel loading, fuel consumption, and pollutant-specific emission factors), two factors alone – fuel loading and fuel consumption – account for up to 80% of the error on smoke emissions estimation (Ottmar, Miranda, & Sandberg, 2008). GEMAC is contributing to a higher accuracy of smoke emission estimates for Mediterranean Climate Areas (MCA) by using the Fuel Characteristic Classification System (FCCS) (Ottmar, Sandberg, Riccardi, & Prichard, 2007), to build fuelbeds for Portugal. The FCCS fuelbeds capture the structural complexity, geographic diversity and potential flammability of a fuelbed, encompassing all fuelbed components that have the potential to burn including trees, shrubs, grasses, woody material, litter, and duff. The FCCS evaluates fuelbed hazard by calculating fire potentials, reaction intensity, flame length, and rate of spread. Typical Portuguese fuelbeds were identified and built using the National Forest Inventory, other fuels datasets, published scientific literature, and fuel photo series. The mapping of the defined fuelbeds using vegetation classification and quantitative vegetation data is under development.

Air Quality Monitoring and Modelling

The gases and particles emitted during a forest fire undergo chemical transformations in the atmosphere as they are being dispersed, and its impacts can be found at long distances from the source. Despite current evidence, the connection between forest fires and air quality is still an ongoing topic, that only during the last decade started to be more frequently addressed. For the fire community, the main concern consisted in its direct effects, such as human fatalities and material damage. On the other hand, the air quality community was mainly focused on anthropogenic sources of pollutants, particularly in traditional sectors of industry and road traffic.
To evaluate the effects of forest fires on air quality both measurements and numerical models can be used. The research team has been involved in several experimental fires performed since 1998 in Serra da Lousã, Central Portugal, the GESTOSA experiments, collecting a large quantity of experimental data (e.g. Miranda 2004, Miranda *et al.* 2005; Valente *et al.* 2007), used to support the development of new methods and models. Figure 2 shows some of the equipment used to measure air pollutant concentrations during GESTOSA experimental fires.

Figure 2- Photo of van nr. 2 and its air quality equipment. Photo of passive samplers.

The GEMAC team has developed numerical models, AIRFIRE (A I Miranda, 2004) and DISPERFIRESTATION (Valente *et al.*, 2007), that are able to simulate the effects of fire emissions on air quality, at different scales. DISPERFIRESTATION is a fire behavior system, developed to estimate fire progression, smoke dispersion and visibility impairment, at local scale, while AIRFIRE is a numerical system, developed to estimate the effects of forest fires on air quality, at the mesoscale, integrating several components, namely the meteorological model MEMO, the photochemical model

MARS and the Rothermel fire spread model. These modelling tools have been applied to various case studies in Portugal, showing that concentrations of pollutants attain levels of concern (e.g. Miranda, 2004; and Valente *et al*., 2007). Figure 3 depicts an output of the DISPERFIRESTATION system, a PM10 concentration field resulting from a burning plot in a GESTOSA experiment, and an AIRFIRE output, showing a vertical profile of wind and CO concentrations.

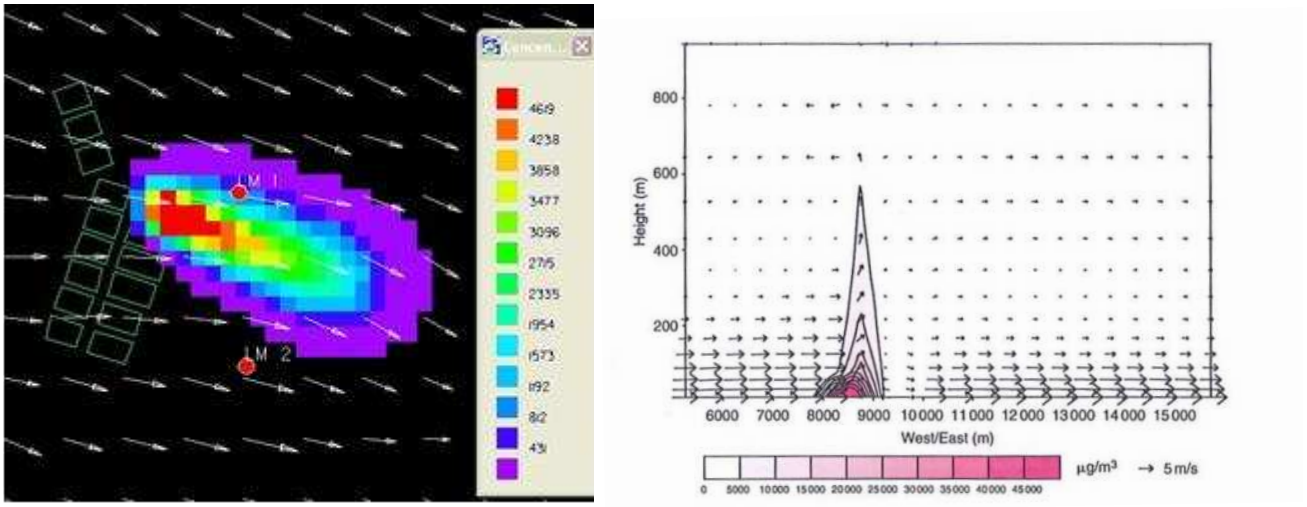

Figure 3. (left) PM10 concentration fields (µg.m^{-3}), at ground level, after the burn of three plots (400m x 330m) at GESTOSA 2004 experiments (Valente et al., 2007). (right) Vertical profile of wind and CO concentration in a forest fire in Arrábida (Portugal)(A I Miranda, 2004) .

At the local scale the effect of fire as a heat source is not considered in DISPERFIRESTATION, but AIRFIRE includes this effect in the simulations.

The GEMAC team also worked on the modelling of wildland urban interface fires. Miranda, Marchi, *et al*. (2009) simulated the temporal evolution of the hourly averaged PM10 concentration fields during September 13, 2003. **Erro! A origem da referência não foi encontrada.**4 shows the surface hourly averaged PM10 concentration patterns for 22.00 LST as estimated by AIRFIRE. There is an obvious contribution by forest fires to the particularly high levels of PM10 measured in the urban area of Lisbon at night.

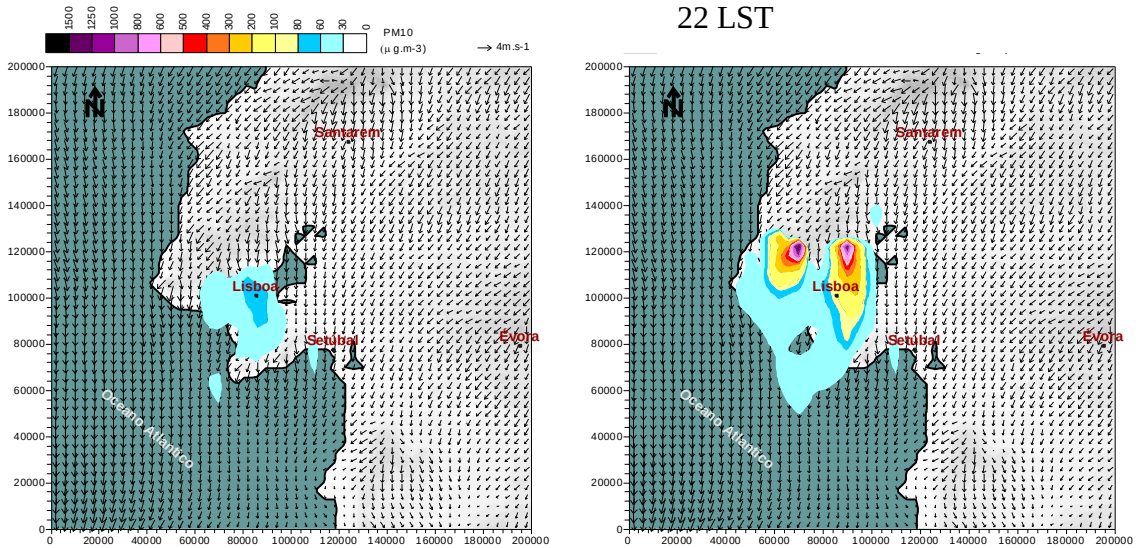

Figure 4. Hourly-averaged surface PM10 concentration (μg m^{-3}) and wind values at 22.00 LST, excluding forest fire emissions(left) and including forest fire emissions (right).

At a larger scale the contribution of 2006 western Russia wildfires, during spring, to the air quality impairment over Europe was evaluated too (A.I Miranda, Sá, Martins, Borrego, & Sofiev, 2010). **Erro! A origem da referência não foi encontrada.**5 presents simulation and measurement results of the PM10 hourly midday spatial distribution for one of the simulation days.

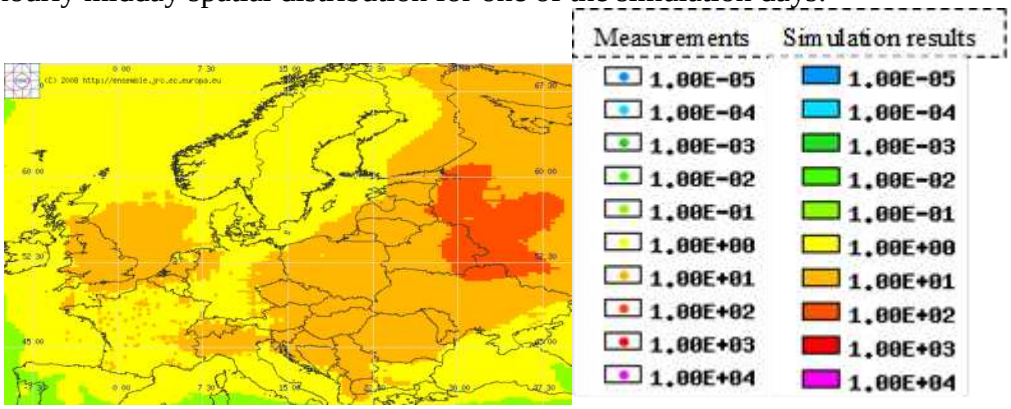

Figure 5. Spatial distribution of PM10 hourly midday concentration values (μg.m^{-3}) May 4 (A.I Miranda et al., 2010).

This simulation of the 2006 spring fires over Europe allowed confirming the transboundary characteristics of wildland fires, clearly showing the impact of fires spreading over Russia in several European countries. The evaluation of the impact of wildfires on the air quality should be included in air quality assessment procedures at the European level, and air quality modelling systems can be important tools to achieve this goal.

Safety

Wildland firefighting implies many hazards to firefighters, including burns, heat stress, tripping and falling hazards, and inhalation exposure to smoke. Personal monitoring is a reliable way of estimating the exposure of an individual to a specific air pollutant. It assesses an individuals' inhalation exposure based on the measurement of a pollutant concentration within a person's breathing zone for a defined time.

Recently, exposure studies were conducted in Portugal to determine firefighter's individual exposure to smoke, using for that purpose personnel sampling devices to monitor CO, VOC, and nitrogen dioxide (NO_2) and a GPS instrument to track their position on site (A. I. Miranda *et al*., 2010; Ana Isabel Miranda *et al*., 2012). The measurement of firefighters individual exposure to smoke was conducted in 2008 and 2009: (i) in Gestosa fire experiments, in Central Portugal, at the end of the spring season; and (ii) during the fire season (May to October) in Central Portugal. Data on individual exposure to CO, PM2.5 and NO_2 were measured for a group of ten firefighters equipped with portable measuring devices.

The selection of monitoring equipment was based on toughness, weight, possibility of continuous data acquisition, and ease of operation. Table 3 presents the main characteristics of the equipment used in the exposure monitoring.

Table 3- Characteristics of the equipment.

Pollutant	Type of data	Equipment	Characteristics	
			Range	Resolution
NO_2	Continuous measurement: 5 seconds interval	GasAlertMicro 5 PID from BW Technologies	0-99.9 ppm	0.1 ppm
CO	Continuous measurement: 5 seconds interval	GasAlertMicroClip from BW Technologies	0-500 ppm	0.1 ppm
		GasAlertextreme from BW Technologies	0-1,000 ppm	1 ppm
PM2.5	Continuous measurement: 1 minute interval	Personal Aerosol Monitor SidePack AM510 from TSI	0-20 $mg.m^{-3}$	0.001 $mg.m^{-3}$

Exposure results were compared to the occupational exposure standards (OES) defined for different air pollutants. According to the American Conference of Governmental Industrial Hygienists (ACGHI), OES are presented as the:

- threshold limit value (TLV) of the time-weighted average (TWA);
- TLV of the short-term exposure limit (STEL); and
- peak limit.

The TWA is calculated over a normal 8-hours working day and a five days working week. The TLV-STEL corresponds to a 15-minutes time-weighted average exposure that should not be exceeded at any time during a workday, even if the 8-hours TWA is under the TLV. The TLV-STEL is the highest concentration to which it is believed that workers can be exposed continuously for a short period of time without suffering effects. **Erro! A origem da referência não foi encontrada.**4 presents the OES values for the different air pollutants analysed under this study.

Table 4. OES limit values for different air pollutants contained in biomass burning smoke. For some VOC these values are not available (n.a.) in National or International regulations.

Air pollutant	TLV-TWA	Reference	TLV-STEL	Reference	Peak Limit	Reference
CO	25 ppm	NP 1796:2007	200 ppm	Australian legislation	400 ppm	Australian legislation
NO_2	3 ppm		5 ppm	NP 1796:2007	20 ppm	NIOSH
Respirable particles without other classification	3 $mg.m^{-3}$	NP 1796:2007	n.a.	n.a.	n.a.	n.a.

Most firefighters use a bandana for respiratory protection, nevertheless, according to (Reh, Letts, & Deitchman, 1994) the pore size of this type of bandanas is approximately 200 μm x 200 μm, roughly

500 to 2000 times larger than the smaller smoke particles (0.100-0.400 μm), and consequently, gases and fine particulate matter can pass through the fabric.
Several exceedances to the OES values for CO were observed (maximum registered was 1000 ppm which is the equipment upper detection limit), meaning that firefighters are exposed to levels higher than the allowed limits of current legislation. NO_2 values are within the OES, except for some peak values exceedances (maximum registered was 33 ppm). Measured PM2.5 is within the OES, however, it should be noted that the OES is much higher than the standard defined by the World Health Organization for air quality.

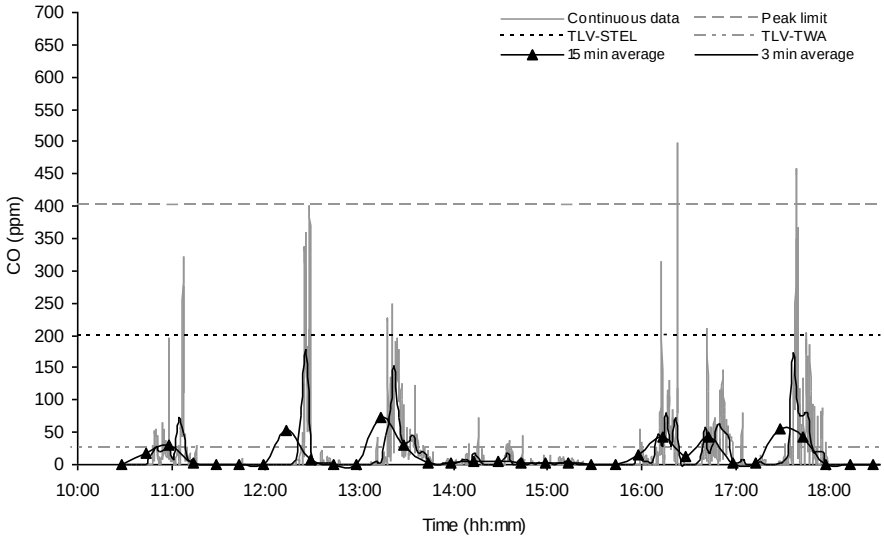

Figure 6. CO concentrations (ppm) measured for one of the firefighters during an experimental fire in GESTOSA.

This data (**Erro! A origem da referência não foi encontrada.**6) shows the magnitude of the exposure peaks that occurred during regular firefighting operations, indicating that the firefighters are exposed to CO concentrations that pose their health and safety at risk and diminish their capability of taking decisions in emergency situations.
Medical tests conducted on the firefighters also indicate a considerable effect on measured medical parameters, with a large increase of CO and a decrease of NO in the exhaled air of majority of the firefighters (Ana Isabel Miranda *et al*., 2012).
Visibility reduction and air quality degradation are a common consequence of biomass burning and a recurring problem in almost every parts of the world. It may lead to a pronounced diminishing of safety conditions during firefighting operations and terrestrial and aerial traffic, even in small scale experimental fires. Valente *et al.* (2007) developed and integrated in a smoke dispersion model, a specific module to calculate the visibility impairment caused by forest fire pollutants emissions, based on its concentrations in the atmosphere.

Suppression

GEMAC's work on fire suppression has been focused on both aerial and ground-based operations. These two lines of research share the objective of optimizing the efficiency of operations while guaranteeing the safety of personnel and civilians in the affected fire zones.
The efficiency of the aerial drop of firefighting agents (water and retardants) using airplanes or helicopters is highly conditioned by local atmospheric conditions (e.g., wind intensity, wind gusts, air turbulence, fire intensity, visibility), together with flight parameters (e.g., altitude, speed, route) and pilot perception. Despite these, and contrarily to commercial aviation, on-board systems for computer-

assisted drops have not yet been used operationally. Aiming to provide an enhanced understanding of the behaviour of aerially delivered firefighting liquids and the factors that influence the overall suppression effectiveness, Amorim (2011a, 2011b) developed the Aerial Drop Model ADM, for water and chemical retardant applications, that can potentially be used in training activities with firefighters; or in testing the effectiveness of new firefighting chemicals or delivery systems, complementing the data obtained from real scale drop tests. This numerical tool allows a near real-time simulation of aerial drops with fixed-wing aircraft, while covering the fundamental stages of the process. It copes with a wide range of product viscosities, from water to highly thickened long-term retardants. **Erro! A origem da referência não foi encontrada.**7 presents a result of a retardant cloud drop as simulated by ADM.

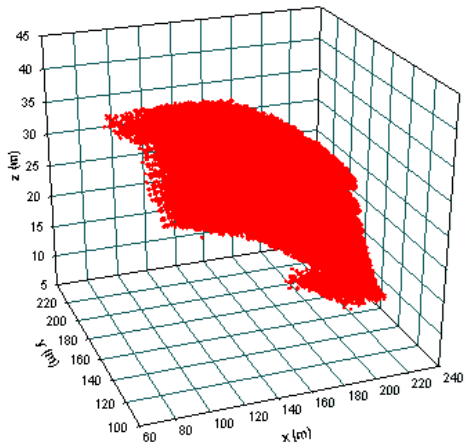

Figure 7. ADM simulation of a 3D retardant cloud, 3s after release initiation.

ADM was validated against experimental data acquired in a large number of real-scale drop tests carried out in Europe and in the United States of America. In general, the model produced a good representation of the spatial distribution of the agent in the ground for various coverage levels and its accuracy was, in fact, within the statistical uncertainty of the experimental sampling method.

On an operational basis too, GEMAC team is currently working on the development of a firefighting Decision Support System, that will combine the monitoring and forecast of smoke exposure, to help decision making in an operational scenario. The goal of this research is to develop an emergency response support system for firefighting ground-based operations during forest fire events. The target of the under-development computational tool is to provide knowledge-based aid to firefighters at critical decision-making situations, helping with the safe and successful management of fire. This DSS will support the following features:

- capture of 'live' sensor data from a set of wearable monitoring equipment that will be based on a previously developed certified medical wearable technology named "VitalJacket®";
- capture of meteorological observations from a mast placed in one of the vehicles;
- enable projections of fire progression, smoke levels and critical exposure in a predefined time-step (up to 30 minutes);
- interpretation of results in an easy and intuitive form to be used by fire managers or firefighters involved in operations.

To achieve this goal hardware technology (e.g. wearable, mobile, communications) was combined with processing/simulation software algorithms and user interactive interfaces. A data assimilation technique will allow near real-time observations from wearable monitoring equipment to be integrated into the exposure forecast modelling system, increasing the accuracy of the estimates.

A first prototype of the DSS, running in off-line mode, will be tested in the terrain during the fire season of 2014. An improved online version of the prototype will be tested in the following autumn in a series of prescribed burns.
In conclusion, this work proposes the development and testing (under real conditions) of a DSS intended to provide optimized firefighting efficiency, enhanced hazard awareness, and knowledge-based response to forest fire events. Advances in the computational modelling of fire and smoke behaviour, in conjunction with personal monitoring data, provide near real-time simulation of local fire conditions and short-term smoke exposure forecasts, with the needed advance in time to permit the safe and efficient positioning of crews in the terrain.

Climate change

Greenhouse gases emissions by forest fires can have an important contribution in climate change (A. I. Miranda, Coutinho, & Borrego, 1994). Forest fire activity and air quality under a changing climate are considered one of the main threats to sustainable development. Carvalho *et al.* (2008a, 2010) investigated the impact of future climate change on fire activity across Portugal, assessing the fire weather and subsequent fire activity under a $2 \times CO_2$ scenario and studying the relationship between the weather, the Fire Weather Index (FWI) System components, and both the area burned and fire occurrence across Portugal. Temperature was predicted to increase and precipitation to decrease, resulting in an increased FWI in all areas studied along with more severe and longer fire seasons. Future fire activity will increase dramatically across the entire country, with area burned and fire occurrence both rising substantially.
Air quality modelling results for Portugal (A. Carvalho *et al*., 2011) pointed out that future forest fire activity will increase the ozone concentration levels by almost 23 $\mu g\ m^{-3}$ by 2100 but a decrease of approximately 6 $\mu g\ m^{-3}$ is expected close to the main forest fire locations. Future forest fire emissions will also impact the PM10 concentrations over Portugal with increases reaching 20 $\mu g\ m^{-3}$ along the Northern coastal region in July. The highest increases are estimated over the north and centre of Portugal where the area burned projections in future climate are higher.

Final Remarks

Due to the frequency of occurrence and the magnitude of forest fires, and also to their effects on the environment, health, economy and security, they have increasingly become a major subject of concern for decision-makers, firefighters, scientists and citizens in general, in many regions of the world, including the southern European countries.
Experimental field fires represent a valuable tool for understanding wildfires in all its extension: behaviour, impacts on environment, security conditions and health, suppression techniques efficiency, among others.
The application of numerical emissions and air quality modelling systems is also an added value when evaluating and assessing air quality levels in areas affected by forest fires. Environmental policies, in particular the south-European ones must integrate both the traditional air pollution-oriented and the forested-land management issues into a unique system. Better forested-land management can help to reduce both the number of air pollution episodes and the risk of unwanted fires.
Wildland firefighting implies many hazards to the population in general, but also for firefighters, including burns, heat stress, tripping and falling hazards, and inhalation exposure to smoke. The development of monitoring solutions and solid science based DSS is of paramount importance both for fire management, but also for the personal safety of operational personnel.
These predicted increases in fire activity in a changing climate will have environmental, social, and economic impacts and would dramatically impact the organizational structures that deal with wildland fire and also society in general.

Abstract
A series of experimental fires were conducted to investigate the effect of ground-fuel structure and fuel moisture content in controlling fire severity in a *Calluna vulgaris* dominated environment. Their influence on fire-induced temperature pulses into the soil (peat) was quantified. The effect of fire-related changes in fuel structure on peat microclimate was also examined. We found the moss and litter (M/L) layer to be important in insulating peat from fire-induced temperature pulses, especially at the peat surface. We recorded higher fire-induced peat temperatures and residence times in microplots where a drought had been simulated, with climatic conditions playing a key role. The removal of the heather canopy due to burning and the change in structure of the M/L layer were found to similarly increase both peat daily temperature fluctuation and peat mean temperature.

Keywords*: Calluna vulgaris, drought, fire severity, FMC, litter, moss, peat*

Introduction

Peatlands in high-latitude regions represent a large soil carbon reservoir, and their degradation could have important implications for the climate – ecosystem feedback governed by the carbon cycle (Heimann & Reichstein 2008). As summer droughts in northern regions are projected to intensify due to climate change (IPCC 2013), thus laying the foundations for more severe fires, it is necessary to understand the key mechanisms controlling fire effects on peatlands.
Peat deposits in the U.K. are usually covered by a mixture of mosses and dead shrub foliage a few cm deep. The moisture content of these ground fuel layers respond quickly to weather conditions. The M/L layer is thought to be important in insulating peat from temperature pulses, and possibly ignition, during the passage of a flaming fire-front. The structure of the M/L layer may therefore be a critical factor in keeping fire severity low despite high fire intensity. Drought conditions may lower the moisture content of the M/L layer below its flammability threshold (Davies and Legg 2010), leading to a step change in fire behaviour and fire severity that threatens carbon stores through peat combustion, altered soil respiration or post-fire degradation. We currently have no quantitative evidence demonstrating the extent to which peat is heated or scorched during burning and how the M/L layer mitigates the effects of the fire, both in terms of temperature penetration during burning and post-fire peat microclimate.
We hypothesise that the M/L layer is a key mechanism in controlling fire behaviour and fire severity. To investigate this we conducted a series of experimental fires in Glen Tanar (Aberdeenshire, Scotland, UK), in a heather (*Calluna vulgaris* (L.) Hull) dominated moorland where prescribed burning has traditionally been used to improve habitat for red grouse (*Lagopus lagopus scoticus*), and in Braehead Moss (South Lanarkshire, Scotland), a Special Site of Scientific Interest (SSSI) designated raised bog.

Methods

Ground fuel structure and below-ground temperature penetration

To examine the role of the M/L layer in temperature penetration a series of experimental fires were completed where the M/L layer was manipulated. The M/L layer was either left untouched, removed after the fire, or removed before the fire in 1 x 1 m microplots. Control microplots where set up outside the fire area. This allowed us to separate the relative importance for peat microclimate of the M/L layer, the heather canopy and scorching of the peat surface during the fire. A total of seven experimental fires ignited as head fires were completed in Glen Tanar, with two replicate microplots of each treatment per fire. To study temperature penetration during the fire, two Hobo^{TM} loggers connected to a K-type twisted pair thermocouple were buried at the peat surface and two cm below in each microplot. The loggers were retrieved after 35 min of the start of the fire. As for changes in peat microclimate, long-term peat temperature were recorded two cm below the top of the peat in one microplot per treatment in each fire using an iButton^{TM} temperature logger (0.5°C accuracy, 2h logging interval). Peat microclimate was recorded from April 2013 to April 2014.

The effect of drought on ground fuel moisture content, flammability and fire severity

To investigate the extent to which M/L layer moisture content and flammability controls variation in fire severity, summer drought was simulated in 2 m x 2 m microplots using rain-out shelters (Figure 1). Ten experimental fires were completed in Glen Tanar and another ten in Braehead Moss between September 2013 and September 2014. Each fire comprised two drought-treated microplots and two untreated microplots. Measurements included: fuel load and structure assessment following the FuelRule method (Davies *et al*. 2008), pre-fire peat, M/L layer, live heather and dead heather fuel moisture content (FMC), moss depth above the thermocouple, fire-induced below-ground temperature pulses, weather conditions and moss consumption.

Figure 1. Rain-out shelter (left) and post-fire ground fuel smouldering limited to treated microplots (right)

Results

Ground fuel structure and below-ground temperature penetration

A substantial increase in peat temperature residence (in °C s) was observed at the peat surface in microplots where the M/L layer had been removed: microplots where the M/L layer hadn't been removed presented an average 7800 °C s (SD = 7000, n = 28) while microplots where the M/L layer had been removed had an average temperature residence of 19000 °C s (SD = 11100, n = 14). Effects

2 cm below the top of the peat were less evident although still substantial (Figure 2). Average temperature residence values were 1900 °C s (SD = 2300, n = 26) in microplots where the M/L layer were present at the time of the fire, and 3900 (SD = 3900, n = 12) in microplots where the M/L layer had been removed.

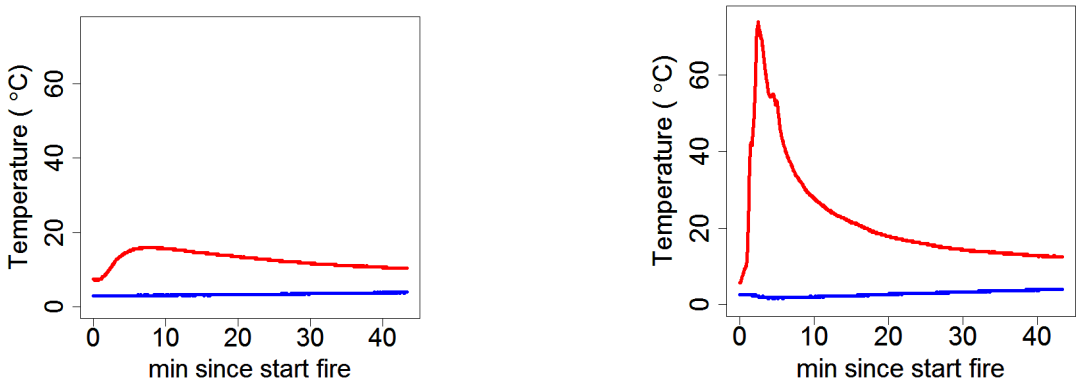

Figure 2. Temperature-time curves during a fire from a microplot with (left) and without (right) the moss and litter layer. Red and blue lines indicate temperatures measured at the top of the peat and 2cm below, respectively.

The peat microclimate data showed that burnt microplots presented higher below-ground daily temperature fluctuations than control microplots. Diurnal fluctuations were further increased in microplots where the M/L layer had been removed (Figure 3). A provisional seasonal linear model was fitted to the data and it was found that mean daily temperature was higher in burnt and burnt and M/L layer removed microplots in spring and summer but the opposite was true in autumn and winter (Figure 4).

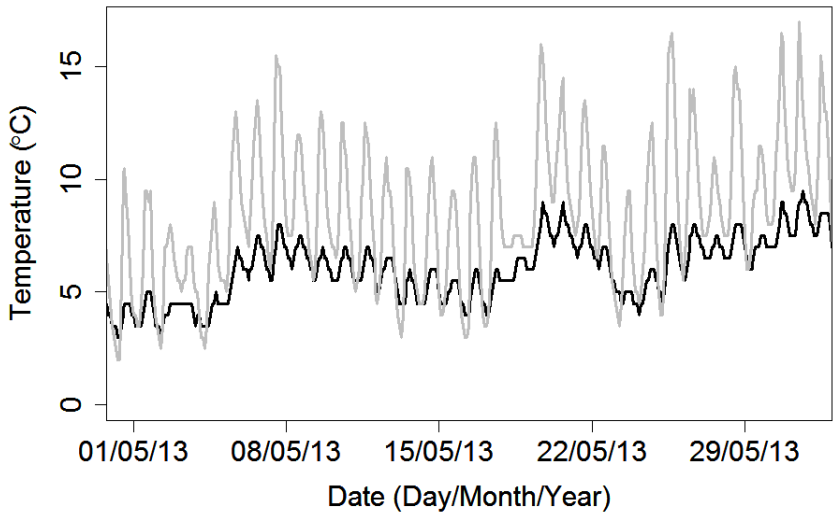

Figure 3. Post-fire peat micro-climate at 2cm depth in a control microplot (black line) and in a burnt microplot where the M/L had been removed (grey line).

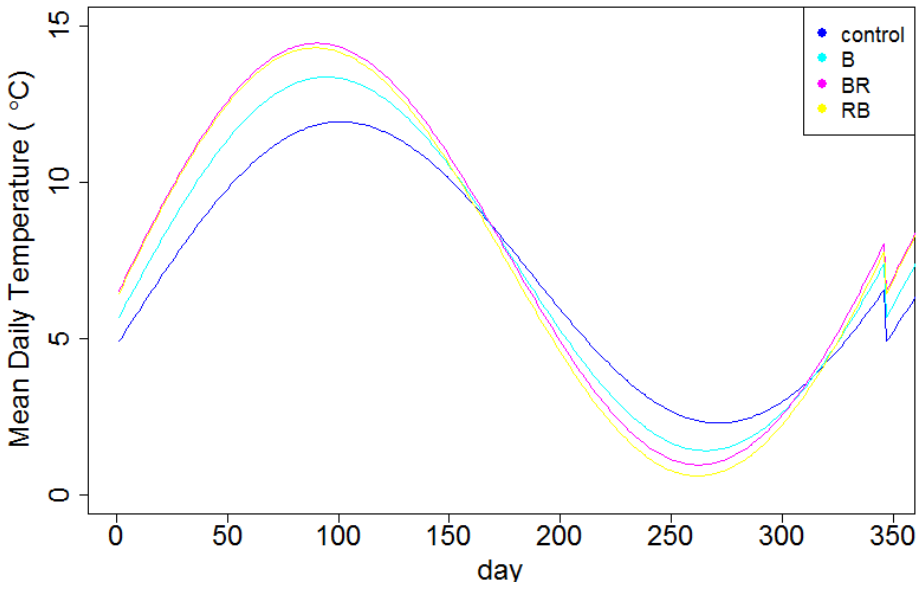

Figure 4. Predicted mean peat temperature values of the seasonal model for the four different treatments. Sampling started in April 2013 and finished in April 2014. "control", unburnt microplots; "B", burnt microplots; "BR", burnt microplots where the M/L layer was removed after the fire; "RB", burnt microplots where the M/L layer was removed before the fire.

The effect of drought on ground fuel moisture content, flammability and fire severity

Rain-out shelters reduced the FMC of the M/L layer in dry heath from an average of 304% in dry base (SD = 186, n = 16) to 124% (SD = 75%, n = 16). Average M/L layer consumption was 0.7 cm (SD = 1.6, n = 16) in control microplots and 2.4 (SD = 2.4, n = 16) in drought microplots. Microplots burnt under simulated summer drought conditions showed higher temperature residence times than untreated microplots at both the peat surface and at a depth of 2 cm (Figure 5).

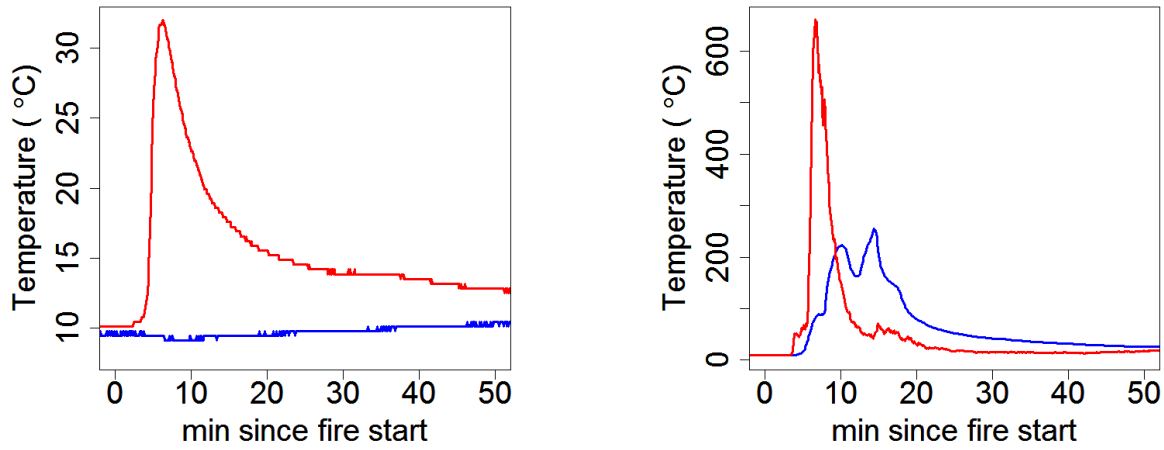

Figure 5. Temperature-time curves during a fire from a control microplot (left) and a drought microplot (right). Red and blue lines indicate temperatures measured at the top of the peat and 2cm below, respectively.

Conclusions

Our results show that the M/L layer has a critical ecosystem function by preventing peat from being exposed to significant temperature pulses during burning. The change in fire severity associated with

a decrease in the moisture content of the M/L layer under drought conditions could have important implications for peat carbon dynamics and post-fire vegetation regeneration. Variation in fire severity can also drive changes in belowground micro-climate with potentially important implications for soil ecosystem function. On-going work is examining how this variation in fire severity and post-fire microclimate affects carbon fluxes following burning.

High resolution spatial and temporal variability of fine dead fuel moisture content in complex terrain

[a]*The Department of Forest and Ecosystem Science, The University of Melbourne, Parkville 3010, Melbourne, Australia, sheridan@unimelb.edu.au*

Abstract

The moisture content of fine dead fuel plays an important role in forest fire behaviour, affecting the probability of ignition at the fire front, the probability of night-time extinguishment, and the availability of the depth of fine fuel for burning. A recent review of dead fuel moisture research by Matthews (2014) concluded that one of the key research and modeling needs is the capacity to represent the complexity of vegetation structure and topography and forecast fuel moisture content across the landscape. Fine fuel moisture content varies at a range of spatial scales due to many factors, however in complex, steep and dissected landscapes, topographic aspect can play a significant role in small-scale (ie. scales in the order of 10's ha) variability.

Experimental sites for monitoring microclimate variables and moisture content in litter and in near-surface soils were established at a control site and on four contrasting aspects (north, south, east and west) in southeast Australia. At each of the four microclimate sites sensors are arranged to measure the soil moisture (2 replicates), fine dead surface fuel moisture at 2.5cm depth (12 replicates), precipitation throughfall (3 replicates), radiation (3 replicates), and screen level relative humidity, air temperature, leaf wetness, and wind speed (1 replicate of each). Temperature and relative humidity are also measured within the dead fine surface fuel using Ibutton's (4 replicates).

All measurements are logged continuously at 15 min intervals. The moisture content of the fine dead surface fuel is estimated using high-replication of low-cost continuous soil moisture sensors placed at the centre of a 5cm deep sample of fine dead surface fuel, referred to here as "dead fine fuel packs" . The dead fine fuel packs were constructed from fuels collected from the area surrounding the microclimate site. The initial results show the moisture regime on the forest floor was highly sensitive to the incoming shortwave radiation, which was up to 6 times higher in the north-facing (equatorial) slopes due to slope orientation and the sparse vegetation compared to vegetation on the south-facing (polar facing) slopes. Differences in shortwave radiation resulted in peak temperatures within the litter that were up to 2 times higher on the equatorial-facing site than those on the polar-facing site. For instance, on a day in November 2013 with maximum open air temperature of 35o C, the temperatures within the litter layer at the north-facing and south-facing sites were 54o C and 32o C, respectively, despite air temperature at the two sites differing by less than 2o C. The minimum gravimetric water content in the litter layer on the same day was 21% on the equatorial-facing slope and 85% on the polar-facing slope. The experimental data is being used to calibrate and test models of fuel moisture spatial variability against an independently collected gravimetric fuel moisture dataset.

Keywords*: aspect, litter, wildfire,*

Introduction

The moisture content of fine dead fuel plays an important role in forest fire behaviour, affecting the probability of ignition at the fire front, the probability of night-time extinguishment, and the availability of the depth of fine fuel for burning. A recent review of dead fuel moisture research by Matthews (2014) concluded that one of the key research and modeling needs is the capacity to represent the complexity of vegetation structure and topography and forecast FMC across the landscape.

Fine fuel moisture content varies at a range of spatial scales due to many factors, however in complex, steep and dissected landscapes, slope orientation (aspect and slope) can play a significant role in small-

scale (ie. in the order of 10's ha) variability. This is because ddifferent topographic positions are often associated with different soils, soil moisture conditions, and forest structure. Forest canopies create distinct understory micro-climates (Geiger 1995, Lee 1978, Oke 1987, Mc- Caughey *et al*. 1997, Grimmond *et al*. 2000). Below the forest canopy, solar radiation and day-time temperature and wind speed is reduced, while humidity is increased. All these factors affect the dead fine fuel moisture content and therefore spatial patterns of fuel moisture (Sharples 2009).
The relationship between slope orientation, soil, vegetation structure, micro-climate and fine fuel moisture dynamics is poorly understood and has not been sufficiently represented or parameterised in models. This project aims to improve the prediction of short- range variability in dead fine fuel moisture using field measurement of aspect related differences in soil, vegetation and microclimate.

Methods

Topographic micro-climate experimental sites

Experimental sites for monitoring microclimate variables and moisture content in dead fine fuels and in near-surface soils were established in March 2013 on the upper slopes of four contrasting aspects (north, south, east and west) within a 0.5km radius in the Upper Yarra Catchment in Victoria, southeast Australia. Rainfall, ambient air temperature, geology, and drainage position, are similar across the four sites, so measured differences between the experimental sites at the ground level are assumed to be due to aspect-related microclimatic-variability. An additional weather station was established in a nearby open, ridgetop position to quantify precipitation, temperature, relative humidity, windspeed and direction for the area. Measurement from these five sites is ongoing.

Microclimate instrumentation

At each of the four microclimate sites sensors are arranged to measure the soil moisture (2 replicates), fine dead surface fuel moisture at 2.5cm depth (12 replicates), precipitation throughfall (3 replicates), radiation (3 replicates), and screen level relative humidity, air temperature, leaf wetness, and wind speed (1 replicate of each). Temperature and relative humidity are also measured within the dead fine surface fuel using ibuttons (Hydrochron, DS1923) (4 replicates). All measurements are logged continuously at 15 min intervals. The layout of the sensors at each microclimate site is illustrated in **Erro! A origem da referência não foi encontrada.**Figure 1.

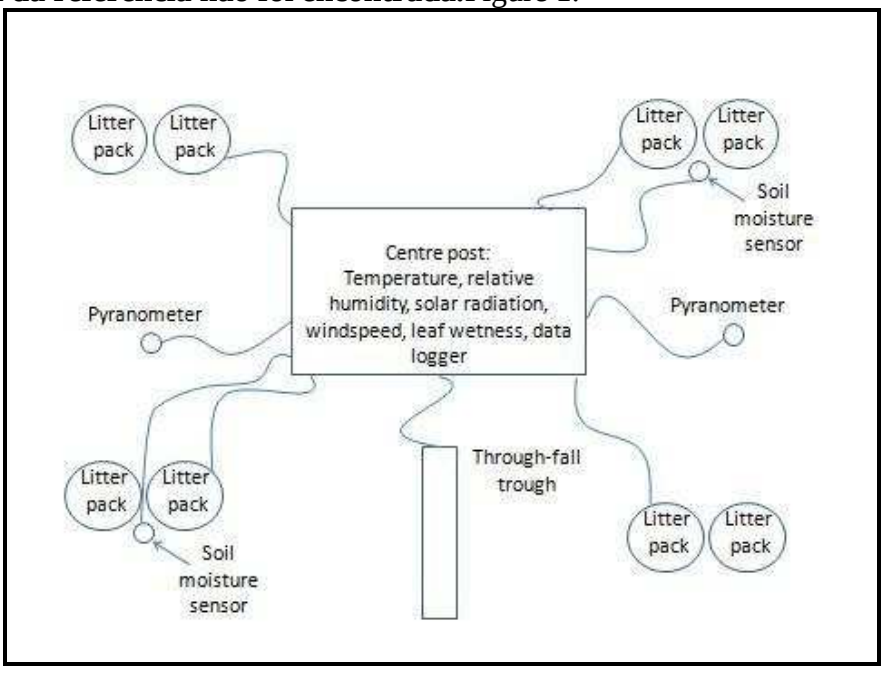

Figure 1 –An illustration of the layout of the instrumentation and sensors at one of the four instrumented microclimate sites.

There have been few attempts to continuously measure fine fuel moisture under field conditions. Here, the moisture content of the fine dead surface fuel is estimated using high replication of low-cost continuous soil moisture sensors (VH400, Vegetronix, Inc., Riverton, USA) (see Figure 2) placed at the centre of a 5cm deep sample of fine dead surface fuel, referred to here as "litter packs".

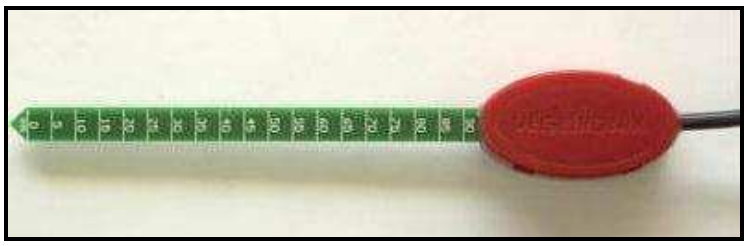

Figure 2. A vegetronix VH400 soil water content probe, used in this study to continuously estimate the gravimetric water content of fine dead surface fuels. (Source: www.vegetronix.com) .

The litter packs were constructed from fuels collected from the area surrounding the microclimate site. Each of the pairs of fuel packs (4 pairs, a total of 8 litter packs at each micro climate site) includes one continuously monitored pack (logged every 10 mins) that contains 3 Vegetronix soil moisture sensors, and one pack that is used to measure fuel moisture content gravimetrically during field visits. The gravimetric litter pack was used to build an empirical relationship between the measured gravimetric fuel moisture content, and the Vegetronix voltage output, under field conditions. This relationship was used to produce a continuous estimate of the fuel moisture content of the dead fine fuel layer. An example of the dead fine fuel packs installed at one of the microclimate sites is shown in Figure 3.

Figure 3. Two of the dead fine surface fuel sample packs used in this study to monitor fuel moisture. The left hand pack is fitted with three Vegetronix VH400 soil water content sensors, recording every 15 minutes. The right hand pack is used for manual gravimetric measurements during field site service visits. (Source: www.vegetronix.com).

The continuous fuel moisture monitoring methods described above were supported by four seasonal field campaigns to quantify dead fine fuel moisture content from 3 additional replicated locations for each aspect, and to measure variability in fine fuel depth, density and spatial arrangement as a function of aspect.

Results & Discussion

The first year of data from the microclimate sites is currently being analysed and the sensors calibrated using recently collected summer field campaign data. As a consequence, no detailed results are available at the time of writing this abstract. However, some interesting observations can be noted. The moisture regime on the forest floor was highly sensitive to the incoming shortwave radiation, which was up to 6 times higher in the north-facing (equatorial) slopes due to slope orientation and the sparse vegetation compared to vegetation on the south-facing (polar facing) slopes. Differences in shortwave radiation resulted in peak temperatures within the litter that were up to 2 times higher on the equatorial-facing site than those on the polar-facing site. For instance, on November 2013 with maximum open air temperature of 35^{o} C, the temperatures within the litter layer at the north-facing and south-facing sites were 54^{o} C and 32^{o} C, respectively, despite air temperature at the two sites differing by less than 2^{o} C. The minimum gravimetric water content in the litter layer on the same day was 21% on the equatorial-facing slope and 85% on the polar-facing slope. A full analysis and summary of the experimental data will be available for the conference presentation. The implications for modelling spatial variability in fuel moisture will be discussed.

Abstract
This paper reports infrared thermal-image-based temperature changes on cardboard fuel surfaces during ignition. Two sets of experiments were designed to separately test the effect of convective heating and radiative heating on ignition of cardboard fuel samples. An air torch was used to provide the convective heating, and a crib fire was used for the radiative heating. An infrared thermography technique developed in our laboratory was used to obtain thermal profiles/signature of the heated cardboard sample surface under two different heating rates, from which the surface temperature change was obtained as a function of heating time. We found that radiation effects increased with an increase in the cardboard sample surface area exposed to radiation while the effects from convection dominated the smaller surface area samples. This finding qualitatively explains the United States Department of Agriculture's (USDA) original findings that millimeter diameter pine needles cannot be ignited by radiation only, even under a long duration fire generated radiant heat flux of an average 10.3 kW/m^2. Our experimental results also justify the use of the cardboard fuelbeds to simulate fire behavior of large scale forest fires.

Keywords*: Ignition, Fuelbed, Fuel Particle, Heat Transfer*

Introduction

Wildland fires are unpredictable and destructive events that use enormous amounts of resources to fight and contain, particularly in the wildland-urban interface where numerous amounts of resources are utilized to protect homes and other structures.

Scientific advances in the form of spread rate models have paved the way in providing more effective means for firefighting and containment for large fires. Such fire behavior models form the core for decision support system (Noonan-Wright, et al., 2011).

Given the limitations and empirical nature of current fire behavior models, the question remains of how to enhance physical understanding and someday enhance operational fire spread modeling (Gollner, 2012). As surmised by Finney *et al*. (2012), correct application of the heat transfer mechanisms contributing to ignition have yet to be reliably applied to fire spread models. Therefore, a more thorough understanding of the underlying physics and theory behind ignition on forest fuels (including live fuels) is needed to develop a coherent theory on the heat transfer mechanisms affecting it. The flame is the source to provide sufficient heat to pyrolyze (solid) forest fuel, and the pyrolyzed gas phase products will then mix with air. When this fuel-air mixture satisfies flammability limit under the ignition temperature, ignition occurs creating flammable combustion. This repeating pattern is the mechanism which allows the flame front to spread, where heat transfer from the front to the unburned fuel particles and gas phase kinetics play an important role (Fernandez-Pello & Hirano, 1983).

Radiation has been thought as the primary mechanism in wildland fire spread, similar to upward flame spread along vertical walls under natural convection (Brehob & Kulkarni, 1998; Brehob, Kim, & Kulkarni, 2001) and flame spread across a continuous horizontal fuel bed under a very high horizontal wind velocity (Steward, 1971). These laboratory experiments use PMMA and wood samples under well controlled laboratory boundary conditions, while flame spread over forest fuel beds involves

many other additional parameters. These parameters include complex mixtures of different types of live and dead fuels, non-uniform porous fuel structure, different terrain, and changing wind speed among others. Emori and Iguchi *et al*. (1988) mimicked forest fuel with excelsior and vertically oriented paper strips coated with candle wax, whose geometry is similar to the cardboard fuelbeds, and showed that flame spread over inclined fuel beds for the paper strip fuels and horizontal and inclined excelsior fuel beds is controlled by convection (Emori, *et al*., 1988). Adam *et al* (2013) further studied scaling laws on flame spread by bringing a Strouhal-Froude number flow instability to convection heat transfer, predicting that flame spread through forest fuelbeds would satisfy these convection-controlled scaling law conditions.

Experimental Methods

To ensure homogenous properties and physical attributes among the fuel samples being used, we engineered cardboard particles 1.27 mm thick with approximately 60% recycled content using a laser engraver. We measured the transient temperature history of the fuel particles when subjected to various heat sources using a FLIR SC4000™ infrared camera (spectral range of 3-5 μm, fitted with a broadband flame filter with spectral range of 3.7 - 4.2 μm, with spatial resolution of 320 x 256 pixels). To reduce the amount of noise and saturation captured in each video image, we employed a super-framing algorithm which takes a set of four images (subframes) of the scene at progressively shorter exposure times, in rapid succession, and then repeats this cycle. The sub-frames from each cycle are then merged into a single super-frame to combine the best features of the four sub-frames. This process, called collapsing, can provide thermal images both high in contrast and wide in temperature range.
The following section provides results from two sets of experiments: convective dominated heating from an air torch and radiative dominated heating from a crib fire.

Convection Dominated Heating: Air Torch Experiment

The cardboard fuel elements were heated from ambient temperature by a convective heater to achieve ignition (recognized by the establishment of a visible flame). Figure 1 depicts a schematic of convection heating experiment. A vertically oriented convection heater provided forced convective heat flow parallel to the cardboard elements suspended approximately 0.5 cm above the exit of the air torch, where two different temperature settings (500 °C and 750 °C) were used. The mass flow rate of air is controlled and held constant, so the airflow velocity at the exit of the torch varied from 1.3 to 1.5 m/s for the two temperatures tested.

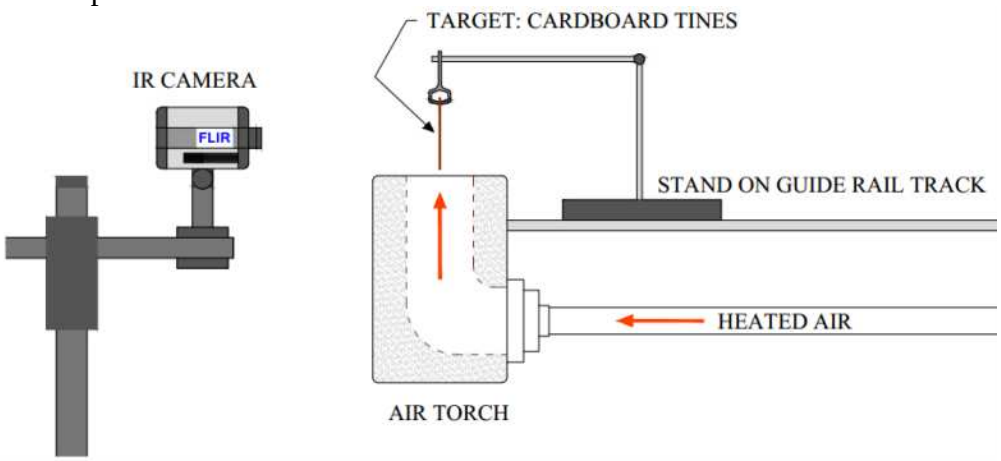

Figure 1. Experimental setup: Air torch - Side view

Three common tine geometries, shown in Figure 2, were used and each experiment was repeated ten times per geometry. Every effort was made to ensure all experimental conditions remained the same and the results were repeatable, since the temperature distribution at the circular exit of the torch was not symmetric which could lead to an uneven temperature distribution across the hot exiting air stream. The cardboard tine samples were suspended in a downward facing manner, as shown in Figure 3, throughout the duration of the experiment to mimic the condition of heated vertical plates subjected to forced convection from an imposed parallel flow.

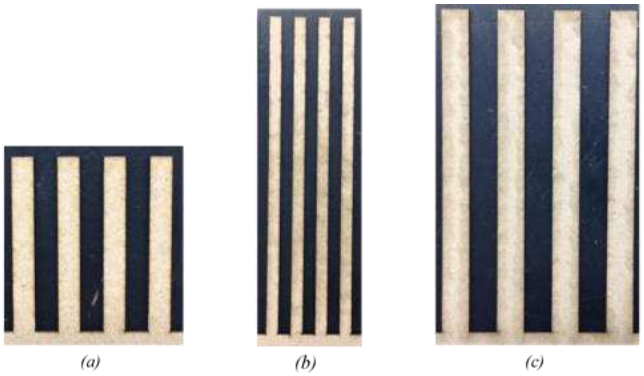

Figure 2 - Tine geometries (a) 0.635 cm wide x 5.08 cm high (b) 0.635 cm wide x 15.24 cm high (c) 1.27 cm wide x 15.24 cm high

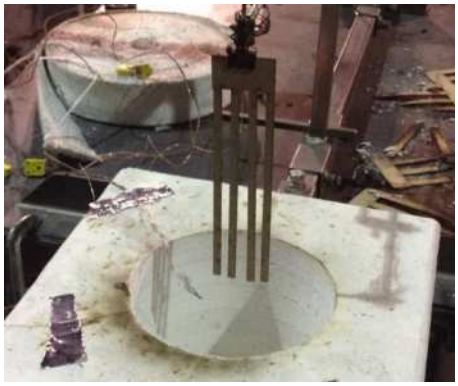

Figure 3 – Tine orientation

Radiation Dominated Heating: Crib Fire

A wood crib (91.44 cm wide x 76.2 cm tall x 91.44 cm long) constructed of Ponderosa pine (*Pinus ponderosa*) sticks was used to provide radiative heating to the cardboard samples under circumstances as close to wildland fires conditions as possible. A schematic of the experimental set up is shown in Figure 4. The crib was constructed with 2.54 cm square sticks with six sticks per layer and 30 layers, such that it burned in the loosely-packed regime. The crib was placed on cinder blocks providing 19.5 cm of space between the crib and the support platform. The crib was housed within a large (12.4 m x 12.4 m x 19.6 m) sealed burn chamber with no imposed flow. This allowed minimal incoming and outgoing drafts, thus limiting convective heating and cooling effects and maximizing the radiative heating effects. Equation (1) can describe the above heat balance

$$\frac{dq''}{dt} = E(T_s^4 - T_{sur}^4) + h(T_s - T_\infty) \quad (1)$$

where E represents the product of the Stefan-Boltzmann constant (5.67 x 10^{-8} W/m^2-K^4), the integrated emissivity of the cardboard elements, and a geometrical view factor and the $h(T_s - T_\infty)$ term is used to define the convective cooling effects.

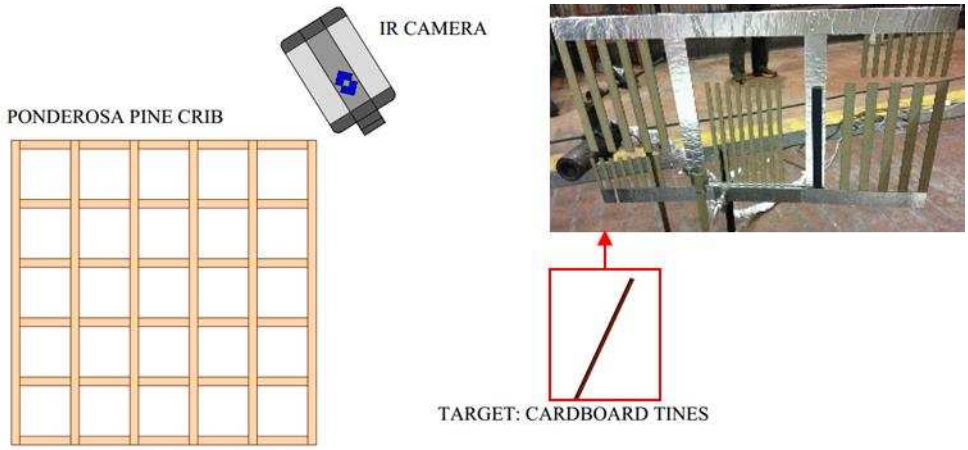

Figure 4 - Crib schematic: Plan view

Three cardboard tine geometries were used for this experiment: 0.635 cm wide x 5.08 cm high, 0.635 cm wide x 15.24 cm high, and 1.27 cm wide x 15.24 cm high. The tines were originally constructed into two foot sections, but cut into smaller segments and taped together using reflective aluminum adhesive tape. To achieve the best viewing angle as possible between the IR camera and the fuel, the tines were positioned at an angle of 25° with respect to the crib with the closest end measuring 91.44 cm away from the edge of the crib and the furthest measuring 109.22 cm away.
A separate cardboard tine was coated with high carbon content black paint ($\varepsilon = 0.95$) to serve as a black body for the IR camera. Additionally, a 1 mm K-type thermocouple was taped to the bottom of the cardboard sample to measure the surrounding air temperature during the heating experiment.

3. Results

3.1. Convection Dominated Heating: Air Torch

The recorded infrared video images provided a rich database for all 30 fuel samples, but this paper only reports the results for the 0.635 cm wide x 5.08 cm high cardboard elements due to space limitations. It should be noted that the results presented are not representative of a single test but rather depict the average of all ten trials for the 0.635 cm wide x 5.08 cm high fuel element.
The software ExaminIR™ (FLIR Systems, Inc., 2014) was used to evaluate the IR video image data. Specific regions of interests (ROI's) located at the tip of each tine were used to determine a temperature history of the cardboard fuel elements. These ROI's were labelled from left to right as Cursor one through four. In the grayscale image, white is representative of hotter temperatures, while dark is indicative of colder temperatures. The results for the air torch outlet temperature of 500 °C show a steady progression in temperature up to the point of flame visibility at approximately 315 °C where temperature rises sharply (Figure 5).

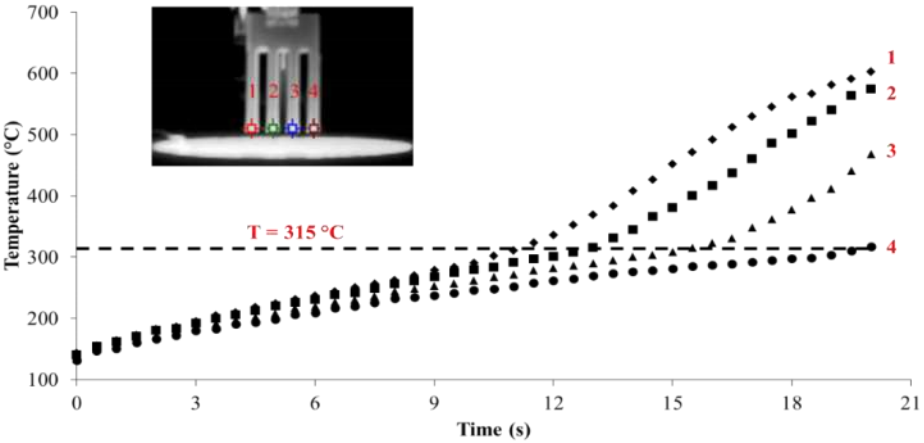

Figure 5. Temperature history for the 0.635 cm wide x 5.08 cm high fuel element subjected to an outlet temperature of 500 °C

Once a stable flame was established, the tines were pulled away from the outlet of the torch to prevent burning fuel elements from falling into the air torch and possibly damaging the equipment. In evaluating each cursor, fluctuations due to flame movements and CO_2 interference, which are visible in the spectral range of the filter, are represented by a larger standard deviation. These fluctuations are shown for Cursor one and Cursor four in Figure 6.

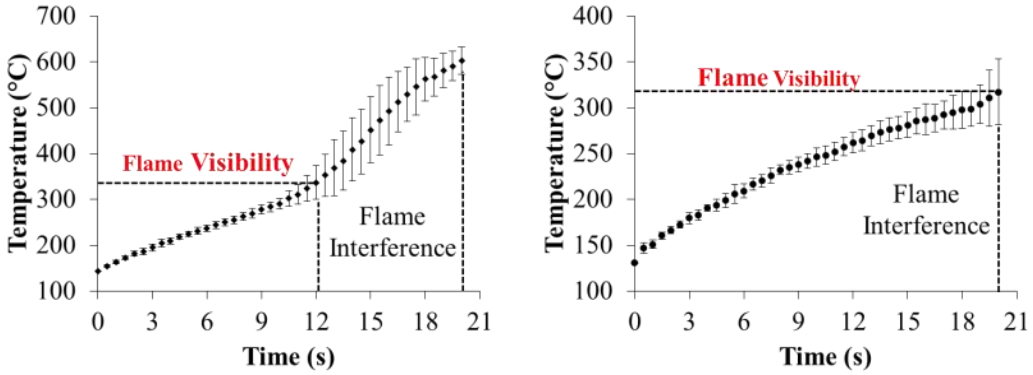

Figure 6. Temperature history showing standard deviations as a result of flame movement and CO2 interference for an outlet temperature of 500 °C for Cursor 1 and Cursor 4

For the case of an outlet temperature of 750 °C (Figure 7), the results show a decrease in flame visibility temperature (307 °C) with an increase in heat flux, as expected (Atreya & Abu-Zaid, 1991). Additionally, more fluctuations in the temperature progression are present as a result of increased turbulence in the airflow (Figure 8). Note that for an outlet temperature of 500°C, it took approximately 12 seconds to reach ignition, while for an outlet temperature of 750 °C it took roughly 1.5 seconds, indicating that an increase in the heat flux increases convective heat transfer rate to the unburned fuel element and consequently increasing the rate of flame spread.

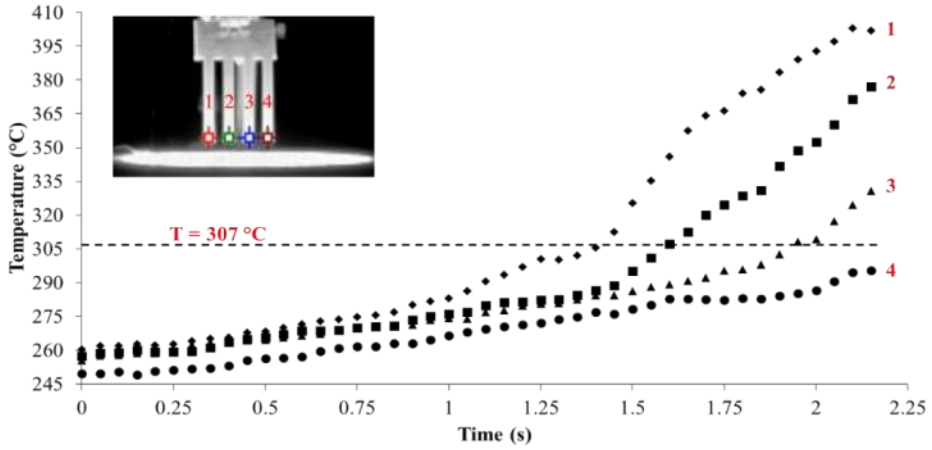

Figure 7. Temperature history for the 0.635 cm wide x 5.08 cm high fuel element subjected to an outlet temperature of 750 °C

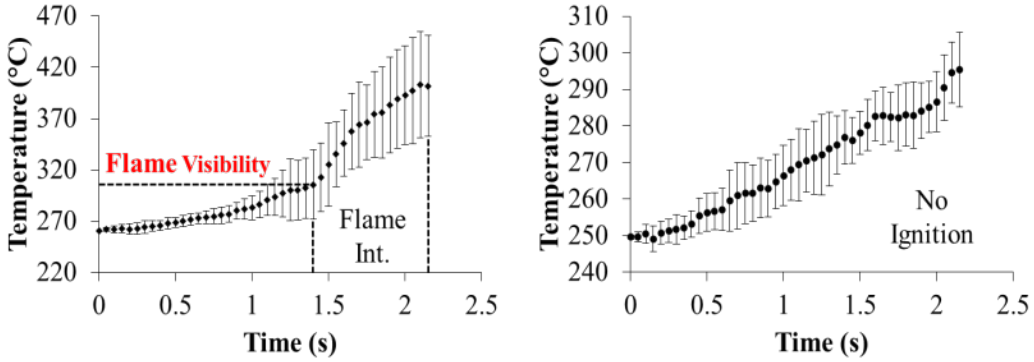

Figure 8. Temperature history showing standard deviations as a result of flame movement and CO2 interference for an outlet temperature of 750 °C for Cursor 1 and Cursor 4

Radiation Dominated Heating: Crib Fire

A similar procedure was used to determine the temperature history of the cardboard fuel elements when subjected to primarily radiative heating. The average radiative heat flux of the crib fire was approximately 10.3 kW/m^2. Within ExaminIR, specific areas of interest were placed at the tip, middle, and bottom of the cardboard fuel elements closest to the burning crib, as these tines were exposed to the largest amount of radiative heat. These fuel particles included the 0.635 cm wide x 5.08 cm high tines and the 1.27 cm wide x 15.24 cm high cardboard elements shown in Figure 9(c).

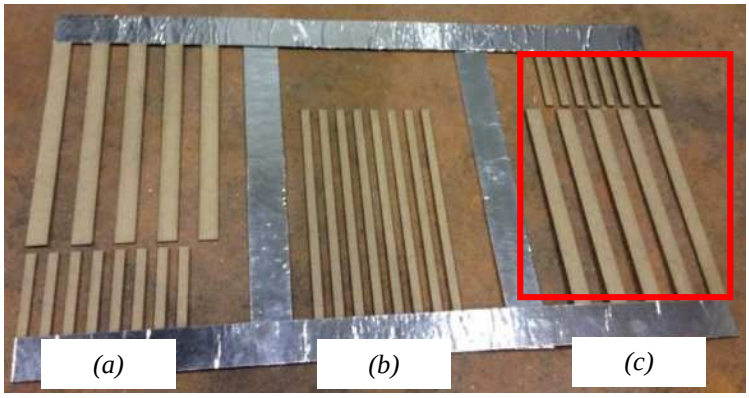

Figure 9 – Tine geometries: (a) 0.635 cm wide x 5.08 cm high (b) 0.635 cm wide x 15.24 cm high (c) 1.27 cm wide x 15.24 cm high

During radiative heating, a natural convection thermal boundary layer will be developed over the heated fuel surface bringing two different benefits for ignition: reducing the heat loss from its heated surface to the surrounding air and promoting a fuel-air mixture layer within the boundary layer. Both are favourable for ignition.

Examining the ratio of exposed heating area to total fuel surface area, we realized that the potential for receiving radiant heat as opposed to losing energy to the surroundings from natural convective cooling was greater for the larger fuel particles. This explains the results of Figure 10 where the larger tines (1.27 cm wide x 15.24 cm high) were able to ignite at the tip.

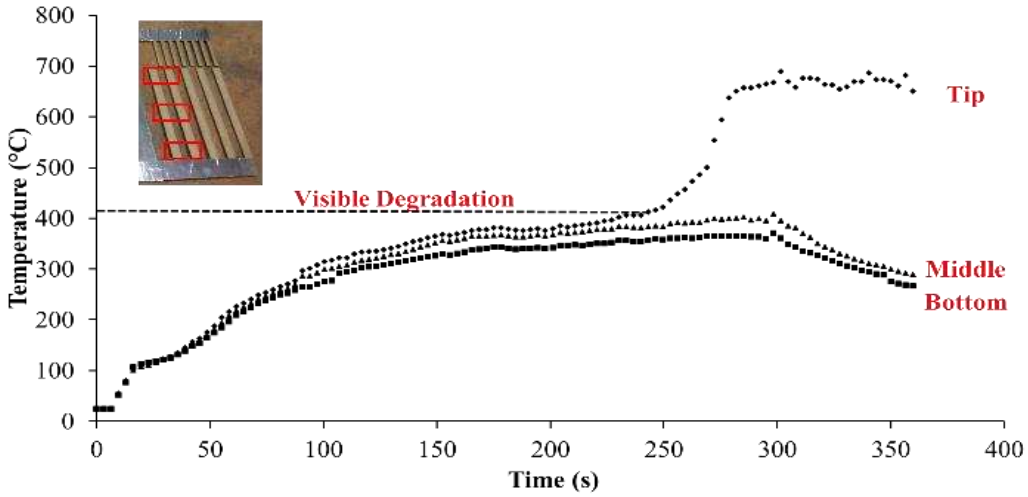

Figure 10 - Temperature history of the 1.27 cm wide x 15.24 cm high fuel element subjected to predominately radiative heating

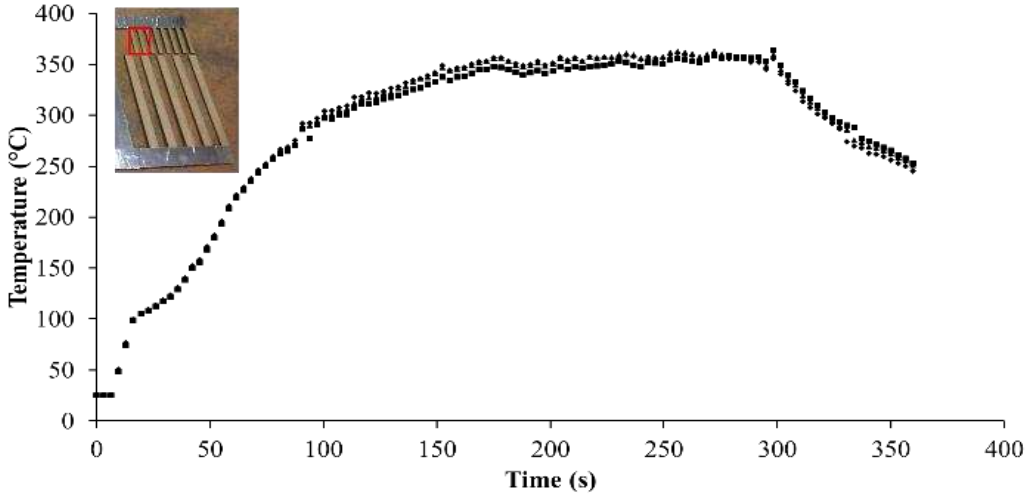

Figure 11 - Temperature history of the 0.635 cm wide x 5.08 cm high fuel element subjected to predominately radiative heating

It should be noted that the ratio of the exposed heating area to the total fuel surface area is an important indicator to assess the effect of radiation on ignition not only for cardboard fuel samples but possibly for actual dead forest fuels, since the underlining governing physics can be also applied. But a more thorough scaling study, perhaps based on previous studies by Adam *et al*. (2013), Emori and Saito (1983), and Emori and Iguchi *et al* (1988), is required to justify whether or not this ratio can be an important scaling factor. As for live forest fuels, however, the above finding may not be directly applicable due to its complex fuel structure (McAllister & Finney, 2014) and therefore, a fundamental study to reveal ignition behaviour of live fuels is certainly needed.

Summary

This paper reports IR thermal image-based temperature history and ignition behavior of engineered cardboard fuel elements subjected to convective and radiative heating. Our results support the USDA's original findings that millimeter diameter pine needles cannot be ignited by radiation only even under a long duration fire generated radiant heat flux of an average 10.3 kW/m^2.
The objective of the air torch experiment was to examine convective heating of fuel particles. The tines above the torch represented the unburned fuel particles that are receiving flame contact near a spreading fire. This layout, however, does not exactly represent forest fire conditions, where fuel particles receive heat from a cross-flow as opposed to a parallel flow. We are planning to perform an additional experiment using a heat gun to simulate forced convection due to an imposed flow along and around cardboard fuel elements in cross-flow.

[b] *FCT – University of Coimbra - Pinhal de Marrocos - Pólo II - 3030 Coimbra, Portugal*

Abstract
The influence of the radiative heat exchanges between the fire front and vehicle passengers' in a road is made in this study. Numerical software, that simulates the vehicle thermal behaviour with complex topology and the human thermal response, in transient conditions, is developed and used.
The numerical model that simulates the vehicle thermal behaviour and the passenger thermal response is based in energy and mass balance integral equations and works in transient conditions. These equations, solved by the Runge-Kutta-Felberg method with error control, are based in conduction, convection and radiation phenomena. All coefficients used in these equations are evaluated by a sub-model that calculates the internal and external view factors, radiative heat exchanges, glass radiative properties, occupation cycle, ventilation strategy, human thermo-physiology and heat and mass transfer coefficients by convection using empirical expressions.
In the numerical simulation a bus, that runs in a road nearby a fire front, occupied with 52 passengers is used. The radiative heat exchanges numerical model between the fire front and the vehicle and between the vehicle and the passengers, based in Mean Radiant Temperature method, is used.
The work is divided in three parts: the bus geometry, the passenger geometry and the fire front geometry (1), the view factor inside the and outside the bus passenger compartment (2) and the Mean Radiant Temperature that each bus bodies and human body section are subject (3).

Keywords*: Vehicle Thermal Behaviour, Human and Clothing Thermal Response, Mean Radiant Temperature, Numerical Simulation, view factors.*

Introduction

The vehicles and the passengers placed near a fire front are subjected to high radiative heat exchange. The passenger is subjected to thermal discomfort and the vehicles are, inclusively, subjected to ignition phenomena. Thus, it is an important and interesting topic to be analysed in detail.
In this preliminary study a numerical simulation of a bus, that runs in a road nearby a fire front, occupied with 52 passengers is used. The radiative heat exchanges numerical model between the fire front and the vehicle and between the vehicle and the passengers, based in Mean Radiant Temperature method, is developed and applied.
This study is a continuation of Conceição *et al*. (1997), Conceição *et al*. (1997), Conceição *et al*. (1997), Conceição *et al*. (2000), Conceição *et al*. (2000) and Conceição (2001). In the previous work only vehicle thermal behaviour and the internal airflow are analysed, while in this and in the following works the vehicle, the passengers and the fire front are considered.
In the vehicle thermal behaviour numerical models, analysed by several authors, have been given special attention to the passenger compartment, namely, the vehicle body (main and interior bodies and windows) and thermal phenomena (radiation, convection, human generation, glass radiative properties, air renovation and others).
The numerical model that simulates the vehicles thermal behaviour, presented in this work, considers all spaces and all vehicle bodies spatially defined. It calculates not only the solar radiation incident in the internal and external surfaces, but also the radiative heat exchange between internal, in each space, and external surfaces, between vehicle and surrounding bodies. In the radiative calculus are considered, in the internal and external calculus, the shading effect.

Finally, to evaluate the passengers thermal comfort level is used a human multi-node comfort model (see, as example, Conceição, 2000, Conceição *et al*., 2006 and Conceição and Lúcio, 2010). More details of the multi-node comfort model, based in Stolwijk (1970), can be see Conceição *et al*. (2014).

Physical Model

In the physical model, the numerical program defines the vehicle, passengers and fire front geometry. The vehicle, in general, is divides in several compartments (passengers, luggage and motor), main bodies (panels, doors, ceiling and floor), interior bodies (benches and motors) and glasses.
The passengers are divided in 25 cylindrical or spherical elements and each element is sub-divided in 12 cylindrical or spherical layers and could be still protected of the external environment through several clothing slices.
The fire front is identifying using one, or more, geometric surfaces.
Using the geometry inputs the programs built the energy and mass balance equations system.

Vehicle Mathematical Model

The vehicles thermal behaviour model is based not only in energy balance integral equations for the air inside each spaces, different slices of vehicle main bodies, several windows glasses and interiors bodies, but also in mass balance integral equations for the several air contaminants inside the spaces. It considers the convective (natural, forced and mixed), conductive (in the main bodies divided in several slices), radiative (shortwave and long wave radiation outside and inside the vehicle) and mass transfer (inside the compartments) phenomena.

In the radiative calculus each surface is sub-divided in several small areas. In the vehicle external surfaces are considered:

- the absorbed solar radiation by the main bodies and windows glasses surfaces;
- the long wave radiative heat exchange between the vehicle external surfaces and the nocturnal sky, during the night, and the surrounding surfaces, during the day.

In the internal surfaces are considered:

- the solar radiation transmitted through the glasses and received by the main and interior bodies surfaces;
- the long wave radiative heat exchange between the internal surfaces (glasses and main and interior bodies), of each space. The diffuse radiations between grey surfaces, in each enclosure, are determined by radiosity equations system and view factors.

It is considered the shading effect caused by the surrounding surfaces (buildings or other vehicles), when the car is parked, and the internal surfaces (main and interior bodies in each compartment).
In the mass transfer inside each space are considered the human respiration and transpiration, outdoor infiltration and mass exchange between different compartments. Using the water vapour concentration and the air temperature value the model calculates the air relative humidity.

Heat exchanges by radiation

The radiant heat exchanges by long wave phenomena are calculated, in this work, using the Mean Radiant Temperature method (Fanger, 1970). The Mean Radiant Temperature, used to evaluate the heat exchanges that each human body section is subjected, considers the view factors calculated between the human body sections and the surrounding surfaces and the surrounding surfaces temperature. In the methodologies used in view factors determination each human body element, vehicle surfaces and external surfaces, with inclinations and dimensions equal to the respective body,

are divided in infinitesimal areas. In the radiation by long wave phenomena calculus are also considered the shading effects that the body elements surfaces promote in each element.

The Mean Radiant Temperature method, with correction, is divided in two parts:
- Heat exchange in the human body;
- Heat exchange in the vehicle.

The human body consider:
- heat exchanges between the human body sections and the surrounding surfaces (main and interiors bodies and glass);
- heat exchanges between the human bodies sections of each passenger and between the human bodies sections of different passengers;

The vehicle body consider:
- heat exchanges between the vehicle surfaces (main and interiors bodies and glass) itself;
- heat exchanges between the vehicle surfaces (main and interiors bodies and glass) and the passengers;
- heat exchanges between the vehicle surfaces (main and interiors bodies and glass) and the external surfaces (floor, environment and fire front).

The Mean Radiant Temperature method, with correction, calculates, step by step, the Mean Radiant Temperature, using the human body and vehicles bodies, calculated in each iteration, and the pre-calculated view factors.

Results and Discussion

This preliminary work is divided in three parts:
- the bus geometry, the passenger geometry and the fire front geometry;
- the view factor inside the and outside the bus passenger compartment;
- the Mean Radiant Temperature that each bus bodies and human body section are subject.

In the bus studied, divided in 6 compartments (frontal ventilation ducts, luggage, motor, passengers and two ventilation ducts over the seats), are considered 99 main bodies, 18 window glasses and 105 interior bodies (see figure 1). The same figure, as example, show also a small fire front, placed in the vehicle left side.
Each of these surfaces, in order to evaluate the view factors, is divided in several infinitesimal areas. In general, in accordance with previously numerical simulation obtained in the view factors determination, all surfaces are subdivided in both directions in a grid spaced in a maximum of 0.2 m and divided in a minimum of 100 elementary areas.
Figure 2 show the grid generation in the vehicle passenger's compartment surfaces and the 52 passengers used in the view factor determination. The passengers considered has 1.7 m of height, 70 kg of weight and 1 met of activity and 0.8 Clo of clothing level.
In figure 2 the vehicles surfaces are subdivided in elementary surfaces, defined previously, while in the passengers the spherical head is divided in 64 elementary areas (a grid in the azimuthal angle direction of 8 divisions and a grid in the polar angle direction of 8 divisions), while the others passenger bodies cylindrical elements are also divided in 64 elements (a grid in the longitudinal direction of 8 divisions and a grid in the radial direction of 8 divisions).
In the geometry definition all vehicles surfaces (main bodies and transparent bodies) are in contact. However, in the interior bodies only the seats, defined by a vertical and an inclined surface, are defined. In the passengers all elements are disposed in similar way to the human body posture. The neck, the arms divided in four and the legs divided in four are connected to the trunk with dimensions and angles

similar to the human body sections. The head is connected to the neck, the hands are connected to the arms and the feet are connected to the legs. In the neck, shoulders, elbows, hips, knees and ankles are placed rotation elements. The dimensions and inclination of each element are obtained using a numerical model based in the human body weight and height.
All passengers are not in contact between them and all passengers are not in contact with the seat and with all vehicle surfaces.

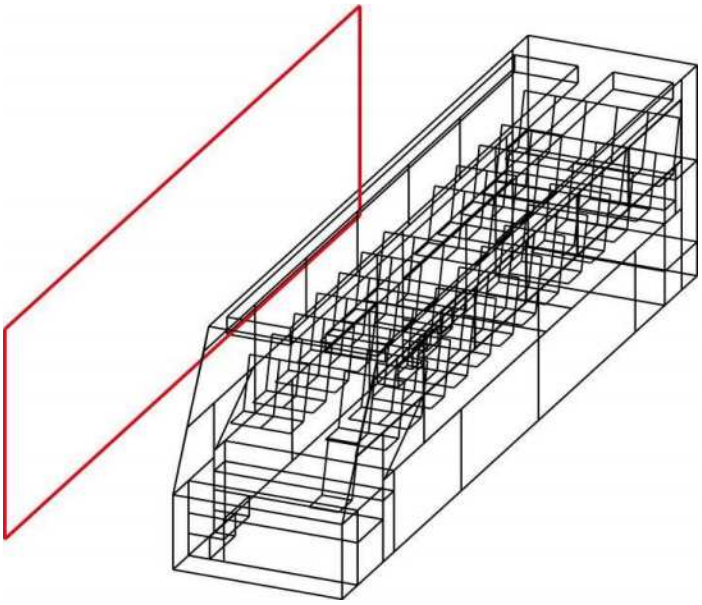

Figure 1. Scheme of a bus with 6 spaces, 99 main bodies, 105 interior bodies, 18 windows and 1 fire front.

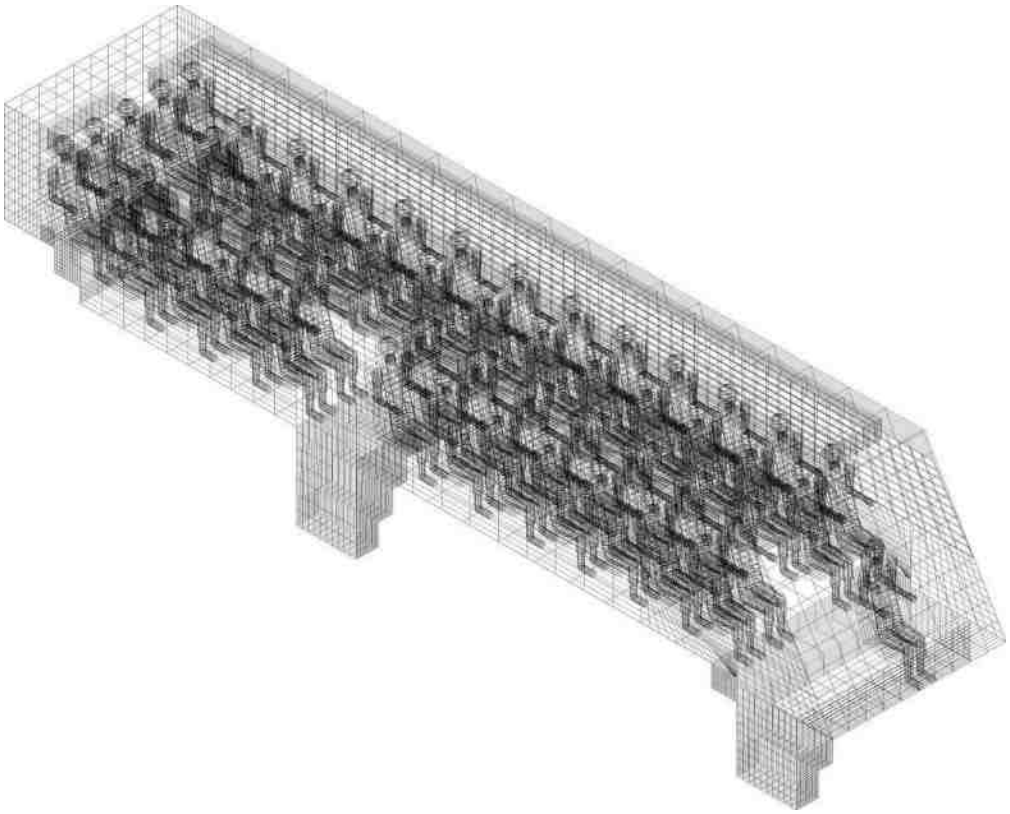

Figure 2. Grid generation in the vehicle passenger's compartment surfaces and in the 52 passengers used in the view factor determination.

In figure 3, as example, the Mean Radiant Temperature that each human body sections are subjected is presented. In these calculus the air temperature and relative humidity, evaluated in the external environment are, respectively, 18 ºC and 50 %, while the external floor is 18 ºC.

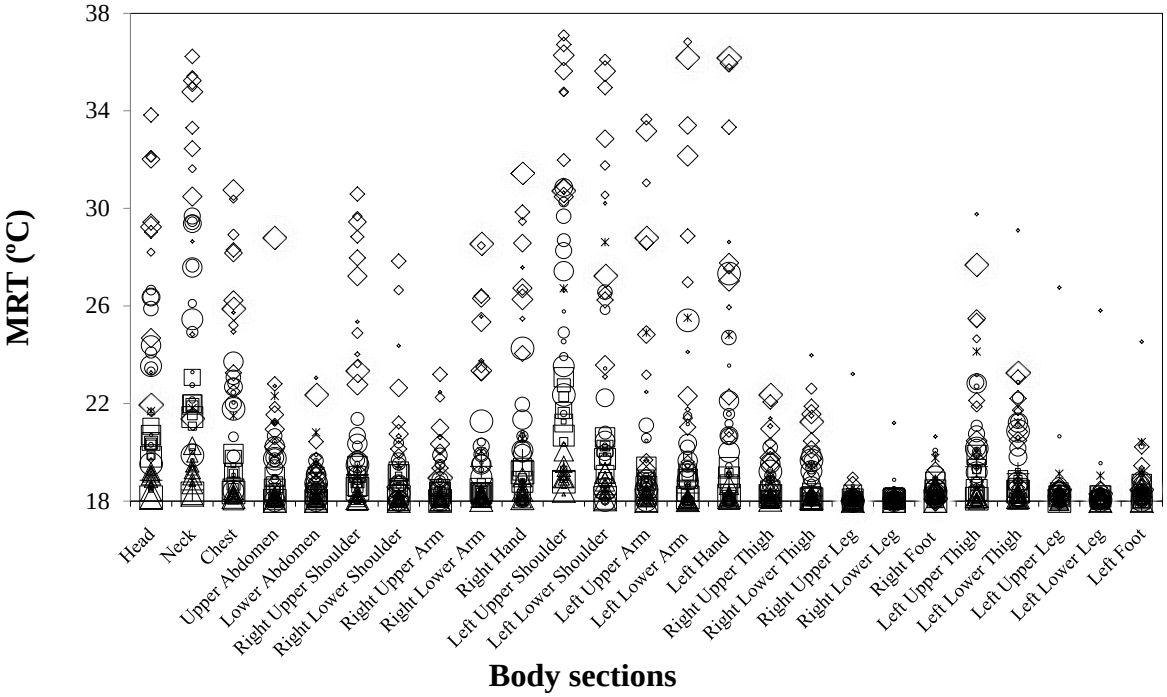

Figure 3. Distribution of the Mean Radiant Temperature that each human body section of the 52 passengers are subjected.

In accordance with the obtained results, in this preliminary study, is possible to verify that:

- The Mean Radiant Temperature is highest for passenger located near the left side vehicle;
- The Mean Radiant Temperature is higher for the left side passenger sections than right side passenger sections;
- The Mean Radiant Temperature is higher in upper passenger sections than in lower passenger sections.

Conclusions

In this work the influence of the radiative heat exchanges between the fire front and vehicle passengers' in a road is made. In the study a numerical software that integrate the vehicle thermal behavior with complex topology and the human thermal response, in transient conditions, is developed and used.
In this preliminary study, divided in three parts, are defined the bus geometry, the passenger geometry and the fire front geometry (1), are calculated the view factor inside the and outside the bus passenger compartment (2) and are evaluated the Mean Radiant Temperature that each bus bodies and human body section are subject (3).
In accordance the obtained preliminary results the grid generation in the vehicle geometry, in the passenger geometry and in the fire front geometry, in general, promote a good compromise between the view factors obtained and the computational time used. The increase of the grid generation increase substantially the computational time used, while the reduction cannot obtained good view factors values.
The preliminary obtained values show a slight asymmetry in the Mean Radiant Temperature values. The Mean Radiant Temperature is highest for passenger located near the left side vehicle, the Mean Radiant Temperature is higher for the left side passenger sections than right side passenger sections

and the Mean Radiant Temperature is higher in upper passenger sections than in lower passenger sections.
In the future the obtained information will be used in the evaluation of the vehicle temperature distribution and the human body temperature distribution. The vehicle temperature distribution will be used to evaluate the ignition risk that a vehicle is subjected near a fire front, while the human body temperature distribution will be used to evaluate the human thermal comfort and local discomfort levels.

Abstract
This work presents an interesting and unique analysis of an open air fire plume extrapolated from a large amount of paragliders tracks flying over a sugarcane fire during a world cup super final event in february 2013 Columbia. Vertical speeds of over 20 m/s were observed into a narrow core just over the fire. Simulation of the same event shown the relatively good ability of micro-scale meteorological models to represent quantitatively the velocity fields and behavior.

Keywords*: fire meteorology, fire weather, plume, convection, simulation, modelling, paragliding*

Introduction

An understanding of the interaction between a free spreading fire and the surrounding weather system requires knowledge on the dynamics of the buoyant fire plume. Insight into this dynamics, namely how the energy released by the fire sustains this plume can be studied experimentally [clements 2007, Church and snow 1985] and numerically. Nevertheless instrumenting a fire plumes is quite a complex task, particularly due to the nature of the energy source and the height to which instruments would need to be located. Remote sensing has also been used to capture the plume dynamics in large fires, although because the signals can be severely blinded by the amount of large particles in the air it is not clear how certain the remotely sensed data reflects the inside of the plume. In situ measurements may be done using Unmanned Aerial Vehicles (UAV) [clements 2007] but as well are limited by extreme flight conditions caused by flying embers and strong convection
A recent paragliding competition (the 2012 World Cup Super Final held in Roldanillo ,Colombia) offered an unique opportunity to characterize the structure of a buoyant plume above a fire. In this event a large number of paragliding pilots flew into a fire plume developing above a controlled burn in a sugarcane field. Mandatory GPS and variometer instruments carried out by the pilots recorded their detailed movement as they navigated the plume. The pilots can be considered synchronized passive tracers that allow us to reconstruct the plume dynamics and namely inform us on the intensity of the convection within the plume and up to a high altitude.
In our unique study we quantify the energy source of the sugarcane fire, present the 3D dynamics of the plume as characterized by the dataset and compare it with a simulation from coupled fire/atmosphere micro meteorological model in order to (1) verify the relevance of such models for such plumes and (2) see if it may be used to generalise the result.
The first part of the study present the dataset, providing specific insight on sugarcane fuels, and how the flight logs were analysed and convection fields extrapolated. Results are presented in the second part, with first guess analyses of simulation results compared to post-processed tracks.

2. Method

Fuel source

The fuel complex is a sugar cane plantation prior to harvesting. At this stage the standing crop is

approximately 3 m tall and carrying an overall biomass varying between 7.5 and 10 kg/m2. Standing biomass will largely depend on the watering and fertilized regime provided to the standing crop. About 20% of the biomass is dead suspended leaves along the stalk and litter forming a well-aerated fuel layer in the lower 1 – 1.5 m of the stand. This dead biomass is the fuel that will be consumed in pre-harvest burning. It is well accepted that these burns will consume between 1.5 and 2 kg/m2 (Cheney, Sullivan 2008)

The high intensity burning in Fig 1 is indicative of productive sites and varieties, so we can confidently assume a fuel consumption in the high end of the range, i.e., 2 kg/m2. Cheney and Just (1974) suggest flame heights of about 9-11 m (from the ground) in 3 m tall crops with good fuel accumulation. These flame heights are consistent with the ones recorded photographically by several pilots (as per Fig 1). Tabled values for sugarcane heat content vary between 18500 kJ/kg (higher) and 17700 kJ/kg (lower). Considering a fuel load of 2 kg/m2 and an heat content of 18000 kJ/kg it will be appropriate to consider a heat per unit area of 36 MJ/m2. The size of the sugarcane field was 5 ha, corresponding to a total energy released of 1.8 GJ.

The photos taken by several of the paraglider pilots as they approached the plume suggest an ignition pattern characteristic of sugarcane burning. The ignition method consist of two igniters walking along the longer sides of the field with one of them slightly ahead of the other. If we assume that (1) the igniters are moving at a rate of 1.4 m/s (walking pace) as they light the long edge of the sugar field; (2) as they move along the plot the two fire fronts merge and move along the igniters direction of travel at 1.4 m/s (Fig 1); then we can assume that the fire front is spreading at 1.4 m/s spread rate.

Given the approximately 500 m length of the sugarcane field, the lighters took about 6 minutes (357 s to be more exact) to burn the full 50000 m2 of the sugarcane block. A raw analysis from pilots pictures during the event are in relative agreement with this estimate (between 6 and 8 minutes as fire front position is difficult to locate precisely). Overall the full burn duration is considered to be about 9 minutes, 6 minutes of lightning procedure and 3 more minutes for the full burn out.

From this and the assumption that the fire is spreading at a steady state determined by the igniters pace, it is possible to estimate the energy release rate from the combustion of those fine dead fuels. Considering a burning duration of 40 seconds, and that 50% of the combustion energy is converted to convective heat fluxes, the surface instantaneous heat fluxes for the numerical model is parameterized as 450Kw.m2 for these 40 second. The propagation pattern is force to mimics the actual fire as seen from the photographs, with fires spreading towards the center of the field.

Tracklogs

The study attempts to leverage the opportunity offered by task 3 of the 2012 paragliding world cup super final that occurred in Roldanillo (near Cali), Columbia the 19th of January 2013, that happened to be at the same time that large sugarcane fields were set to burn before harvest.

More than 120 of the world best competitors were free-flying in this large valley with equatorial climate, all searching for the quickest way to gain altitude in order to reach the finish line first. to be a very effective way to gain altitude, a flock of 80 pilots entered this fire thermal and exited within 10 minutes gaining about 1600 meters in average. This fire thermal was intense enough that some had to deploy their reserve parachute, risking to fall into flames with 20kg of nylon wing and it is since that day forbidden to fly over a fire in the PWC championship rules.

As the format of the competitions requires that tracks must be logged with relatively high frequencies for verification, the resulting dataset may be regarded as a set of relatively well spread and synchronized passive tracers that may inform on the intensity of the convection within the plume and up to a high altitude. The frequency of the tracklogs is in between 5 and 10 seconds, depending on the pilots equipment, all these track points were first compiled into a timed dataset with the computation of the instantaneous vertical velocity for each glider at each point. This vertical velocity was taken as the altitude difference between a point and its next point in time, divided by the duration between those

2 points (5 to 10 seconds). We then subtracted a typical competition glider sink rate (0.7 m/s) to the value.
The second operation required to reconstruct a volume from this dataset in order to interpolate vertical paragliders velocities inside the plume, for that all points within a 120 seconds window were extracted and used to perform a Delaunay triangulation of a volume. Within this volume vertical velocity can then be interpolated as the bilinear interpolate between grid points.
To reconstruct the timely evolution of the plume, the 120 seconds window is moved 10 seconds at a time during the overall burn duration, with a triangulation performed with each window dataset. An animation of this plume rise taken from these tracklogs may be found here: youtube.com/watch?v=Ogsq2yINV6o.

Figure 1 - View of the plume from the sugarcane burn

2.3. Model Set-Up

The coupled simulations were run on a 2.5km×2.5km×3km domain discretized on a 80×80×60 mesh for the atmospheric model simulation ($\Delta x = \Delta y$, 40m, vertical grid up to 5000m, vertical resolution increasing from 20M (ground) to 200m (top)).
Atmospheric conditions were initialized with radio soundings extracted from global model analyses. Simulations were run on a parallel 8 cores computer, with a speedup ration of 0.9 (0.9 seconds of computation for 1 seconds of real time). Mesonh/ForeFire [Filippi *et al* 2010, Filippi *et al* 2013] code was used to perform the computation.

3. Results

Figure 2 presents the reconstructed wind field when the fire was approximately towards the end of the burn and much gliders present, we can see areas in excess of 20 m.s vertical speed. Obviously vertical velocity may be extrapolated only where data is present, but with 80 tracers, this field is composed of about 4800 real points. It is possible to observe a relatively narrow convection core (about 200 meters) rising with some negative velocities area its outer edges of this core.

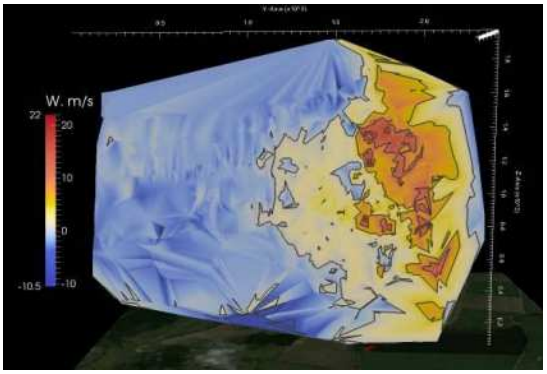

Figure 2 - View of reconstructed plume

The very basic idealized simulations that were performed are presented in figure 3. It might be observed that overall a similar (although obviously much more smooth) vertical velocity pattern is formed. These results shows in particular a nice accordance between the maximum vertical rate, and as well a 200m wide convective core and a plume that rises at about the same height (although no glider went higher than +2000m, so higher than that, no data is there for comparison). The vertical downdrafts is less intense in the simulation, but still present and at the outer edge of the main core.

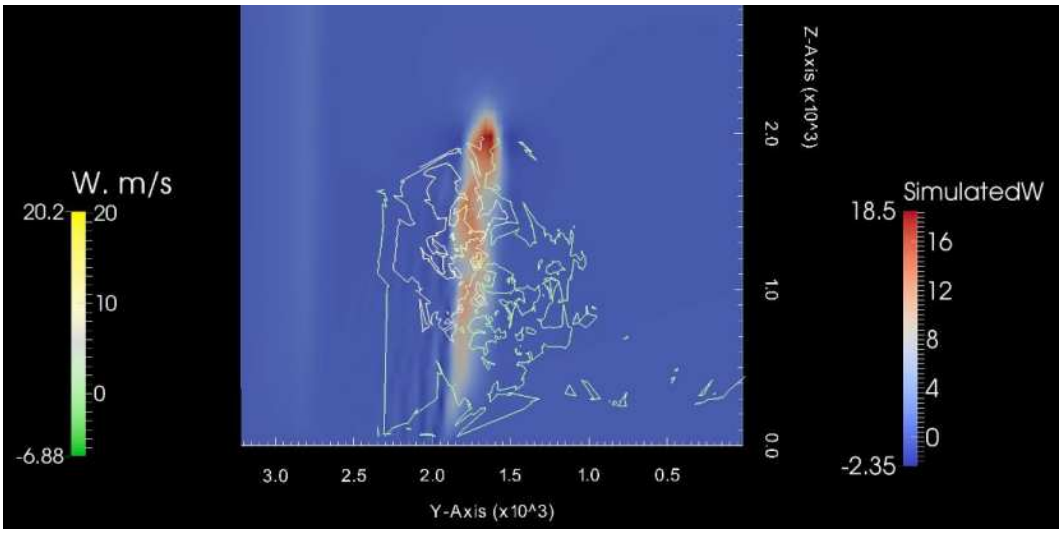

Figure 3. Simulated plume (red/blue vertical wind velocity) and approximately synchronized isolines of the estimated vertical paragliders velocities (-5,0,5,10,15,20 m/s). Time = Ignition + 340s.

Conclusion

This work presented an interesting and unique analysis of an open air fire plume extrapolated from a large amount of paragliders tracks. Vertical speeds of over 20 m/s were observed into a narrow core just over the fire. Simulation of the same event shown the relatively good ability of microscale meteorological models to represent quantitatively the velocity fields and behaviour even with very crude parameterisation consequence of the lack of field data.

Acknownlegements

Authors wishes to thanks competitor Charles Cazaux for its insights, data and contacts with other competitors, Team Russia and S. Gattini for the pictures and the MesoNH team for teir support.

Live fuel moisture and wildland fire behaviour

Philip Zylstra[a]

[a] *Centre for Environmental Risk Management of Bushfires, University of Wollongong, Northfields Ave, Wollongong NSW 2522, pzylstra@uow.edu.au*

Abstract

Live fuel moisture content (LFMC) is a parameter that affects the flammability of plants, and the capacity to measure it remotely makes it an accessible variable for use in fire behaviour models. Although the effect of LFMC on the flammability of fuel particles has clear theoretical support however, the way in which this relates to fire behaviour is complex and difficult to quantify so that empirical studies of heath and forest fires at times yield weak or ambiguous results.

This study examines the way in which moisture affects fire behaviour by using a process-based conceptual framework (Zylstra 2011) to identify feedbacks and complexities that may confound empirical analysis.

Z11 links empirically-derived sub-models of flammability characteristics within a dynamic physical framework where heat is transferred convectively across spaces between leaves, branches, plants and plant strata. The ignitability, combustibility and sustainability of flame from burning leaves interacts with the geometry of the fuel array to determine whether flame will spread across horizontal spaces affecting rates of spread, and vertical spaces affecting flame heights.

Factors are identified that should be considered explicitly in experimental design if LFMC is a consideration, and physical arguments presented to show that where such a range of conditions is not present in the experimental design, the results are inadequate to draw conclusions. In some cases, practical considerations will prevent the lighting of experimental fires under the full range of necessary conditions so that the best understanding will be derived from modelling results. In such cases, misleading conclusions will be drawn unless the model can adequately reflect the complexity presented here.

There exists a strong physical argument for the effect of LFMC on fire behaviour, however this effect is not straightforward and will drive threshold changes and feedbacks. Such changes may represent sudden and dangerous escalations in fire behaviour, so understanding and quantifying these is important. Z11 is a model that can calculate such thresholds and can be used to both inform experimental design and risk-based decision making.

Keywords*: Fire behaviour, live fuel moisture, flammability, Forest Flammability Model, complex systems*

Introduction

Live fuel moisture content (LFMC) is a readily accessible metric that can be measured to varying levels of precision via remote sensing (Yebra *et al.* 2013). Physical arguments suggest that it has an influence on fire behaviour as the presence of moisture affects the flammability or ignitability, combustibility and sustainability (Anderson 1970) of leaves; however debate exists as to the extent and nature of the influence in field conditions and it is therefore rarely or inadequately considered as a component of fire behaviour modelling.

Ignitability has two components – the minimum temperature of ignition (Philpot 1970) and the time to ignition (Gill and Zylstra 2005). While the minimum temperature or endotherm appears to be a chemical property, time to ignition is the time taken for a leaf to be heated to ignition and relates to both the surface area to volume ratio and the thermal inertia of the leaf. Various studies (e.g. Xanthopoulos and Wakimoto 1993; Weise *et al.* 2005; Madrigal *et al.* 2011) have identified moisture content as a major influence in this, although more recent studies at higher temperatures (Engstrom *et al.* 2004; Fletcher *et al.* 2007) have failed to find a relationship.

While the effect of moisture on particle ignition is widely accepted under most conditions, the

influence of LFMC on fire behaviour as a whole is more complex. It has been strongly implicated in the incidence and scale of fires across several landscape studies (e.g. Schoenberg *et al.* 2003; Chuvieco *et al.* 2009; Dennison and Moritz 2009; Caccamo *et al.* 2012) and identified as a key determinant in the behaviour of fires burning through simple complexes such as heath and shrub lands (Weise, Zhou, *et al.* 2005; Davies *et al.* 2009; Plucinski *et al.* 2010). The interaction however is harder to detect in more complex arrangements. Alexander and Cruz (2013) have summarised the results of a series of laboratory and field experiments looking at LFMC effects on behaviour, noting that the correlation is either ambiguous or non-existent when all studies of heath and crown fires are considered; although its role in facilitating crown fire commencement was not examined.
This paper addresses the conflicts by providing a theoretical analysis of the mechanisms by which moisture affects fire behaviour, describing trends, feedbacks and complexities which may mask correlations in studies that do not specifically account for them.

Methods

The role of moisture is described and quantified mathematically through a process-driven model that addresses the limitations identified for laboratory studies. The model is then described conceptually as a basis for explaining anomalous observations, and to provide some guidelines for effective analysis of the relationship.

Issues to be addressed

Two main concerns have been raised over attempts to model the effect of moisture and other particle flammability properties; these are:

1. *Exaggerated effects of LFMC due to inadequate experimental technique*. Empirical models of time to ignition are frequently constructed using small radiant heat fluxes (Fernandes and Cruz 2012; Alexander and Cruz 2013) when analyses at higher convective fluxes have reported little to no relationship (Engstrom *et al.* 2004; Fletcher *et al.* 2007). In addition, it is at times erroneously assumed that all moisture is evaporated before a leaf ignites (Pickett *et al.* 2010), so that models of time to ignition may over-estimate the effect of LFMC at high temperatures typical of field conditions.
2. *Flawed assumptions*. The flammability of plant parts does not automatically scale to the flammability of the whole plant (Pérez-Harguindeguy *et al.* 2013) or stand (Fernandes and Cruz 2012).

Model description

The fire behaviour model (Zylstra 2011) hereafter referred to as Z11 currently utilises empirical models of leaf flammability that were developed alongside the main model. The equations for combustibility and sustainability were developed from experiments that utilised candle flames, where the point of heating for the leaves used a measured heat flux of 145kW/m^2 (Hamins *et al.* 2005). This exceeds the values of 61kW/m^2 measured in the field by Silvani and Morandini (2009) and approaches the maximum value of 150kW/m^2 measured by Butler (2010). Both models found a significant influence of leaf moisture, and predicted flame length and duration values for leaves across 10 sclerophyllous species and a wide range of moisture values with R^2 values of 0.87 and 0.74 respectively.
The main concern expressed in the literature however relates to models for time to ignition. Equation 1 used in Z11 was developed across six sclerophyllous species with moisture contents ranging from oven dried to 200% with combined convective and radiative heating to temperatures from 220^{o}C to 700^{o}C, explaining 90% of the variability for the species and conditions studied. Surface area to volume ratio had the effect of regulating the conductance of heat into the leaf so that leaf thickness T and the

number of sides *s* to the leaf combined with moisture content *m* to form the ignitability coefficient *IC* (equation 2). The effect of leaf thickness is thereby negated when moisture is zero. The units for these equations are percent, mm and ^{o}C, and leaves have either two sides when flat or four when terete. Time to ignition is ψ and temperature is *t*.

$$\varphi = IC97805.26t^{-2.10} + 6452280.04t^{-2.40} \quad \text{Equation 1}$$

$$IC = \frac{mT}{s} \quad \text{Equation 2}$$

Although the temperatures in the muffle furnace used were not as high as those of the Chaparral studies (Engstrom *et al.* 2004; Fletcher *et al.* 2007) and the heat fluxes were not measured; figure 1 demonstrates that when reported moisture and leaf thickness values are used to predict the times to ignition that were measured in these studies, the model of Z11 was well within the target range and moisture content did not artificially slow expected ignition times.

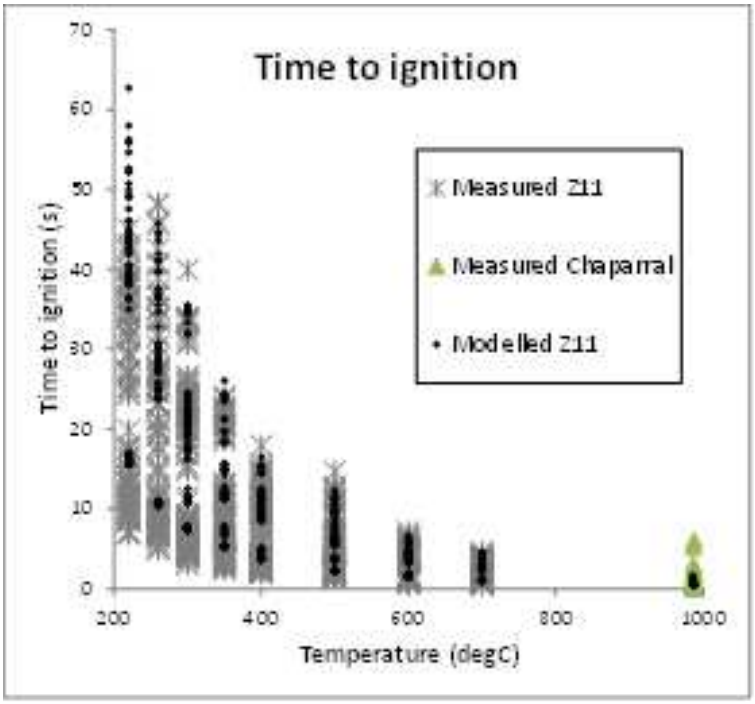

Figure 1. Equation 1 extended to predict the values measured by Engstrom et al. (2004) and Fletcher et al. (2007)

In regard to the second concern, Z11 makes no assumptions about the scaling between leaf flammability and plant or stand flammability, rather this relationship emerges dynamically from a series of interactions calculated in 1s time-steps. Fire propagates in a process analogous to crown fire initiation models such as Xanthopoulos (1990) and Cruz *et al.* (2006), where fuels are ignited by a heat flux that decays across a distance defined by the geometry of the array. Each leaf flammability property explicitly influences propagation as described in Table 1. In this way, the dimensions, position and angle of the flame are adjusted each second according to the capacity for flames to ignite new fuels across spaces between leaves, branches, plants and plant strata, and the time for which these fuels stay ignited.

Table 1. The role of leaf flammability properties in Z11

Flammability component	Influence
Combustibility	The length of flame produced by burning leaves modified by the physics of flame interactions for the number of leaves burning in close proximity defines the flame length for a time-step. Together with the temperature at which these leaves burn, this in turn produces the input to a temperature field. The decay in convective temperature is defined with distance from the base of the flame, and the direction of convective transfer is defined by the angle of the flame as influenced by its length, the wind speed at that point in the forest profile and any blocking effects of the slope.
Sustainability	A cohort of leaves is ignited in each time-step, and these burn for a period of time defined by their sustainability before they extinguish, redefining the flame origin and the total quantity of leaves burning.
Ignitability	Leaves along the vector defined by the flame are exposed to a given temperature defined by their distance from the burning fuels. If this temperature both exceeds the endotherm of the leaves and the time to ignition calculated by equation 1 for that temperature and the ignitability of the leaves is less than the calculation time-step, then the leaves ignite, increasing the quantity of leaves burning. If both conditions are not met, the time-step is considered pre-heating and a proportion of the time to ignition is removed according to the heating received. The leaves are again tested in the next time step.

The way in which the ignitability of a leaf affects flame propagation is shown in figure 2. As the distance increases from the flame base along the *x*-axis, temperature decays along the lower part of the *y*-axis, in this case using the functions given by Weber *et al.* (1995). The time to ignition is modelled against this temperature using equation 1 for a leaf with low ignitability (high moisture content and/or thickness) as shown by the lighter broken line, and for a leaf with high ignitability (low moisture content and/or thickness) by the heavier broken line. At the left of the graph where temperature is highest (such as observed in the chaparral studies), the time to ignition is very short. As temperatures decrease with distance from the flame base, time to ignition increases until it meets the solid horizontal line which marks the time-step used for calculation. The intersection of these lines shows the maximum distance that may be ignited during that time-step. That is, all leaves in a plant crown that lie within this distance will be ignited in that step. As time to ignition is defined by temperature which is in turn defined by distance from the flame base, ignitability can therefore be understood not only as time to ignition, but also as distance to ignition or minimum temperature required to ignite within a given time step.

Equation 1 demonstrates that very high temperatures will indeed overwhelm any small effect of leaf moisture, however high temperatures are not limited to field conditions. Even a candle can produce a temperature of 1400^{o}C (Gaydon and Wolfhard 1979) and thereby exceed the maximum value recorded by Butler (2010) for a crown fire; but in each case this only corresponds to the hottest part of the flame. As time to ignition equates to distance to ignition or minimum temperature required for ignition within a given time, the effect of moisture is to regulate the distance to which leaves can be ignited. Larger gaps can be crossed and more leaves lit simultaneously when they are drier.

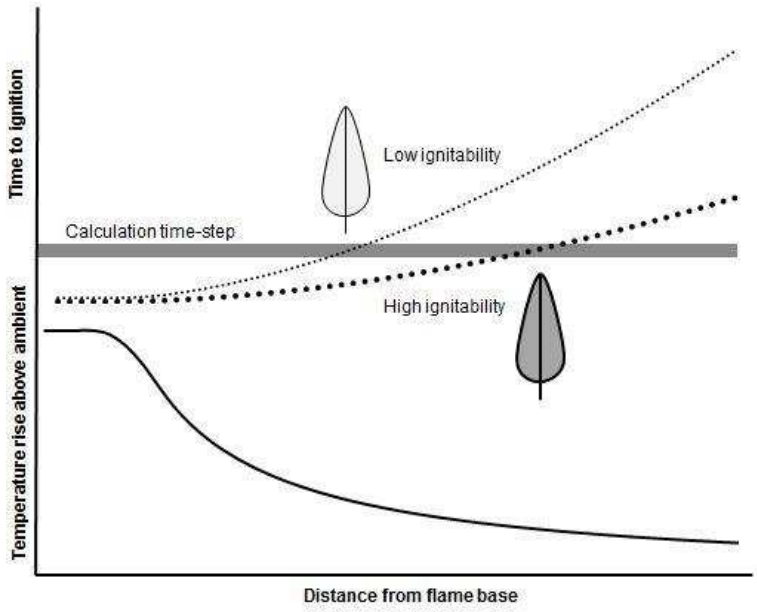

Figure 2. Translating time to ignition into distance to ignition. The curved solid line represents flame temperature, the straight line marks a time-step on the y-axis and the two broken lines mark the time to ignition for two different plant species as calculated using equation 1.

To picture the process, consider a simplified situation where the combustibility and sustainability of leaves are kept constant and can be characterised such that flames are 1.5 times the depth of ignited leaves, the hottest part of any flame is 1300ºC and all leaves burn for 2s. Three different LFMC values will be considered (Table 2) for two-sided leaves in a 0.7m tall shrub with a base extending from the ground, and with leaves separated by 4cm. Pre-heating will be ignored for simplicity and no wind will be considered so that flames are vertical. The value 'minimum temp' in Table 2 is the temperature required to ignite the leaves in 1s or less, found by solving Equation 1 for *t*.

Table 2. Ignitability of leaves in the examples

	Moisture 1	**Moisture 2**	**Moisture 3**
Moisture (%ODW)	70%	220%	250%
Thickness (mm)	0.2	0.2	0.2
IC (Eq. 2)	7.0	22.0	25.5
Minimum temp (ºC)	850	1200	1260

If all three plants are exposed to an identical heat flux from a pilot flame of 0.3m such as might be achieved from a fire burning surface litter, the distances to minimum temperature found using Weber *et al.* (1995) will be 0.28m, 0.12m and 0.08m respectively. That is, in the span of 1s the bottom 28cm of leaves will be ignited in the driest plant producing a plant flame that extends 1.5 times the depth ignited (42cm) beyond the ignited leaves. In the wettest plant however, only 8cm of the lowest leaves will be ignited, producing a flame extending 12cm. The altered heat fields produced by the new flames will allow flame to propagate in the two drier plants, but in the wettest plant the distance to 1260ºC will be less than the separation between leaves and flame will not propagate. As more leaves are ignited in the next second these are added to the total depth of ignited leaves, but because the leaves only burn for 2s the lower cohorts will extinguish in sequence after this time even as new leaves are ignited. The three scenarios are shown in figures 3 to 5.

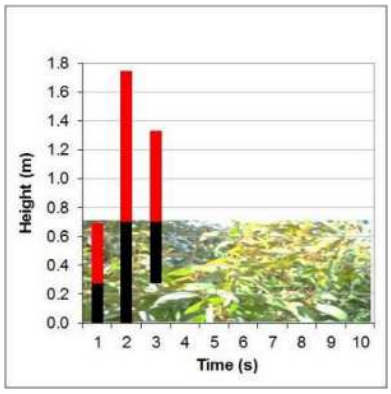

Figure 3. Fire propagation in Moisture 1. Maximum flame height reached is 1.75m, the plant is consumed and flame duration is 3s.

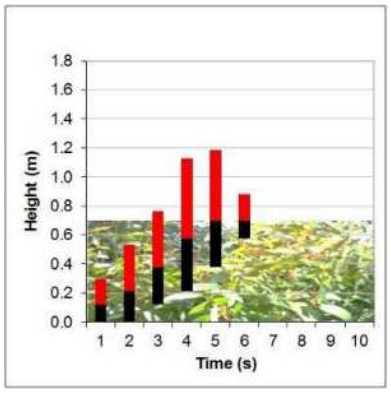

Figure 4. Fire propagation in Moisture 2. Maximum flame height reached is 1.18m, the plant is consumed and flame duration is 6s.

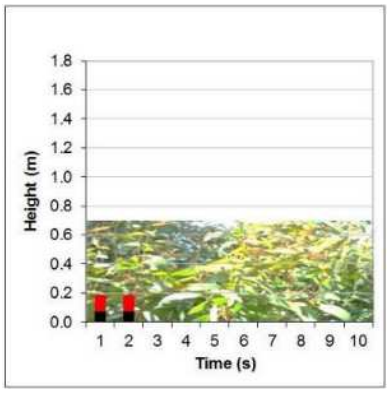

Figure 5. Fire propagation in Moisture 3. Maximum flame height reached is 0.19m, the plant is only partially consumed and flame duration is 2s.

Although these scenarios describe simplified situations and the influence of moisture will be affected to some extent by pre-heating and its effect on combustibility and sustainability of leaves, the basic process by which leaf flammability translates to fire propagation can be understood. Notably, the flammability properties of the leaves did not scale directly to the plant. While only the ignitability of leaves was altered, the sustainability of flame in the plant varied from 2s to 6s and the combustibility varied such that flame heights ranged from 0.19m and 1.75m. In this way, the flammability of plants and stands emerges from numerous factors and should not be assumed from the parts.

Model application

The lack of correlation between LFMC and fire behaviour reported for many field experiments requires explanation, however full treatment is impossible without replication of the exact conditions. In the absence of this information, the principles of fire propagation that have been shown will be used to describe a series of behaviours that can confound the observation of trends.

Much work on fire behaviour has focused on propagation through continuous fuel beds such as dead leaf litter; however such observations can be misleading if applied to discontinuous fuels. Plant communities are characterised by gaps between leaves, branches, plants and plant strata, and the bridging of these gaps can result in threshold changes that are not well captured with statistical methods that do not explicitly account for them.

As convective heat transfer occurs along a vector rather than being radiated in all directions, heat can be directed upward across vertical spaces between strata, or horizontally across gaps between plants. The angle of the trajectory is influenced by the size of the flame providing buoyant uplift, the velocity of the wind acting on the flame and the effect of slope in blocking air intake from one side. In both this way and by the tilting of the fuel array in relation to the flame, the effect of slope may not follow expectations established from fires in continuous surface fuels, but may produce threshold changes in the same way as winds do.

The emergent nature of fire behaviour can introduce feedbacks that obscure trends or even produce opposite trends to those of the larger picture. Consider for example the difference in the height of flames produced in figures 3-5. Larger flames are more buoyant and therefore stand more upright against lateral air movement than do smaller flames, so that if wind was added to those scenarios, the differences in flame height may have been even greater due to tilting of the smaller flames.

Tilting of flames however has the effect of directing the convective stream forward rather than upward, and the propagation of flame between plants in the same stratum requires this forward direction of heat. It can be the case then that when plants produce smaller flames due to higher moisture contents,

the greater tilting of these flames by the wind facilitates forward propagation with resulting faster rates of spread and larger flames as the amount of fuel burning increases. The lowest wind speeds allowing this spread produce a transitional period where temporarily larger flames pulse - in turn standing upright and still due to their size before partially dying out then leaning forward again to spread in a pulsing pattern. Under stronger wind conditions however, the flame of the drier shrub will also propagate forward in the same way, but as it produces a greater convective burst it will also lead to a faster spreading fire.

This phenomenon which may be called *flame angle feedback* is illustrated in figure 6 for a hypothetical heathland modelled with Z11 under two different moisture treatments where LFMC is equal to 80% in one, and doubled to 160% in the other. Rates of spread (ROS) are initially faster in the moist plants than the dry ones, but as wind speeds increase, fire spreads faster in the dry heath.

This is an important aspect that must be factored into experimental design, as the failure to conduct experiments under conditions that will accommodate this feedback can result in weak or erroneous conclusions. Figure 7 illustrates this by examining the correlation between LFMC and ROS for the two scenarios. If experiments in this heath were conducted with winds that did not exceed about 20km/h, it may be concluded that fires spread faster in more moist heaths. It may in fact require experimental burns in wind speeds significantly greater than this threshold speed before any robust correlation can be found. As operational issues frequently preclude burning under such conditions it may be impossible to provide an empirical answer for this situation, however it should be noted that this threshold is specific only to this scenario and others will apply under different slopes, with different species, plant sizes and spacing.

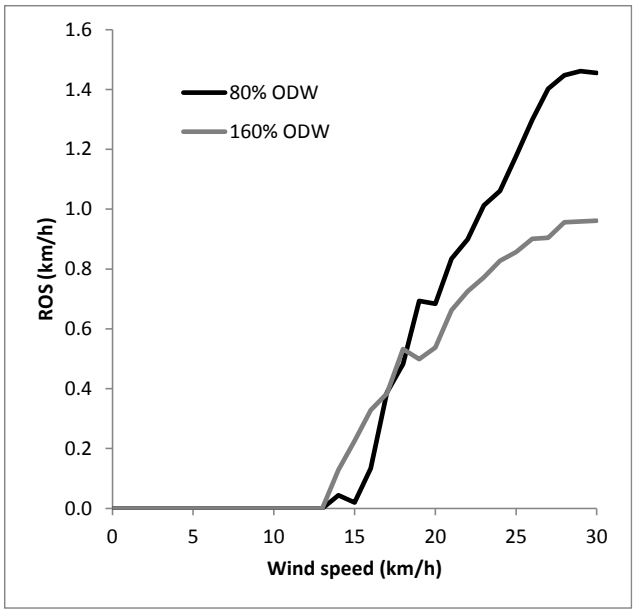

Figure 6. Fire Rate of Spread in two hypothetical heathlands modelled using Z11. Lateral spread initiates under lower wind conditions for the more moist plants, but once initiated, fire spreads faster in the drier plants.

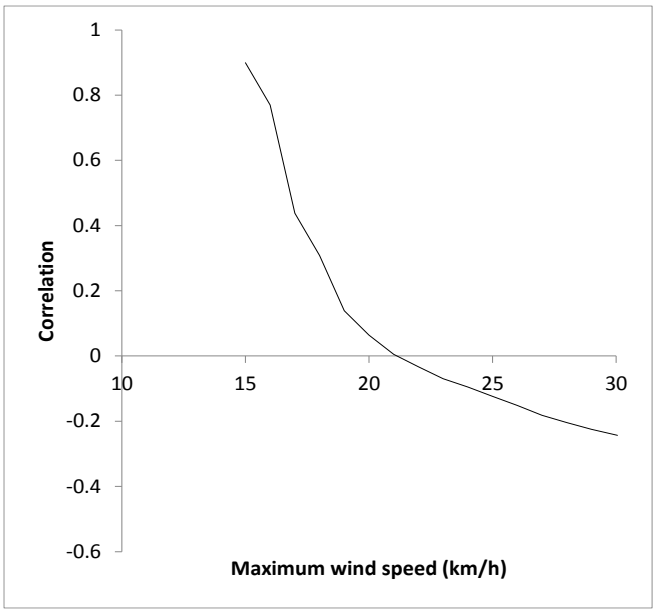

Figure 7. Correlation of ROS with LFMC for the two scenarios in Figure 6. The x-axis indicates the maximum wind speed considered for analysis so that if only fires burning under wind speeds of 20km/h or less are considered, the correlation is positive (i.e. fire spreads faster in more moist fuels). Consideration of higher wind speeds however produces a negative correlation.

Table 3. Summary data from Table 1 in Alexander and Cruz (2013)

Wind speed (km/h)	LFMC (% ODW	ROS (m/min)	Flame height (m)
23	135	16.8	19.8
15	100	10.8	14.8
19	95	27.4	30.5

This relationship is evident in one of the examples reported in Alexander and Cruz (2013), where the results from published fires are summarised in Table 3. As the LFMC is reduced from 135% to 100% the ROS declines along with the flame height, but when the wind speed is increased for a second dry scenario, the ROS and flame height increase to well beyond the value in moist fuels, even though the wind speed remains lower than in this example. Assuming that all other factors are constant, this is exactly the pattern that may be expected if the wind speeds lie across a threshold.

Flame angle feedback becomes more complex when more plant strata are considered, as more vertical gaps between fuels are introduced in the process. High wind speeds may have the effect of tilting the flame so far that crown fire does not initiate (e.g. Luke and McArthur 1978; Buckley 1990) and the fire slows down, or if tilting further forward in a dense shrub layer the greater flame length produced may initiate a crown fire. The response will vary depending again on the flammability, size and density of plants, on the degree of protection from wind provided by the higher strata, and on the vertical gap sizes.

As the length of flame from burning plants relates to the depth of foliage and therefore the number of leaves or quantity of fuels burning, the shape of plant crowns can have an important effect on flame dimensions. In general, the largest flames are produced when the angle of the flame intersects the plant crown at its longest axis, igniting the most leaves. Tall narrow plants will therefore produce the largest flames when the flame angle is close to vertical, so if the leaves are moist and the flame is more easily tilted by wind, the effects of moisture in reducing flame length will be accentuated. Conversely, if the plant is wider than it is tall, smaller initial flames from moist leaves may ultimately ignite more of the plant if directed forward. These effects may however be obscured if plants are in close enough proximity to allow forward spread, as the shape of individual plants will become irrelevant.

Discussion

A fundamental tenet of complex systems theory is that such systems are self-organised (Bak *et al.* 1988); that is, behaviours emerge from many interactions and cannot be predicted from initial trends. While broad trends may be identified, specific predictions cannot be made from these alone and the interactions of the various agents must be modelled. Increasing greenhouse gas concentrations warm the planet for example, but the mean temperature of an upcoming season will not be well predicted without knowledge of factors such as the circulation of heat within the system via the Southern Oscillation Index. The interactions of multiple agents can confound individual predictions, so that even though CO_2 levels increase, global temperatures fall for a short period and even though leaves in a forest become drier, fires under some conditions burn with smaller flames and spread more slowly. The presence of feedbacks and threshold changes (also known as criticality or tipping-points) are part of such systems and do not negate the importance of individual factors.

Modelling of fire behaviour as a complex system suggests that the quantity of moisture in plant leaves is an important influence on the behaviour of wildland fires. The scale and direction of its influence will vary markedly with the conditions, the species and the structure of the fuels burning, but the overall effect is that drier plants produce larger, faster fires.

The apparent influence of LFMC on fire behaviour becomes less discernable as fuel arrays increase in complexity - as expected if the system is self-organised. While Zylstra (2011) showed that the evaporation of water explained 90% of the variability in time to ignition for individual leaves and the

effect of LFMC was discernable in lab experiments with model shrubs etc; field experiments involving more complex fuel arrays have found little correlation. The larger heat fluxes and temperatures involved fail to explain this; however the feedbacks and threshold changes that can be expected from bottom-up simulation of the processes can provide viable answers for these apparent anomalies.
Attempts to quantify the effect of LFMC empirically therefore must be designed around the location of thresholds and account for the influence of feedbacks; although this will not always be possible due to operational constraints. The most vital component of this is that fires are examined across a broad coverage of wind speeds, with less wind required when burning up steeper slopes.
Where adequate studies cannot be carried out for certain fuel arrays, Alexander and Cruz (2013) propose that appropriate physics-based models can be employed to resolve issues. It will be critical that such models are capable of capturing the complexity described here. The Z11 or Forest Flammability Model used in this study is currently undergoing software development and validation through the Centre for Environmental Risk Management of Bushfires at the University of Wollongong.

Abstract
Forest fire is significantly affected by wind. However, meteorological wind is modified by terrain topography in such a way that a different value of wind speed and direction is given on every point. To estimate forest fire propagation on such conditions it is necessary to couple a wind field model to the forest fire propagation model. These models are time consuming from the computational point of view and may be parallelised to make them feasible in an operational scenario. So, a map partitioning has been applied to accelerate wind field calculation. The results show that the wind field and the forest fire propagation prediction are not significantly affected by map partitioning and the time to reach the forest fire prediction is significantly reduced.

***Keywords**: Wind field, map partitioning, data parallelism, forest fire propagation prediction*

Introduction

Forest fire propagation prediction is a difficult task due to the amount of variables that take part in the process, the complexity to develop a computational model that faithfully describe the real phenomenon and the lack of accuracy in certain environmental measurements or terrain features. Therefore, despite there exists several fire spread simulators [1][2][3], the results are still far from real behaviour. To overcome such difficulty a Two-Stage prediction strategy [4][5] was developed to improve the quality of input parameters. In the first stage a Genetic Algorithm (GA) is used to determine the values of the parameters that best reproduce the fire propagation during an observation interval. GAs work in an iterative way where at each iteration a set of individuals (representing fire scenarios) are executed, the provided results are compared to the actual fire propagation to rank them and the genetic operators are applied to determine the next generation. At the end of the iterative process, the best individual is used in the second stage to predict the fire propagation in the next time interval. In this work FARSITE [2] is used as forest fire propagation simulator.
However, certain parameters, such as wind, present a spatial distribution or variation along the terrain due to topographic effects. The wind provided by a global weather forecast model or measured at a meteorological station in some particular point is modified by the topography of the terrain and has a different value at each point of the terrain. Therefore, a single value does not represent the wind in each point of the terrain. To estimate the wind speed and direction at each point of the terrain it is necessary to apply a wind field model that determines those values at each point depending on the terrain topography [6].
When coupling wind field and forest fire propagation models, each individual consists of executing two computing demanding simulations in a pipeline way. First, a wind field model must be executed to provide a high resolution wind field adapted to the underlying topography. The output provided by this wind field model will be fitted into a forest fire spread simulator to generate the fire front evolution Figure 1).

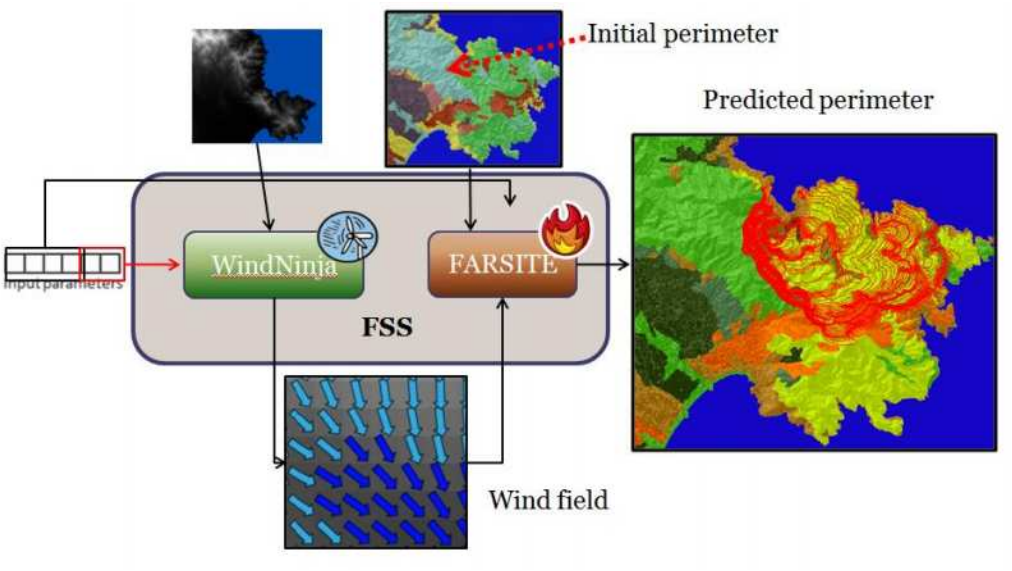

Figure 1 –Coupling Model

WindNinja and map partitioning

WindNinja [7] is a wind field simulator that calculates the effect of topography on wind flow and provides the wind speed and direction at each point of the terrain given a meteorological wind value (Figure 2). The main problem is that, when the map has a considerable size (30x30 Km) and the resolution is high (30x30m), it requires an unaffordable execution time and a huge amount of memory that may not be available on a single computational node. Such limitations make impractical the effective prediction of fire spread with accurate wind field. Moreover, the amount of memory required to solve the wind field increases linearly with the number of cells of the map making unaffordable to be solved a map with a large number of cells in a single node. It means that calculating the wind field of a 1500x1500 cells map on a single node with 4GB of main memory fails and no output is delivered. Therefore, it is necessary to apply some parallelization technique to reduce execution time and memory requirements.

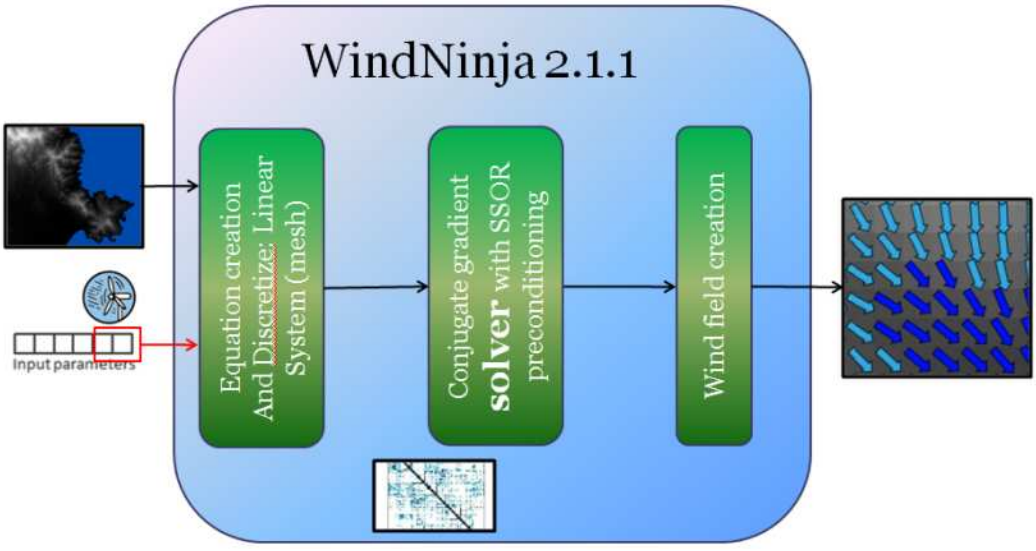

Figure 2 –WindNinja

To reduce the computation time of the wind field calculation a map partitioning method (Figure 3) has been applied to benefit from the parallel architectures. In this case the wind field is calculated in parallel on each part of the map and then the wind fields of the different parts are joined to form the global wind field. Furthermore, by partitioning the terrain map, the data structures necessary to calculate the wind field in each part are reduced significantly and can be stored in the memory of a single node in a current parallel system. Therefore, the existing nodes can perform computation in parallel with data that fit the capacity of the memory on each node.
However, wind field calculation is a complex problem that has certain boundary effects. So, the wind speed and direction in the points close to the boundary of each part may have some variability and differ from those they would have obtained if they were far from the boundary, for example if the wind field is calculated over a single complete map. To solve this problem, it is necessary to include a certain amount of overlapping among the map parts. So, there is a margin from the beginning of each part and the part cells itself. The overall wind field aggregation is obtained by discarding the calculated margin fields overlap of each part. The inclusion of an overlapping to each part increases the execution time, but the variation in the wind field is reduced significantly [8]. This map partitioning approach can easily be implemented in a Master/Worker MPI application where the Master creates the map parts and distributes them to the workers, the workers calculate the wind field for each part and return the results to the Master that aggregates the wind fields in a complete wind field. Once the map partitioning scheme has been applied, the resulting wind field map has the same dimensions as the original one.

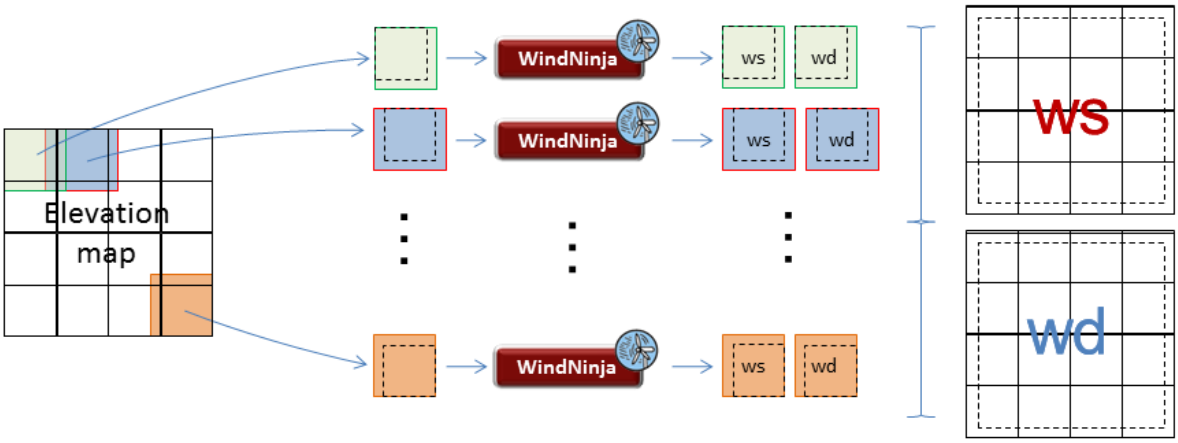

Figure 3. Map partitioning

The methodology has been tested with several terrain maps, and it was found that parts of 400x400 cells with an overlap of 50 cells (table 1) per side provides a reasonable execution time (120 sec) with virtually no variation with respect to the wind field obtained with a global map. With this type of partitioning, each process solves an effective part of a map of 300x300 cells. The inclusion of a wind field should improve the accuracy of forest fire propagation prediction, but it is necessary to test the effect of map partitioning on forest fire propagation prediction.

Table 1- Similarity indexes for different partitioning

Speed (mph)	Partitioning	RSMESp (mph)	Speed >1 (mph)	MaxSp (mph)	RSMEAng (^{0})
5	6x6	0.191	8183	3.76	1.703
5	5x5	0.187	7818	3.76	1.571
5	4x4	0.188	7531	3.76	1.701
10	6x6	0.383	60920	7.50	1.703
10	5x5	0.373	49565	7.50	1.571
10	4x4	0.375	49182	7.50	1.701
15	6x6	0.574	156479	11.3	1.703
15	5x5	0.559	140826	11.3	1.571
15	4x4	0.563	140196	11.3	1.701

Effect of map partitioning on forest fire spread prediction

As it has been stated in previous section map partitioning does not generate extreme differences in wind fields, but it necessary to analyse the influence of such differences in forest fire spread prediction. To carry out such analysis it is necessary to execute a lot of propagation simulations considering maps with different topography terrains, different wind conditions, different vegetation types, different canopy covert and different fire positions. So, different terrain maps corresponding different areas of Spain has been selected. The raster maps used are composed by 1500 rows and 1500 columns with 30m resolution per cell. That means that the map has a dimension of 45km x 45km.
Tables 2 show the difference on burned areas for different types of vegetation (brush, grass, conifer and rough) and different map partitioning considering a meteorological wind of 15mph and a direction of 45º. This meteorological wind has been considered because it is the winds that generate larger differences in wind field. For each configuration, the evolution had shown in the time 24h. In particular, fire rows shows the results considering fire ignition points over terrain zones with a wind speed difference larger than 1mph, shows the results considering fire ignition points near the terrain point with differences larger than 1mph (it means that at some point of the propagation the fire front crosses that zones) and third rows shows the results considering fire ignition points far from those different wind speed zones (it means that the fire front does not cross those zones).

Table 2- Difference for ignition point from different wind zones.

	5x5				15x15			
	Brush	**Conifer**	**Grass**	**Rough**	**Brush**	**Conifer**	**Grass**	**Rough**
Over	0.080	0.213	0.103	0.240	0.114	0.353	0.128	0.420
Near	0.063	0.035	0.072	0.051	0.073	0.047	0.096	0.069
Far	0.037	0.028	0.025	0.013	0.038	0.030	0.040	0.014

From the experiments carried out it can be observed that as the number of parts is increased, the error increases proportionally to that number of parts. This is due to the fact that the wind field generated when the parts are very small has a larger difference from the global map wind field and this larger differences provoke larger differences in fire spread predicted area.
On the other hand, it can be observed, as it was expected, that the position of the fire is very significant. If the fire does not cross points with significant wind speed difference the spread area difference is negligible. When the fire ignition point is on large wind speed difference zones the difference in burned area is larger, but not extremely different. These results are also presented in figures 4 that present an example of each one of the ignition point situation. In these figures the blue dots represent the zones with large wind speed difference, the yellow perimeter represents the Global Map Wind Field fire propagation, the red one represents the partitioning 5x5 map wind field fire propagation and the green

one the partition 15x15 map wind field fire propagation. In figure 4c it can be observed that there is no appreciable difference among the three perimeters. However, figures 4a and 4b show a small difference that is increased when the partitioning divides the map in more parts.
It must be considered that the show results were obtained considering that the fire only cross a large difference zone, but if there are several of such large difference zones on the fire area, differences in fire propagation prediction will be larger since the effects are accumulative.

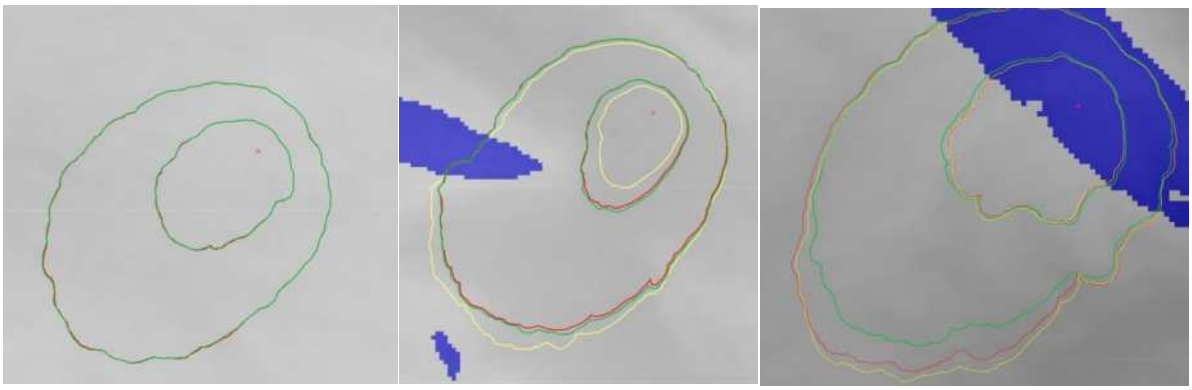

Figure 4 –Propagation Fire

Study case: La jonquera 2012

This analysis was carried out using as study case the fire that occurred in La Jonquera (Catalonia, Spain) in July 2012. In this case, the two-stage methodology has been applied considering 25 individuals per population and iterated for 10 generations. Since the Genetic Algorithm has a stochastic component the experiments have been repeated 3 times using different starting populations. For each case 4 fire fronts are compared:

- The real fire propagation.
- The predicted fire front obtained by considering a homogenous wind value along the whole terrain.
- The predicted fire front obtained by introducing a wind field calculated considering a complete map (1500x1500 cells).
- The predicted fire front obtained by introducing a wind field calculated by map partitioning (5x5 parts of 300x300 cells with 50 cells of overlap on each direction).

The results considered to determine the correctness of the approach are the following ones:

- The RMSE (Root Mean Square Error) estimates the difference among the wind speed (and direction) on each point of the terrain. The Root-Mean-Square Error (RMSE) is shown in equation 1. More precisely, for each map cell (N), the value of wind speed in that particular cell i obtained when no partition is applied to the input DEM map (NP_{ws_i}) is compared to the speed obtained in the same cell when applying the map partitioning strategy with a given partition scheme (SC_{AXBws_i}). The same procedure is also applied to wind direction just changing the corresponding terms of equation 1 to wd.

$$RMSE_{AxB}(ws) = \sqrt{\frac{\sum_{i=0}^{N}(NP_{(ws)_i} - SC_{AxB(ws)_i})^2}{N}} \quad (1)$$

- The Symmetric difference among the real fire perimeter and the fire front obtained by taking into account the three wind field schemes (homogeneous, complete map wind field and map partitioned field). This equation calculates the difference in the number of cells burnt between the predicted area by 2 different WindNinja configurations. In this case, the area predicted using a global map wind field (GMWF) is used as reference propagation. Formally, this equation corresponds to the symmetric difference between the global map wind field area (GMWF) and the partitioned map divided by the GMWF area, so as to express a proportion. ∪(GMCell,PCell) is the union of the number of cells burned in the GMWF and the cells burned in the partitioned map, ∩(GMCell,PCell) is the intersection between the number of cells burned in the GMWF propagation and in the partitioned map wind field, and GMCell is the number of cells burned using Global map wind field.

$$D = \frac{\cup\,(GMCell, PCell) - \cap\,(GMCell, PCell)}{GMCell} \quad (2)$$

- The execution time considering the complete 2 stage process.

4.1. Experimental results

Table 3 summarizes the results. It shows the wind speed RMSE and the prediction error and prediction times for each wind field scheme (homogenous wind, complete map wind field and partition map wind field) considering three initial population. It can be observed that the differences between the wind fields (RMSE) are very small and, on the other hand, the introduction of a wind field improves the quality of the prediction significantly. Comparing the homogenous wind propagation against the complete map wind field propagation the error is reduced between 20% and 35%. When comparing the homogeneous wind propagation against the partition map wind field propagation the error is reduced between 16% and 33%. This means that the map partitioning does not modify the fire propagation prediction significantly. However, the execution time of the two-stage process shows that the execution time to reach a prediction is significantly reduced when applying a map partitioning strategy. The time reduction varies between 47% and 70% which means a significant time saving.

	RSMSE (mph)	**Homogeneous Wind**		**Complete map Wind Field**		**Partition map Wind Field**	
		Pred. Error	**Exec. Time (s)**	**Pred. Error**	**Exec. Time (s)**	**Pred. Error**	**Exec. Time (s)**
Pop. 1	0.14	0.74	255	0.59	967	0.62	295
Pop. 2	0.12	0.53	700	0.42	1407	0.35	739
Pop. 3	0.16	0.42	491	0.28	1195	0.33	530

Table 3.- Comparison of wind field schemes

The four fire perimeters for population 1 are shown in figure 2. The green perimeter represents the real fire propagation, the yellow one represents the homogenous wind fire propagation prediction, the red one represents the complete map wind field fire propagation prediction and the blue one the partition map wind field fire propagation.

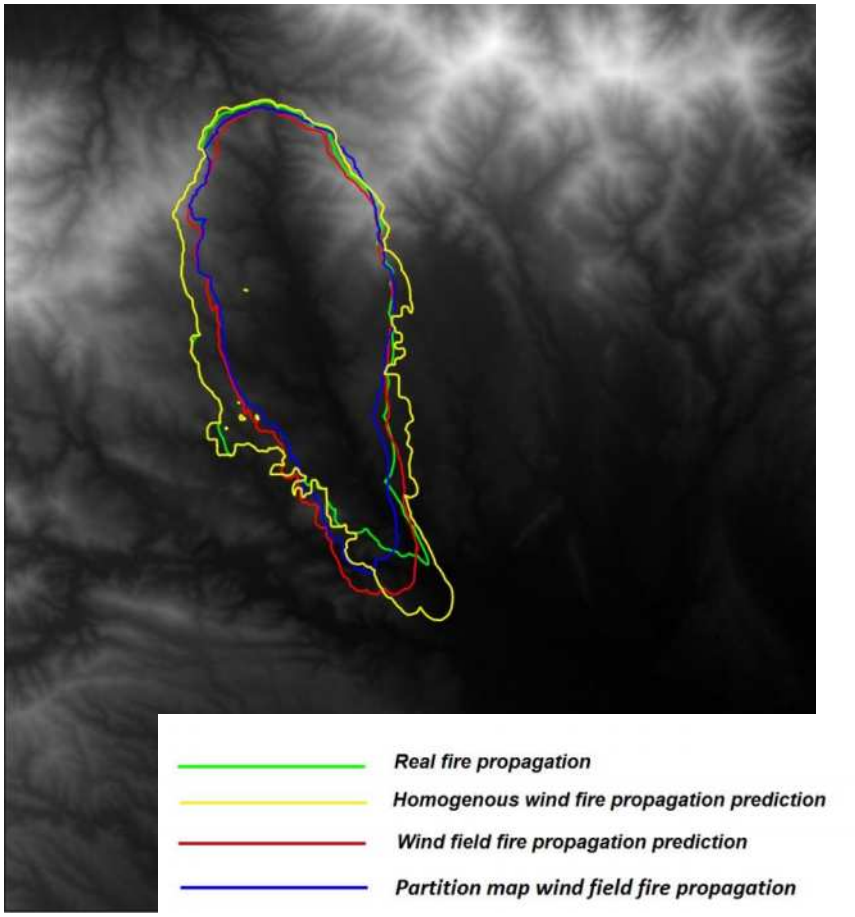

Figure 5. Real and predicted fire perimeters

Conclusions

Coupling wind field and forest fire propagation models is a promising approach to improve forest fire propagation prediction. However, such coupling demands high computing capabilities and takes long execution time. To overcome such difficulties a map partitioning approach has been defined to parallelise wind field calculation and reduce execution time. The results on synthetic and real fires show that the wind field and forest fire propagation prediction are not significantly affected by map partitioning and the parallelisation is effective.

Abstract
Wildfire models have been widely applied to the prediction of fire front evolution, in order to obtain useful information for evacuation plans and fire management. A major difficulty in treating wildland fires is related to the complexity of the phenomena that are involved. In addition, it is difficult to obtain accurate input data for the models, especially in the case of on-going fire events. In fact, wind and weather data, available from meteorological stations, fuel characteristics and orographic characteristics data are often inaccurate. Furthermore, some of these data may change during the fire event, so a prediction is necessary. Results obtained from models are therefore affected by errors. Probabilistic approaches are useful in order to overcome some of these problems, but this requires the use of suitable models in order to perform large number of simulations. Over the last decades, empirical and physical based models have been proposed. Physical based models provide detailed results but requires higher computational cost than empirical models. In order to use physical based models for risk analysis and multi-scenario analysis it is necessary to reduce their computational time, which can be achieved through model reduction techniques.
In this paper, Proper Orthogonal Decomposition technique (POD) is applied to the reduction of a physical model. A simple one-dimensional physical model has been selected in order to test the approach. This model is based on conservation equations and it is built by setting some of the parameters through empirical data collected during field fire experiments. In this first work, slope and wind contribution are not considered. POD permits to extract the spatial basis of the problem and capture the main features of the system with reduced requirement of computational resources. A comparison shows that the results of the reduced model are close to that of the full model, but the computational time for solving the energy equation is reduced to about 10% of that required by the full model.

Keywords*: wildfire, reduced model, Proper Orthogonal Decomposition, fast physical model*

Introduction

Wildfires are complex natural phenomena that threaten both human lives and infrastructures and that have caused various disasters in the last years. Wildfire are particularly destructive and difficult to manage if proper and effective fire fighting actions are not taken in time. For this reason the prediction of wildfire evolution and propagation plays a key role and can greatly help in increasing the efficiency of fire-fighting operations. In the last decades several mathematical models have been developed to study the behavior of wildfires. The models available in the literature can be divided in three groups: theoretical, empirical and semi-empirical (Pastor *et al.* 2003). Theoretical model are also called physics-based model (Mell *et al.* 2007). In the literature various software based on physical models exist, including FIRESTAR, FIRETEC, FIRELES, WFDS (Morvan 2011). Physical models of wildfires are based on the conservation equations that describe mass momentum and energy conservation, radiative heat transfer, reaction and diffusion. Such an approach leads to complex

mathematical models involving a system of coupled, non-linear partial differential equations. As a consequence, the prediction of wildfire propagation through physical models require large computational times and relevant hardware resources (Sullivan 2009). Furthermore, wildfire modeling involves large computational domains and a wide range of time scales which makes physical models not suitable as operational tools for real-time calculations. Empirical models are developed correlating experimental data while semi-empirical model are based on energy conservation but do not distinguish the different modes of heat transfer (Mell *et al.* 2007). Typical examples of empirical models are those one proposed by Rothermel (1972) and McArthur (1965) which have been largely employed because of their simple mathematical structure and the capability of predicting key quantities such as the rate of spread (ROS). Empirical models are typically algebraic and very cheap from a computational point of view. For these reasons they represent a valuable operational tool (Mandela *et al.* 2012). However, empirical models treats the interaction between the physical phenomena in a oversimplified manner. This is the case, for example, of wind-wildfire interaction which is often predetermined and does not account of buoyancy and turbulence fluctuations. Furthermore, empirical models cannot predict key local quantities in a wildfire, such as temperature and heat flux. Empirical models are widely used in order to predict the fire spread because they give predictions with a computational cost that is lower and lower than the event evolution. On the other hand these models in some condition are not able to give accurate results.
In this framework, with the aim to reduce the computational cost of physical models, in this paper an approach of modeling based on proper orthogonal decomposition (POD) has been proposed. It is the first time that POD is applied to a wildfire prediction model. Here a one dimensional model for the investigation of fire propagation over a flat ground is proposed. The model is calibrated using a set of experimental measurements gathered during field fire experiments. Then, POD technique is introduced to derive a reduced order model that allows to investigate the fire phenomenon with a reduced computational effort. Finally, the capabilities of the POD model are assessed and a parametric analysis is carried out. To summarize this paper constitute the first work on the use of model order reduction technique for wildfire analysis.

Experiments and Models description

2.1. Collection of experimental data

Fire behaviour was assessed in four field fire experiments (Figure 1) in North-West Italy (Ascoli *et al.* 2013) carried out on a flat terrain in grassland fuels dominated by *Moliniaarundinacea* Shrank. Fire experiments were conducted under moderate weather at one burnday in 2009 during the winter dry season when grass fuel is fully cured.
Fuel characteristics were measured in all fire experiment sites before burning. At each site, fuels were harvested in six 1 m^2 quadrates and dried in the laboratory to determine the fuel load. Fuels were entirely constituted by dead (fully cured grasses) fine fuels (< 6 mm in diameter). Fuel bed depth and cover were measured every 0.5 m along six linear transects (length =10 m) at each fire site. Flammability parameters (surface area to volume ratio, moisture of extinction, heat content) were derived from published values for similar grass fuels (FCCS Inferred variables)[1].Fuel cover was 100% at all sites while mean fuel bed depth was 14 cm. Fuel load and bulk density ranged between 4.29to 5.50 t ha^{-1}, and 2.2 to 7.1 kg/m^3, respectively. Dead fine fuel moisture was assessed at the time of each fire experiment by collecting five samples of grass leaves (50 g of fresh weight each). Fresh samples were weighed in the field using a portable scale, and then dried in laboratory. Fuel moisture (dry weight basis) ranged between 11-19%. In order to let the fire front reach a pseudo-steady state, each fire

[1]http://www.fs.fed.us/pnw/fera/fccs/inferred_variables/table2_metric/table2_metric.htm

experiment was ignited upwind by line ignitions of 25 m in length, and the fire was allowed to spread for 50 m before being suppressed along a fuel break. During each experiment, fire behaviour was assessed at a microplot scale (Fernandes *et al.* 2001; Vacchiano *et al*. 2014) by measuring the arrival time of the fire front at the vertices of a triangle and computing the rate of spread according to the trigonometric method of Simard *et al*. (1984). At each fire experiment site, 8 equilateral triangles (10 m side) were visualized using 2 m rods placed at each triangle vertex. The time of arrival of the fire front was measured using K-Type thermocouples (0.4 mm in diameter) positioned at each triangle vertex within the grass fuel few centimeters above the soil (< 10 cm) and connected to a data-logger buried one meter apart. This allowed to measure flame temperature every second during all combustion phases. Flame height was assessed by four observers which used as a reference scale the increment markers painted on each rod (0.5 m).
Air temperature and moisture, and wind speed and direction were assessed every 30 seconds by two weather stations positioned at a height of 2 m upwind to the experimental plot, so as to couple weather data to fire behaviour observations. In a few cases, marked changes in wind direction occurred during the burn. However, the microplot approach allowed to identify backfire, flank fire and head fire phases. Time since last rain was 19 days, air temperature and moisture, and wind speed ranged between20 to 27%, 19 to 25°C, and 2.8 to 7.1 km h^{-1}, respectively.

Figure 1. Field fire experiment

In total, 32 rate of spread observations and 32 time-temperature profiles were collected, each associated with fuel characteristics (load; bulk density; moisture), environmental conditions (slope; wind speed) fire behaviour (rate of spread; back, flank or head fire phase) and effects (fuel consumption). Rate of spread ranged between 0.8 to 14.2 m min^{-1}. Only observations corresponding with negligible wind velocity and in flat ground have been considered for the model development. Fuel consumption was assessed soon after the fire by collecting remaining charred fuels in six 1 m^2 quadrats and ranged between 75 and 90% of the pre-fire mean fuel load. Maximum flame temperature ranged between 244°C and 733°C. Average residence time above 60°C and 300°C were 183 and 21 seconds, respectively.

Model description

In this paper a one-dimensional model was developed in order to investigate the fire propagation in a grass-shrub flat and the corresponding temperature time evolution. The computational domain considered is the one described in the previous section. The fire front evolves in the domain where four thermocouples (T1, T2, T3, T4) are located, after 10 m, 20 m, 30 m, 40 m from the ignition point. The four zones between the thermocouples will be later on called section A,B,C,D.

In order to show a better description of the domain, a schematic is reported in Figure 2.

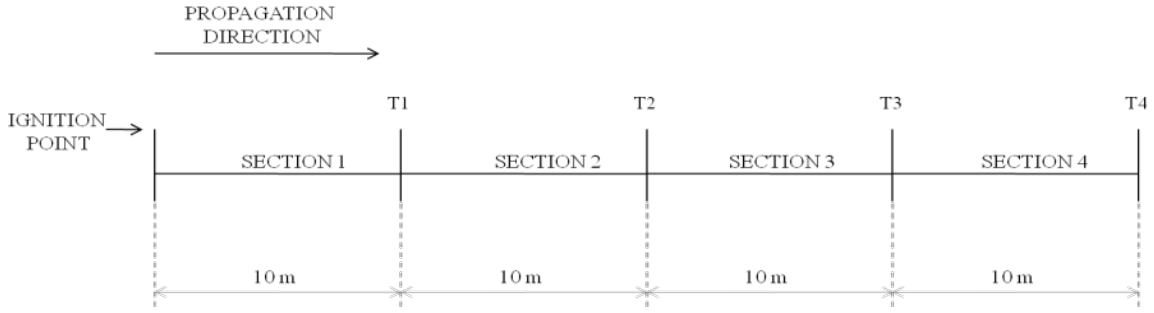

Figure 2. Experimental and model domain

The model is based on energy equation for the fuel array.

$$\rho c \frac{\partial T}{\partial t} = k \frac{\partial^2 T}{\partial x^2} - h(T - T_e) - \frac{H}{s}\frac{dM}{dt} + \Phi_{RAD} \quad (1)$$

The mass rate variation, according to Balbi *et al.* (1999) was described using a constant rate of change after reaching the ignition temperature:

$$\frac{dM}{dt} = -\alpha M \quad (2)$$

The terms of the right-hand side of Eq. (1) account for heat transfer due to thermal diffusion, convection ad radiation. A further term appears and accounts for the heat of reaction due to fuel combustion. Fuel properties are different in the four sections of the domain highlighted in Figure 2. In fact both fuel depth and fuel array density are not the same in all the experimental field. In order to obtain results that describes the overall fire behavior the fuel properties used in the model are the averaged ones. Density and specific heat are evaluated considering the fuel array as a porous medium. The convective losses are considered as proportional to the difference between the fuel array temperature and the environmental temperature. The convective losses coefficient was evaluated using experimental data.

Temperature time evolution measured during the experiment was used to evaluate the unknown coefficient in the energy equation. Experimental temperature profile (Figure 3) was investigated and its portion dominated by convective losses (zone 1) was considered for the evaluation of the convective heat transfer coefficient The linearized reaction rate α was estimated considering the portion of temperature evolution (zone 2) mainly affected by the heat release due to combustion The radiative term was estimated using Stefan-Boltzman law (Incropera, Dewitt 1996). The emissivity has been evaluated as described in Pastor *et al*. (2002) ,while the height of the flame is also experimentally determined. The considered radiative term is:

$$\Phi_{RAD} = r F_{ij} \varepsilon \sigma T^4 \quad (3)$$

where r is evaluated using the same curve used for evaluating convective losses coefficient and mass losses coefficient. In this case the zone C of Figure 3 has been considered, when the arriving flame front exchange radiative thermal flux to thermocouple.

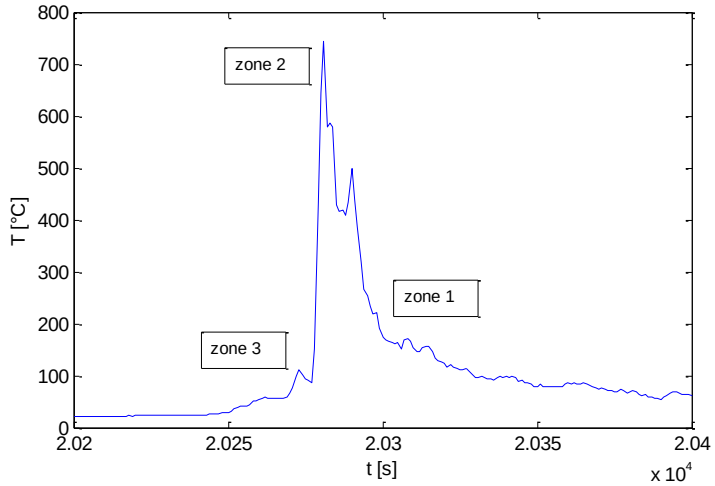

Figure 3. Temperature evolution collected to a thermocouple

Equation (1) is discretized using an implicit finite difference scheme (Ferziger, Peric 2002) and the resulting system of ordinary differential equation is:

$$\boldsymbol{C\dot{T} = AT + DT^4 + f} \tag{4}$$

This is the full-model that is solved in order to obtain the temperature distribution. Time integration is performed using the implicit backward Euler method while non-linearity due to radiative heat transfer are treated through the Newton-Raphson algorithm. Dirichlet boundary conditions were imposed at the left and right boundaries. As initial condition in the first 0.4 m of the domain a sinusoidal temperature distribution with a maximum of 700 K was imposed, in order to represent the fuel ignition. The initial mass per unit area is 0.39 kg/m^2 everywhere.

2.3. POD reduced model

POD is a technique able to capture the main characteristics of a system behavior with a dimensionally reduced model (Sirovich 1987). The reduction is carried out using a collection of sampled values of the considered field called snapshots. The snapshots at M different time are collected in the so-called *snapshot matrix S*, a N x M matrix. Snapshots can be obtained from experiments or simulations. The snapshots matrix can be expressed as:

$$\boldsymbol{S \cong Ba} \tag{5}$$

where $a \in \mathbb{R}^{KxM}$ is the coefficients matrix and $B \in \mathbb{R}^{NxK}$ is the matrix of the truncated basis. N and K are respectively the orders of full model and reduced model.
In order to find the K best "modes" to describes the system an eigenvalue problem is solved. For details refer Bialeki *et al*. (2005). Using this procedure, the system is solved for the temporal contribution of the temperature field α because the space contribution is included yet in the matrix B.

$$\boldsymbol{T = B\alpha} \tag{6}$$

Using (6) and multiplying by B^T equation (4) becomes:

$$\boldsymbol{\tilde{C}\dot{\alpha} = \tilde{A}\alpha + B^T D(B\alpha)^4 + B^T f} \tag{7}$$

where

$$\widetilde{\boldsymbol{C}} = \boldsymbol{B}^{\boldsymbol{T}}\boldsymbol{C}\boldsymbol{B} \text{ and } \widetilde{\boldsymbol{A}} = \boldsymbol{B}^{\boldsymbol{T}}\boldsymbol{A}\boldsymbol{B} \quad (8)$$

The full model dimension is 4000. The POD basis chosen for the analyzed problem are 160, therefore the dimension is reduce to the 5% of the initial one.

Results

Temperature distribution at different instants of time obtained with the full model is detailed in Figure 4. It shows that fire rapidly reaches a shape that does not change anymore in time; this condition will be later on called pseudo steady state. The temperature profile in the combustion region varies only in the first 500 s then pure propagation occurs. As a result, the rate of spread is constant.

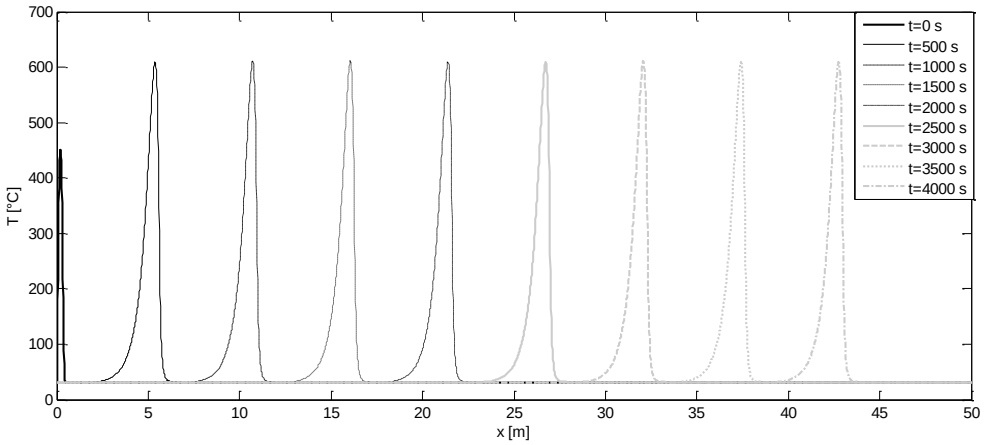

Figure 4. Temperature distribution at different time -Full model

In order to better compare the results obtained with the full model and the experimental ones the average rate of spread in the sections B, C, D of the experiment of the experimental fire front is reported in Figure 5. Figure 5 indicates that a good agreement between experimental ROS and the rate of spread calculated with the proposed model is achieved.

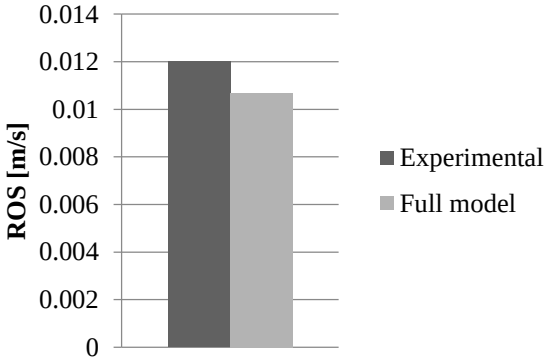

Figure 5. ROS mean value comparison

In Figure 6 the experimental temperature time evolution recorded by thermocouples T1, T2, T3, T4, is reported, which provides information on experimental fire propagation. The evolution of the experimental fire is not constant during time. In fact the front reaches the first thermocouple (section A) after 1000 s, the second after 2000 s, the third after 2800 and the fourth after 3700 s. Therefore , since the thermocouples are equidistant it is clear that the ROS in the sections of the domain are very

different. In Figure 6 the temperature time evolution predicted using the full model is also reported. The results indicate that a good agreement between experimental data and numerical simulation is achieve, although the model slightly under-predicts the fire front velocity in the first half of the domain. Numerical predictions obtained using the POD model are also compared with experimental data and numerical results of the full model. POD model and the full one are in good agreement and also the maximum temperature predicted is very similar. The marginal differences that can be observed in Figure 6 are due to the fact that only 160 autofunctions are used in order to reduce the computational cost. In the case of the described experiment, the computational time required to solve the energy equation using the POD model with a refined grid is about 10% of the full model.

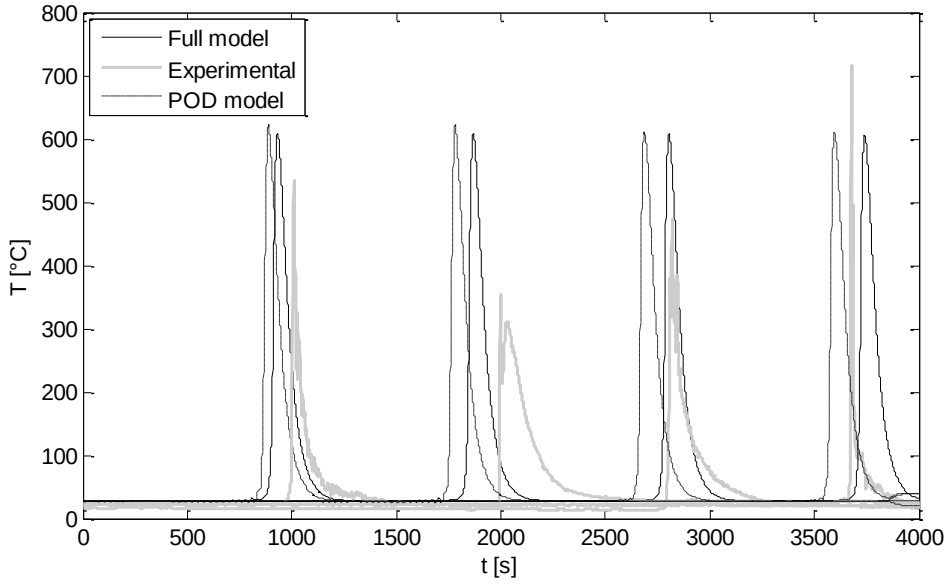

Figure 6. Temperature evolution in the four thermocouple, full model, experimental and POD model

An interesting application of the POD model is the possibility of performing sensitivity or parametric analysis using a reduced model built from a single reference scenario. In particular, it is possible to assess the influence of boundary conditions or model parameters at the expense of small computational costs. In fact the main strength of this approach is the ability to reproduce the behavior of the system with some different characteristics, using snapshots provided to an experiment or simulation executed in other conditions. In this paper the effect of uncertainties in the evaluation of the linearized reaction rate are investigate using the POD model. In particular, a +/- 30% variation of α (Eq. 2) was considered. The resulting variation of ROS are illustrated in Figure 7. The rate of spread evaluated with the full and POD model are very similar; the maximum error obtained is less than 6%. Furthermore the considered case is characterized by a low propagation velocity, therefore the error has a very low value. Figure 7 shows that an higher value of α correspond to a slower propagation, while ROS decrease with smaller value of α.

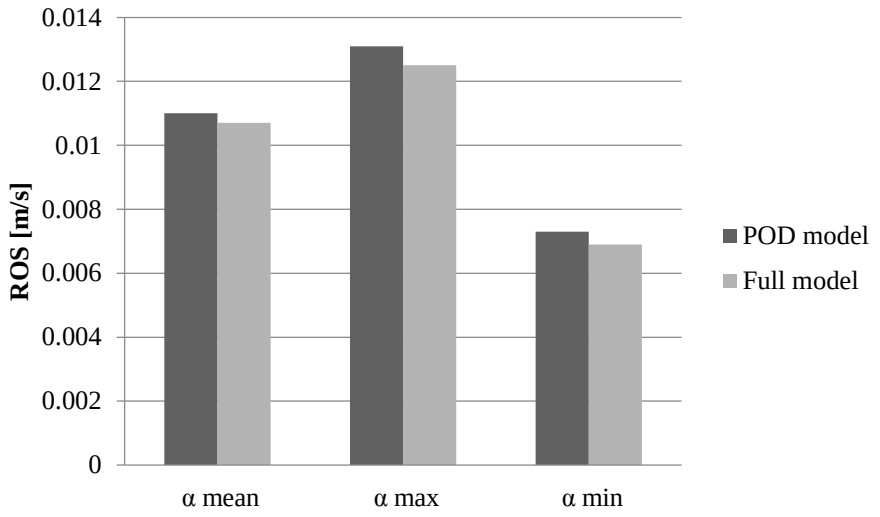

Figure 7. ROS with different mass loss rate coefficient

Conclusions

The present paper reports the use of POD in order to reduce the computational time of wildfire models. POD has been applied to a simple 1D problem based on energy conservation equation. Diffusion, convection, radiation, and heat release associated with the mass rate has been considered. Coefficients are determined experimentally. Time integration is evaluated with the implicit backward Euler method and the resulting nonlinear system of equations is solved using a Newton-Raphson algorithm. This is the first paper in literature that deal with the POD reduction applied to forest fire model.
The full model is able to reproduce the pseudo steady-state behavior of the experimental fire. In fact the ROS of the two model are similar. We found that POD model is able to provide appreciative results using only 160 basis. Therefore the dimension of the solved model is 160 while the dimension of the full one is 4000. The computational time to solve the energy equation is reduced to 10% of the full model. This is a good result but in future in order to increase efficiency of non-linear problems solved using POD techniques as the DEIM decomposition can be used.
The snapshots provided to the full model are used in order to simulate fire evolution with two different value of mass loss rate coefficient. Results show that POD model is able to estimate the ROS with good accuracy, even when the equation parameters differ from that used to obtain the snapshots. Errors are below 6% in each the computed cases. Future work will be focused on increasing of performances of this technique and application to more complex and multi dimensional models.

Nomenclature

c	specific heat of the fuel array	[kJ/kgK]
F_{ij}	view factor	[-]
h	convective coefficient	[W/m^{3}K]
H	heat content of fuel	[kJ/kg]

Abstract
The capabilities of accurately estimating dead fuel moisture content and predicting the likelihood of self-sustained fire spread are crucial to plan prescribed fire operations and achieve the treatment goals, among other fire management objectives. After analysis to determine whether some existing models could be adopted or adapted, we developed user-friendly equations to predict the moisture content of dead fine fuels in blue gum (*Eucalyptus globulus*) litter and examined their prediction ability. Models with vapour pressure deficit, the FFMC code of the Canadian FWI System (or the no. of days since last precipitation in alternative) and noon 10-m open wind speed from the nearest weather station as independent variables fitted the data suitably, as well as a physics based model. The probability of sustained fire propagation in experimental burns carried out in reconstructed blue-gum litter in the laboratory was described through fuel moisture content, litter depth and fire-spread direction (backward or forward). Both types of equations will be further tested in blue gum stands.

Keywords*: Fuel moisture, Eucalyptus globulus, fire behaviour, fire danger, prescribed burning*

Introduction

Blue gum eucalypt (*Eucalyptus globulus* Labill.) stands in Portugal are an important economic resource as well as inherently flammable, hence contributing to the extent of the fire problem. Treatment of fuels in highly flammable forest plantations is an essential component of their sustainable management to minimize burn probability, be able to suppress fire under unfavourable weather conditions, decrease its ecological impact and increase the value of salvaged wood. The advantages of prescribed burning as a fuel management technique warrant investigation of its feasibility in industrial eucalypt plantations. The FIREglobulus project seeks to establish the scientific basis for the technological development of prescribed burning in blue gum plantations. This project studies the behaviour and severity of experimental outdoors fires carried out from autumn to spring, supplemented by laboratory trials data. Data analysis relates fire characteristics with fuel complex descriptors and other environmental factors, examines the performance of currently available fire-behaviour prediction models, and develops predictive relationships for the chain fire environment - fire behaviour - fire effects in blue gum stands.
The moisture content of dead and live fuels plays an important role in fire behaviour and fuel consumption. Usually referred to as 'fuel moisture content' FMC (Viney 1991) it significantly influences fuel flammability and ignition, fuel consumption and overall fire behaviour (Matthews 2006; Pyne *et al.* 1996). Over the past decades several authors have developed research in this area using different approaches. Viney (1991) and more recently Matthews (2014) reviewed the state-of-the art on modelling the moisture of dead fine fuels. The focus of our work is on user-friendly operational models for use in the field, falling inside the group of empirical models based on weather

conditions so that FMC can be expressed through functional relationships like those developed by Pook and Gill (1993), Marsden-Smedley and Catchpole (2001), Ferguson *et al*. (2002), Lin (2004), Sharples *et al*. (2009), Ray *et al*. (2005, 2010) or Sharples and McRea (2011).
Fuel moisture content has been shown to be the main variable determining the likelihood of sustained fire spread in distinct fuel types, but other environmental variables (wind speed, fuel accumulation and continuity, fire direction) further exert an effect (e.g. Fernandes *et al*. 2008; Leonard 2009; Anderson and Anderson 2010; Cruz *et al*. 2013). Prescribed burning is often carried out under marginal conditions, i.e. at the high-end of the fuel moisture range that allows a spreading fire, and so the operational abilities to assess dead fine fuel moisture content and the likelihood of sustained fire spread are critical to plan and carry out prescribed fire operations.
In this study we present modelling results for blue-gum litter concerning (i) estimation of the moisture content of fine litter from environmental variables, and (ii) fire spread sustainability.

Methods

Fuel moisture content

The fuel moisture content of fine surface litter was measured by destructive sampling. The samples were collected daily (n=127) in a forest stand in the UTAD campus (Vila Real, northern Portugal) at 15:00 hours, between August 2012 and December 2013, and were oven-dried for 24 hours at a temperature of 100ºC. The temperature and relative humidity at the time of litter collection were measured at a 1.8-m height and used to calculate vapour pressure deficit (VPD, kPa), which measures the drying power of the air as the difference between the amount of moisture in the air and how much moisture the air can hold when saturated.
Noon weather data from the nearest meteorological station (4 km) and the corresponding indices of the Canadian FWI System (Van Wagner 1987) were also recorded.

Sustainability of fire spread

The sustainability of fire spread was evaluated in indoor burn trials (n=134) for backing (Figure 1) and heading fires under a wide range of litter moisture and structure (load, depth, bulk density) and wind speed.
For each trial we have reconstructed a litter layer (1.5m x 2m) in the combustion table. We tried to cover the natural variation in litter thickness and loading, based in the national forest inventory (2005-2006) data. Fuel loading was estimated by oven drying the material within a randomly-located 0.073 m^2 square. Fuel depth was determined from nails (n=8) inserted in the litter and flushed with its top. Fuel sampling for moisture content assessment proceeded immediately before ignition. Ambient temperature and relative humidity were monitored with a Davis weather station.
The fires were line-ignited (fire front width = 1.5 m) and allowed to propagate downslope with the slope fixed at 30%. The trials were either classified as sustained or non-sustained in case of self-extinction. If the fire failed to spread downslope the trial was repeated upslope with successive laminar-flow wind speeds of 0, 5, 10 and 15 km h^{-1} until attaining sustained fire spread.

Figure 1. A fire-spread sustainability trial in the combustion table.

2.3. Data analysis

We examined the prediction ability of eucalypt litter moisture content models (Gould *et al*. 2007; Sharples *et al*. 2009; Sharples and McRea 2011). FMC was empirically modelled from local weather (and related variables, e.g. vapour pressure deficit) and Canadian FWI moisture codes. FMC was log-transformed and regressed on both the untransformed and log-transformed independent candidate variables; the elected equations were back-transformed and corrected for bias. FMC was also derived through the physically-based model of Matthews (2006), for which hourly weather was estimated using the methods of Matthews *et al*. (2007). Model assessment was based on deviation statistics.

To predict the go/no-go status of fire spread we used two supplementary approaches, respectively CART (Classification and Regression Trees) and logistic regression, which estimates the continuous and non-linear probability *P* of an event (successful fire spread in this case, coded as 1). The logistic equation has the form (Hosmer and Lemeshow 2000):

$$P = 1 / [1 + \exp (- (b_0 + b_1 x_1 + \ldots + b_i x_i))] \quad (1)$$

where x_1 to x_i are the independent variables and b_0 to b_i are the regression coefficients.

Besides FMC we considered fuel structure (litter depth, load, and bulk density) and fire-spread direction as potential independent variables; the number of upslope trials with varying wind speed did not warrant assessment of its effect. The direction of fire spread was coded 0 for backward spread (the downslope back fire) and 1 for forward spread (the upslope head fire). To evaluate model predictions we used concordance analysis and the area under the ROC (receiver operating characteristic) curve, which is independent of an arbitrary decision.

Results and discussion

Fine fuel moisture content

Weather data at the moment of fuel sampling varied in the ranges of 7.0 - 35.8 ºC for ambient temperature, 16.5 - 100% for relative humidity and 0 - 25 km h^{-1} for wind speed. In general, the existing models for eucalypt litter FMC produced underestimates (Table 1), essentially because they were developed to predict the moisture content of fuels unaffected by precipitation. However, multiplying Gould *et al*. (2007) predictions by a factor of 1.5 succeeded in explaining 77% of the observed variation when FMC <35%. The physical model generally produced better predictions because it included precipitation effects. The best-fitting empirical model (Table 2) explained 92% of the observed variation and included the VPD, noon 10-m open wind speed and the FFMC of the Canadian FWI as independent variables (equation A). An alternative, more user-friendly equation (B) that included the number of days since precipitation instead of the FFMC had a poorer fit to data. The performance of both models was comparable to the more complex physical model.

Table 1. Evaluation of the models for estimating the moisture content (%) of fine surface litter.

Model	*n*	FMC range	RMSE	MAE	MAPE
Gould *et al*. (2007)	60	6.1 - 29.2	5.4	4.4	31.5
Sharples *et al*. (2009)	127	6.1 - 193.0	25.1	10.1	24.6
Sharples and McRae (2011)	127	6.1 - 193.0	33.6	15.3	45.3
Matthews (2006)	127	6.1 - 193.0	20.8	8.8	25.1
Matthews (2006)*	107	6.1 - 35.0	4.3	3.1	18.7

RMSE - Root mean square error; MAE - Mean absolute error; MAPE - Mean absolute percent error.
*Subset of results with modelled and observed moisture content below 35%

Table 2. Equations for estimating the moisture content (%) of fine surface litter. Standard errors of regression coefficients appear below the equations by the same order. All independent variables are significant at p<0.001.

Model	Equation	R2	MAE	MAPE
A	77.707 VPD-0,385 exp(-0.018 FFMC) exp(-0.012 U) (8.493; 0.001; 0.004; 0.029)	0.92	4.5	16.9
B	28.701 VPD-0,571 NDWR-0,157 exp(-0.021 U) (1.919; 0.032; 0.034, 0.005)	0.85	6.8	21.8

VPD – Vapour pressure deficit (kPa); FFMC- Fine Fuel Moisture Code; U – 10-m wind speed in the open (km h^{-1}); NDWR - Number of days since precipitation. R^2- Coefficient of determination; MAE - Mean absolute error; MAPE - Mean absolute percent error.

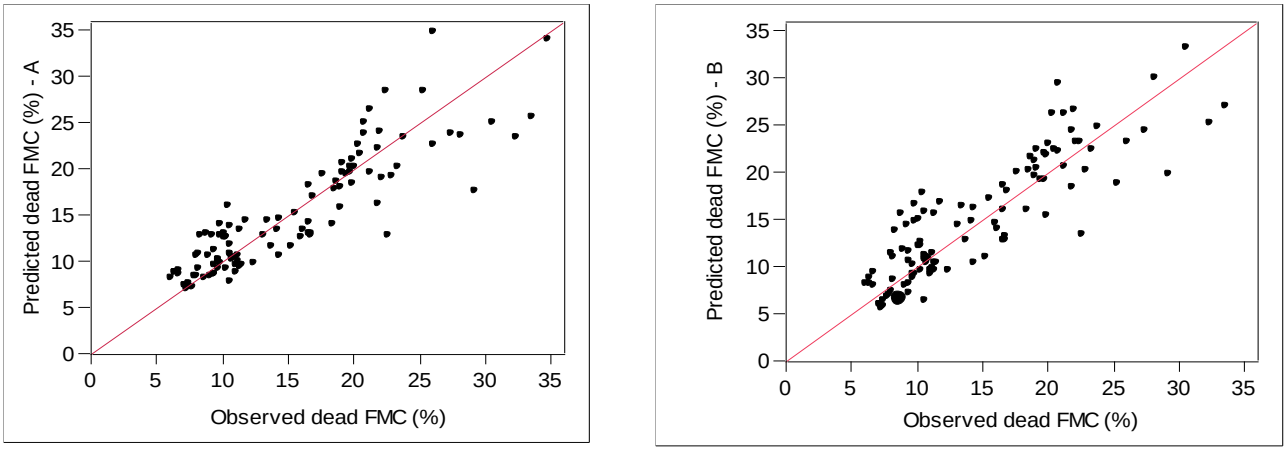

Figure 2. Observed versus predicted blue-gum litter moisture content using models A and B. The line of perfect agreement is overlaid.

Fire spread sustainability

FMC during the burn trials varied from 10.4 to 68%. The CART analysis indicates litter moisture content, its depth (which exerted the major effect) and fire-spread direction (forward or backward in relation to wind and slope) as the variables influent in the sustainability of fire spread (Table 3). When FMC is lower than 32.4% and litter depth is greater than or equal to 3.7 cm, sustained fire spread is virtually certain. In contrast, fire spread is highly unlikely for FMC above 32%, independently of other variables.

The model developed to predict the likelihood of sustained fire spread (Table 4 and Figure 3) has an area under the ROC curve of 0.925, which Hosmer and Lemeshow (2000) consider outstanding. Nevertheless, a comparison between Table 3 and Figure 3 indicates the logistic regression tends to be conservative, i.e. underestimates the fire-spread potential. In fact model predictions are quite sensitive to litter depth, e.g. the likelihood of fire spread increases substantially when LD changes from 3.0 (the data set average) to 3.5 cm. Litter depth probably expresses the effect of fuel continuity in addition to the effect of fuel loading, as the former tends to be partial at shallow depths due to the morphology of blue gum leaves. The fire-spread outcome was correctly predicted by the model in 85% of the experimental trials; out of the failed predictions 10% were underestimates and 5% were overestimates.

Table 3. CART analysis of the likelihood of sustained fire spread in blue gum litter.

<table>
<tr><th colspan="5">Variables and thresholds</th><th>Fire spread probability</th></tr>

Table 4. Coefficients (standard errors) of the model for estimating the probability of sustained fire spread.

Intercept	FMC	LD	FD
3.0182 (0.9490)	0.1852 (0.0342)	-2.3181 (0.4799)	-2.7597 (0.6287)
p=0.0015	p<0.0001	p<0.0001	p<0.0001

FMC – Fuel moisture content (%); LD – litter depth (cm); FD – Fire-spread direction

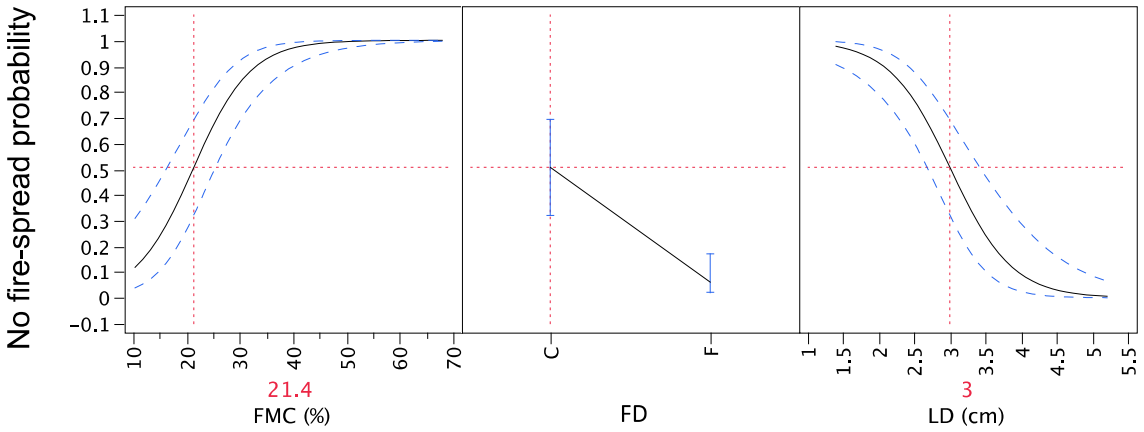

Figure 3. Fire-spread probability with confidence intervals as per the logistic model in Table 4. FMC = 21.4% is the threshold between go / no-go for a back fire and the mean observed litter depth.

Conclusions

Expedite and reasonably accurate estimation of the moisture content of fine surface litter for operational purposes is possible by using an empirical model based on temperature and relative humidity (in the form of the VPD), supplemented by other less relevant variables that account for the drying effects of time since last rainfall and wind speed. The physical model performs similarly, but its use by fire managers is not practical.

Fire-spread sustainability was highly influenced by fuel structure, which contrary to expectations (and because of the experimental design) exceeded the importance of FMC. The performance of the laboratory-base model for fire spread sustainability needs to be assessed during outdoors experimental fires. In case the results indicate good predictive ability, scaling problems will then be ruled out and it will be reasonable to extrapolate the lab-based results to the field and to management-ignited fires. The results will be part of the prescribed burning guide for blue gum plantations.

Multi-scale kinetic model for forest fuel degradation

Dominique Cancellieri, Valérie Leroy-Cancellieri, Eric Leoni

SPE - UMR CNRS 6134, University of Corsica, Corte, France. vcancellieri@univ-corse.fr

Abstract
In modelling wildfire behaviour, a good knowledge of mechanisms and kinetic parameters controlling the thermal decomposition of forest fuel is of great importance. Generally, the pyrolysis models are determined from experiments carried out in thermal device (i.e. TGA and DSC). This kind of tools ensures an accurate determination of kinetic parameters in perfectly controlled conditions. But the gap of a larger scale, for their uses in forest fire conditions, is still far. To corroborate the kinetic models in realistic forest fire conditions, a mass loss device specially designed for field scale has been developed. The system includes three load cells with a max load at 400 g and 2.7 Hertz for the frequency acquisition. Each load cell is sit on top of a stainless tube in which the sample is hold. The position and height of the sample in the tube could be adjusted to optimize the interaction with the height of the flame and the sample. To obtain the temperature impacting the sample, a thermocouple K is placed at the end of each tube set to the same frequency acquisition as load cells. The device is integrated in a welded ceramic box that was lined with a 15 mm thick refractory lining. The acquisition system is included into an armored thermal box. For this first campaign of measures, we have selected species which have been previously studied for the kinetic modeling and presenting different typologies: Rockrose, Heather and Pine. One of the main advantages of this prototype is that 3 different species can be submitted, in line, to the same external heating conditions and are simultaneous analyzed. The heating source is a fire spread of wood wool bed. This fuel have been selected for a good repeatability of heating conditions Before each test, a fuel bed with various loads (0.5, 1 and 2 kg/m2) has been uniformly distributed and the prototype has been placed around the end of the bed to ensure the steady state. In these experimental conditions the samples, of intact branches and leaves, are closest to their natural state. Experimental field-scale results have been compared to numerical simulations based on Arrhenius law.
The simulations have been performed considering a two-steps mechanism previously obtained by the authors using TGA data. In a general point of view, the simulations have a good agreement with the experimental mass loss rate even if some differences appear (as attempt). For the rockrose, the model do not match accurately in the range of $0.7 < m/m0 < 0.9$ probably because the mechanisms of initiation and preheating are more complex than a simple Arrhenius equation of order n. Concerning the heather, experiments exhibit an accelerate degradation process which can be explain by the very fine structure of this specie. Conversely, Pine has a different structure which is constituted by a single branch with a diameter of 6 mm. This thickness of sample involves an incomplete degradation. Considering the very important gap between laboratory and field scale, the kinetic scheme gives satisfactory modeling.

Introduction

In studying forest fire propagation, kinetic modeling of thermal degradation mechanisms is one of the main prerequisites for the determination of source terms, allowing the development of realistic models. Numerous Computational Fluid Dynamics (CFD) codes have been developed for predicting fire spread and providing operational tools for land managers. Those codes include various sub-models describing the different phenomenon involved in case of fire such as the pyrolysis model (Morvan and Dupuy 2004) which describes the thermal decomposition of the solid.
In order to describe the evolution of the solid phase, the mass loss rate of the solid is one of the most important parameters. Indeed it is directly linked with the pyrolysis gas flow rate and represents the initial factor of the combustion process.

In modelling fire behaviour the knowledge of the mechanisms and kinetic parameters controlling the thermal decomposition of forest fuel it is of great important. Indeed, adequate kinetic mechanisms should be coupled with the description of transport phenomena (heat, mass and momentum transfer) in order to provide detailed process simulation.
The thermoanalytical technique commonly used in solid-phase thermal degradation studies is the ThermoGravimetric Analysis (TGA) (Ninan 1989; White *et al.* 2011) which has gained widespread currency in thermal studies of biomass pyrolysis (Di Blasi 2008). TGA measures the decrease in substrate mass caused by the release of volatiles, or devolatilization, during thermal decomposition. In TGA, the mass of a sample being heated at a specific rate is monitored as a function of temperature or time. The TGA requires sample sizes sufficiently small such that the diffusion effects become negligible and the pyrolysis is kinetically controlled (Miller and Bellan 1997). The experimental data gathered in the perfectly controlled conditions of the TGA ensures an accurate determination of kinetic mechanism. Unfortunately, these experimental conditions are not realistic with those encountered in real forest fire. Sometimes, experiments were performed in calorimetry (with cone or FPA)(Schemel *et al*. 2008), but the gap of a larger scale is still far.
Based on these observations, the aim of this study is to propose a kinetic model for Mediterranean fuels adapted to realistic forest fire conditions. In this purpose, a mass loss device specially designed for field scale has been developed. This device can record in real time and simultaneously the mass loss and the temperature of 3 samples when they are submitted to a heat flux. Always with the aim of bringing it closer to a forest fire, the heat flux is a flame front created by the spread of a bed of straw. The experimental values conducted at field-scale have been compared to kinetic laws established in TGA.

Materials and Methods

Biomass fuels

Plant materials have been collected in Corsica from a natural Mediterranean ecosystem situated far away from urban areas in order to prevent any pollution on the samples. Heather, Rockrose and Pine are the representative species of different strata of vegetation concerned by wildland fires. The properties of the species are shown in Table 1. All the fuels are expressed in their chemical equivalent formula, which is a function of their major elements (C, H and O) obtained from the ultimate analysis on a dry basis. The heating values (high and low) were measured using a bomb calorimeter and the calorific capacities were determined using a Differential Scanning Calorimeter (DSC). The surface-to-volume ratio and density were measured following the methodology proposed by Moro (Moro 2006).

Table 1. Physico-chemical parameters of fuels

Properties	Parameters	Rockrose	Heather	Pine
Chemical	Formula	C4,24 H6,49 O 2,66	C4,58 H7,32 O 2,35	C4,26 H6,83 O 2,62
Thermal	High Heating Value (kJ kg-1)	20905	20988	21566
	Low Heating Value (kJ kg-1)	19745	19703	20239
	Calorific capacity (kJ kg-1 °C-1)	1912	1939	2050
Physiologic	Surface to volume ratio (m-1)	2217	3801	3057
	Fuel density (kg m-3)	912	614	511

2.2. Laboratory experiments

For kinetic characterization of thermal degradation mechanisms the mass loss is one of the main prerequisites. This parameter has been chosen as the major driving parameter for the characterization of source terms. Moreover, the mass loss provides qualitative and quantitative information regarding the different reactions taking place in the heated solid (Kissinger H.E. 1957). Thermogravimetric experiments were carried out in a thermogravimetric analyzer (PerkinElmer Pyris 1 TGA). The precision of the temperature measurement was ±2 K. For each sample, 5 mg of dried and ground biomass was heated from 350 K up to 900 K under dynamic conditions at heating rates of 20 K min^{-1}. During the experiments the furnace of the TGA is flushed with 20 mL min^{-1} air to maintain an oxidative atmosphere for thermal degradation of particles. Each experiment was repeated at least three times.

2.3. Field experiments

To cross the gap of real fire, we transpose the principle of the TGA at the field scale. In this purpose, we have created a device in which samples are exposed to a heating source (a fire front) and the weight loss and temperature are simultaneously recorded. The next sections are dedicated to the description of this mass loss prototype and its use.

2.3.1. *Differential mass loss prototype set up*

The prototype consists of two parts: one dedicated to measurement and the other dedicated to data acquisition. The characteristics of each are detailed below.

The instrumental part:

The size of the device has been calculated to be 1/5 of the width of the plot to burn. In this way, the system will completely encompass during the propagation.
The device includes 3 load cells which are integrated in a welded ceramic box (1260 mm × 170 mm × 100 mm) that was lined with a 50 mm thick refractory lining (Thermal Ceramics Kaowool 1600).
Given that the meteorological and fire conditions are difficult to perfectly reproduce, we make the choice of install 3 load cells on apparatus to follow the behaviour for 3 species submitted to the same fire propagation. With three species on the prototype, a differential analysis between samples becomes possible free from the external conditions.
The 3 load cells (Futek®) have a maximum lift of 450 g for 6.8 mm width, 19 mm height and 17.5 mm length. A stainless tube is sit on top of each load cell in order to insert the sample inside. The height and the diameter of this tube (190 mm x 20 mm) have been reckoned to avoid any lift effect. Moreover, the position and height of the sample in the tube could be adjusted to optimize the interaction with the height of the flame and the sample.
The distance between each supporting tube (500 mm) has been chosen so that the decomposition of a branch does not affect the neighbouring branch. Thus, the plant will only be affected by the fire front of the beforehand device.
To obtain the temperature impacting the sample and the punctual heating rate of the fire propagation, thermocouples are placed at the end of each tube. Thermocouples K have been selected according to their temperature ranging to 1300 ± 0.5 °C (Omega® HKMTSS-010G-8) diameter: 25 µm.

The acquisition part:

The acquisition system is integrated into a thermal Multi-Layer Aluminization (Z-Flex®) shield box. A deported wireless acquisition system is actually impossible to use because of disturbances caused by the thermal shield. The temperature inside the thermal box is controlled using a thermocouple and adjusted if necessary by a fan if the temperature of the thermal box is rising. Inside the box, a laptop

is included in which the data are simultaneously transmitted through a USB interface and using custom software.

The mass loss data are recorded using Sensit the Futek's software with a frequency of 2.5 Hz.
The temperature data are synchronized with mass losses data acquisition recorded with the same frequency thanks to acquisition unit Omega® TC-08. This system can accommodate up to 8 thermocouples with an acquisition frequency of 10 Hz. The figure 1 presents the whole mass loss prototype.

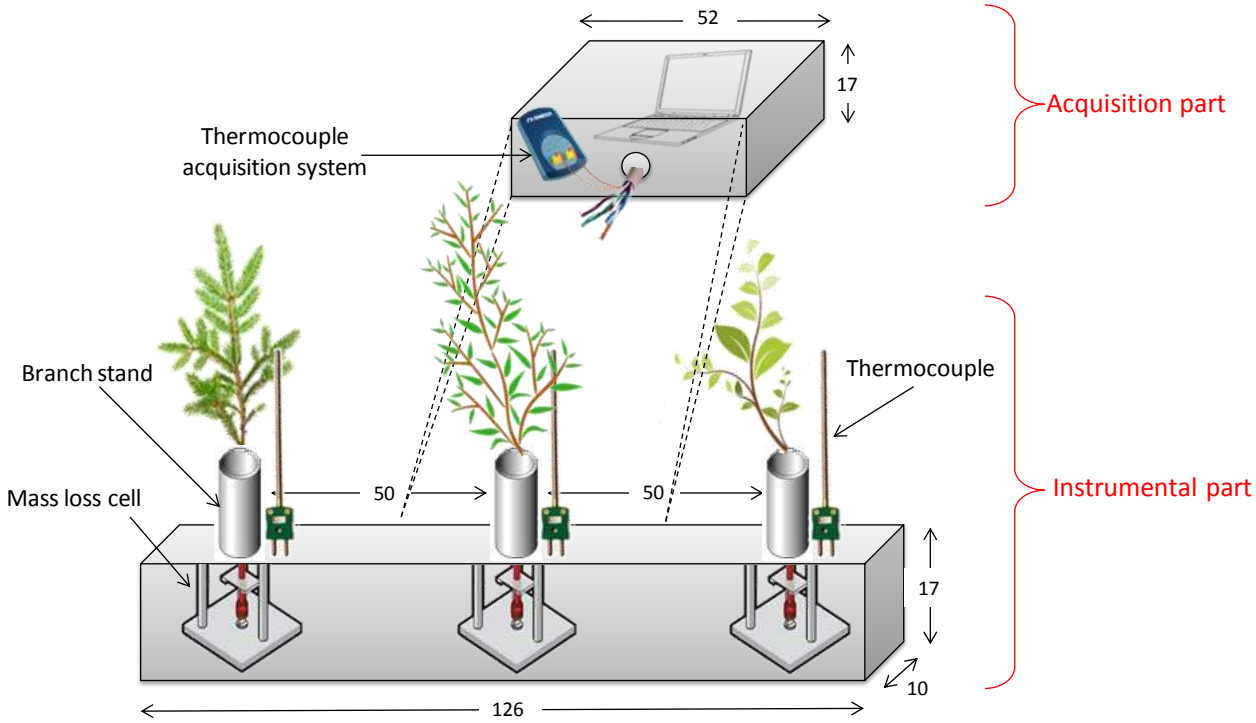

Figure 1. The differential mass loss prototype

One of the main advantages of this prototype is that 3 different species can be submitted, in line, to the same external heating conditions and are simultaneous analyzed in the same field conditions.

2.3.2. *Experimental conditions*

All experiments have been carried out on 3 species presenting different typologies: Rockrose, Heather and Pine. In these experimental conditions the samples of intact branches and leaves, are closest to their natural state. This initial mass of the sample (around 50g) represent a factor 10000 compared to experiments performed at laboratory scale with crushed samples.
The 3 species are submitted to the same heating source which is a fire spread of wood wool bed. This fuel has been selected for a good repeatability of heating conditions.
Before each test, a fuel bed of 6 m wide and 10 m long has been uniformly distributed with a fuel load of 2 kg m^{-2}. The prototype is placed around the end of the bed to ensure the steady state of propagation. The experiments have been performed in an area with no wind and no slope and were replicated three times.

Figure 2. Differential mass loss prototype in field conditions

2.4. Kinetic Analysis

The thermogravimetric data have been used to find the best set of kinetic parameters for three species. Using TGA experiments, in case of non-isothermal conditions, the rate of heterogeneous solid-state reactions can be described by:

$$\frac{d\alpha}{dt} = \frac{1}{\beta} A\, e^{-\frac{E_a}{RT}} f(\alpha) \qquad \text{(Eq. 1)}$$

where f(α) is the conversion function (reaction model) with $\alpha = m_0 - m/m_0 - m_\infty$, A is the pre-exponential factor, Ea is the activation energy, R is the gas constant and β is the heating rate.

The estimation of the kinetic parameters (*A*, E_a, *f(α)*) from TGA experimental data can be done with a variety of techniques (Vyazovkin and Wight 1998; Vyazovkin *et al.* 2011). In order to obtain a reliable kinetic description of the investigated processes, we used an approach that combines the accuracy of isoconversional methods with model-fitting methods (Pratap *et al.* 2007; Chrissafis 2009). This approach, called Hybrid Kinetic Method (HKM), has been developed in a earlier work (Cancellieri *et al.* 2005). It is based on two steps; the first uses isoconversional methods to provide $E_a(\alpha)$ and the reaction model. The second step requires these initiation data to be injected in a model fitting method to obtain the pre-exponential factor and n^{th}-order. This allows selection of models that might otherwise be indistinguishable based on the quality of the regression fit alone. From your point of view, such an approach gives the highest probability of selecting the most accurate kinetic triplet (*A*, E_a, and the model).

3. Results

3.1. TGA experiments

During thermal degradation in air, weight loss occurs continuously until the weight becomes almost constant. Figure 3 presents the experimental results of fuels thermal degradation from 350 to 900 K, under air sweeping.

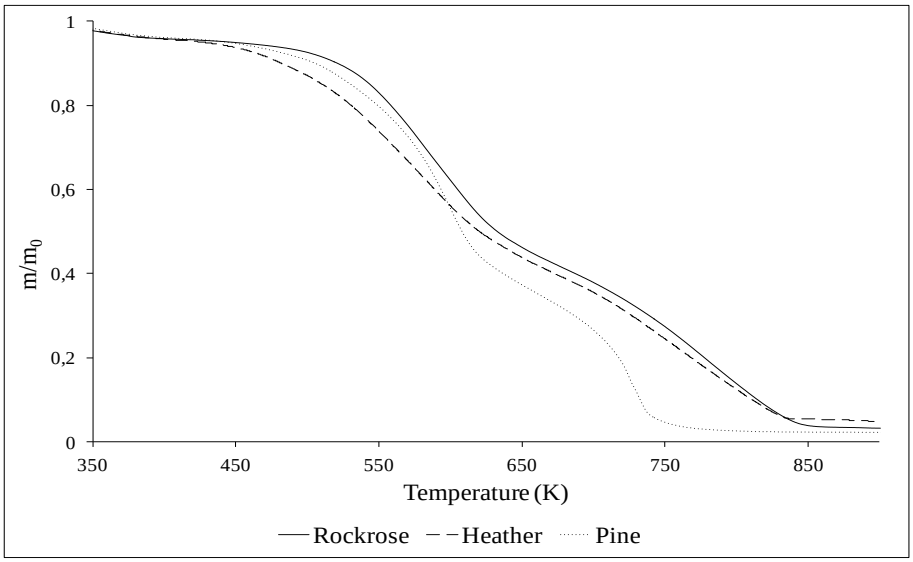

Figure 3: TGA curves of samples obtained with a linear heating rate of 20 K min^{-1} under air atmosphere.

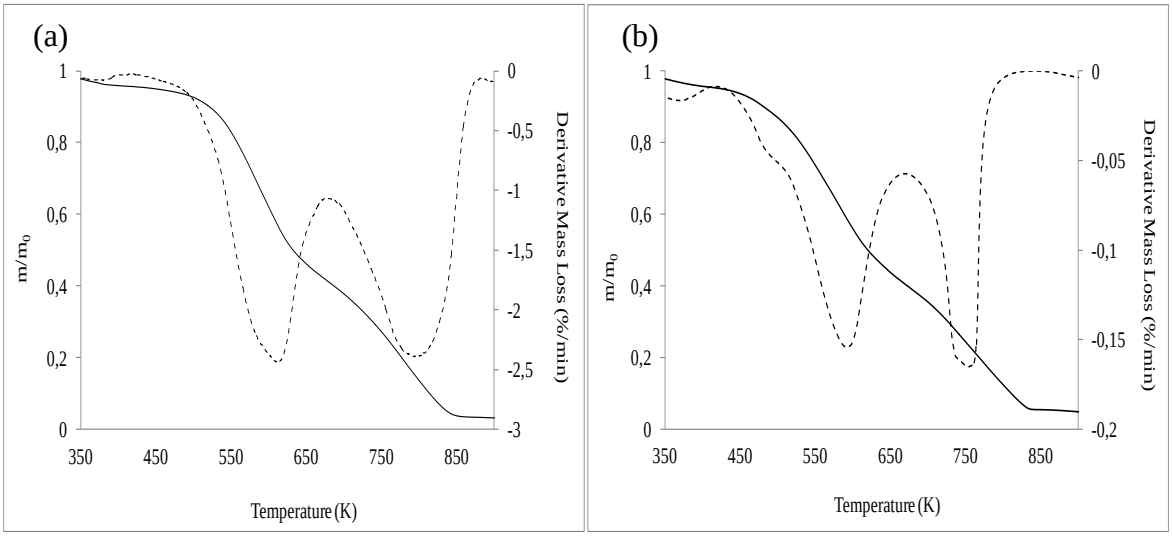
Despite of the complex composition and chemical process, experimental observations suggest that a 2-steps of global reactions can capture the most important behaviour of the thermal and oxidative degradation of plants. Figure 3 highlights that for the heating rate considered in this work, Heather has the lower onset temperature, followed by Pine and in fine, Rockrose. This criterion is very helpful as it can be used as an ignition criterion since onset temperature measures the starting of oxidation reactions. The fuels with low onset temperature are the most ignitable and they burn easily. These results will be confronted to field scale experiments.

Taking the first derivative of such thermogravimetric curves (i.e., −dm/dt) curves, known as derivative thermogravimetry (DTG), provides the maximum reaction rate. The nature of a TGA curve in combination with the corresponding DTG peaks gives a clear indication of the number of stages of the thermal degradation.



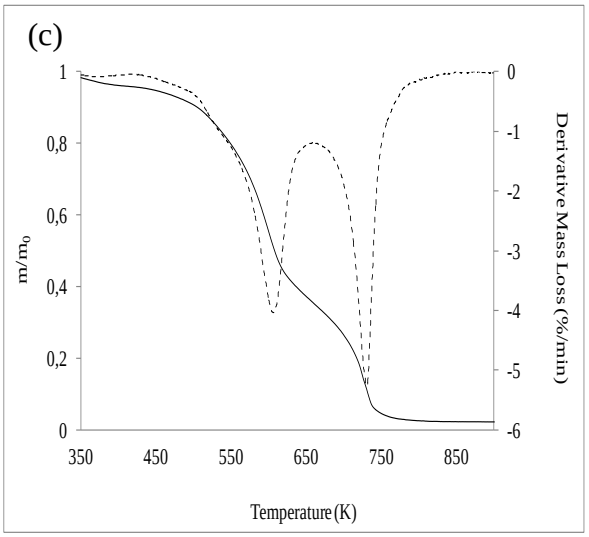


Figure 4: TGA (lines) and DTG (dotted) of oven dried of Rockrose (a), Heather (b), Pine (c) samples obtained with a linear heating rate of 20 K.min^{-1} under air atmosphere (Cancellieri et al. 2013)

TGA curves show two steps of weight loss confirmed in DTG by 2 peaks. The oxidative process is claimed to have two steps: the first step is volatilization of the main biomass constituents and production of char residue at low temperature; the second step includes the decomposition of lignin and the combustion of the charcoal generated in the early stage (Fang *et al.* 2006). The same phenomena are observed and recorded by other authors (Branca and Di Blasi 2004; Safi *et al.* 2004; Shen *et al.* 2009).

Kinetic parameters

According to laboratory experiments, it would seem wise to consider a 2-steps mechanism. This scheme seems to be suitable for the 3 species. The first process is modeled as:

$Virgin_{(s)} \rightarrow Char_{(s)} + Gas_{(g)}$ (1)

The second reaction concerns the oxidation of chars formed during the first process: $Char_{(s)} \rightarrow Residue_{(s)} + Gas'_{(g)}$ (2)

The two reactions (1) and (2) can be traduced in the two following differential equations (Eq. 2) and (Eq. 3), considering a n-th order model.

$$\frac{d\alpha_1}{dt} = \frac{1}{\beta} k_{01}\, e^{-\frac{E_{a1}}{RT}}\, (1-\alpha_1)^{n_1} \quad \text{(Eq. 2)}$$

$$\frac{d\alpha_2}{dt} = \frac{1}{\beta} k_{02}\, e^{-\frac{E_{a2}}{RT}}\, (\alpha_1-\alpha_2)^{n_2} \quad \text{(Eq. 3)}$$

Applying the HKM has allowed to obtain the kinetics parameters presented in the table 2.

Table 2 : Summary of kinetics parameters (Cancellieri et al. 2013).

	$Virgin_{(s)} \rightarrow Char_{(s)} + Gas_{(g)}$			$Char_{(s)} \rightarrow residue_{(s)} + Gas_{(g)}$		
	n_1	Ea_1 (kJ.mol^{-1})	ln k_{01}	n_2	Ea_2 (kJ.mol^{-1})	ln k_{02}
Heather	2.63	80	12.90	0.52	114	12.50
Pine	3.97	118	23.20	0.43	128	14.20
Rockrose	3.74	120	22.10	0.52	128	14.50

3.3. Field Experiements

The experimental campaign took place on 21 June 2012 in Corsica, in the South of France. The plot is located in an area with no slope. The figure 5 presents the temperature versus time data recorded during the burn of a plot.

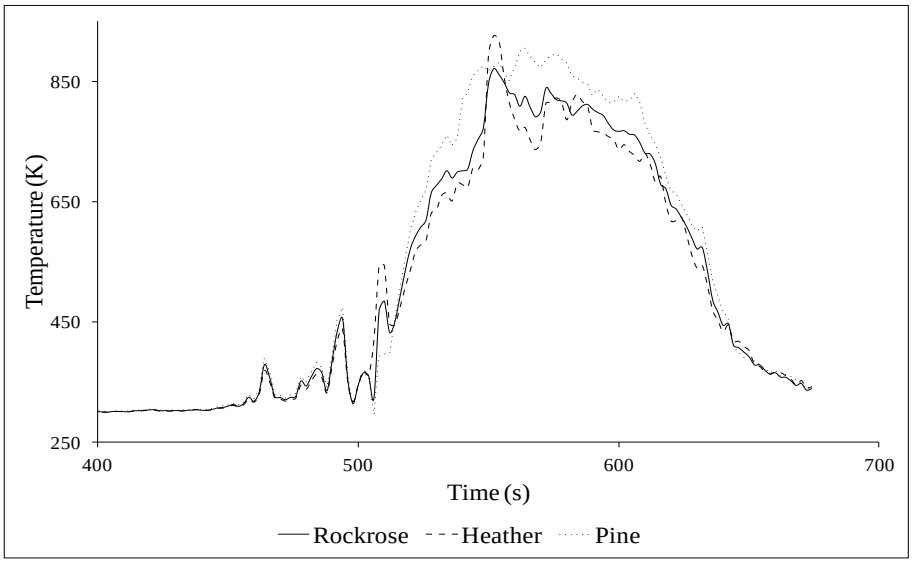

Figure 5: Temperature vs. Time obtained during a field experiment.

The temperature profiles were sensibly the same for the 3 species with a maximum at 926 K. The behavior of the temperature indicates that the fire front can be considered as a straight line impacting the prototype. It is important to note that the temperature behavior is the similar for the 2 other repetitions made during the campaign. Using the evolution of the temperature during the experiment, the heating rate is deduced for each plant. The maximum heating rates obtained are 13.2 for Pine, 12.1 for Heather and 11.1 K s^{-1} for Rockrose. The figure 6 exhibits the mass loss synchronized to the temperature and time data displayed above.

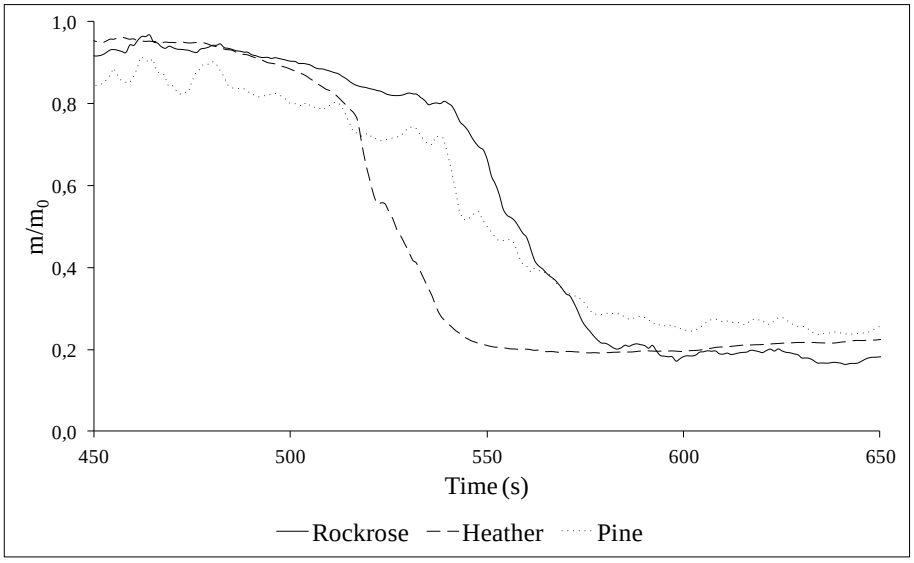

Figure 6. Experimental mass losses obtained at field scale.

The mass loss of Heather starts quickly compared to Rockrose and Pine. This observation is in agreed with the laboratory experiments. Indeed, the Heather presents a low onset which indicates that it is the specie which will ignite firstly compared to the 2 others. The behavior exhibit in TGA is corroborated at field scale. For Heather and Rockrose the degradation is fast while for Pine is slower.

3.4. Comparisons

Experimental field-scale results have been compared to numerical simulations based on Arrhenius law with kinetic parameters obtained for laboratory scale. According to the figure 5 the heating rates deducted are used for the simulations. The simulations have been performed considering the 2-steps mechanism and the kinetic parameters presented in the table 2. The figure 5 compares for each species the mass loss obtained experimentally and the data modelled according to the Eq. 2 and Eq. 3.

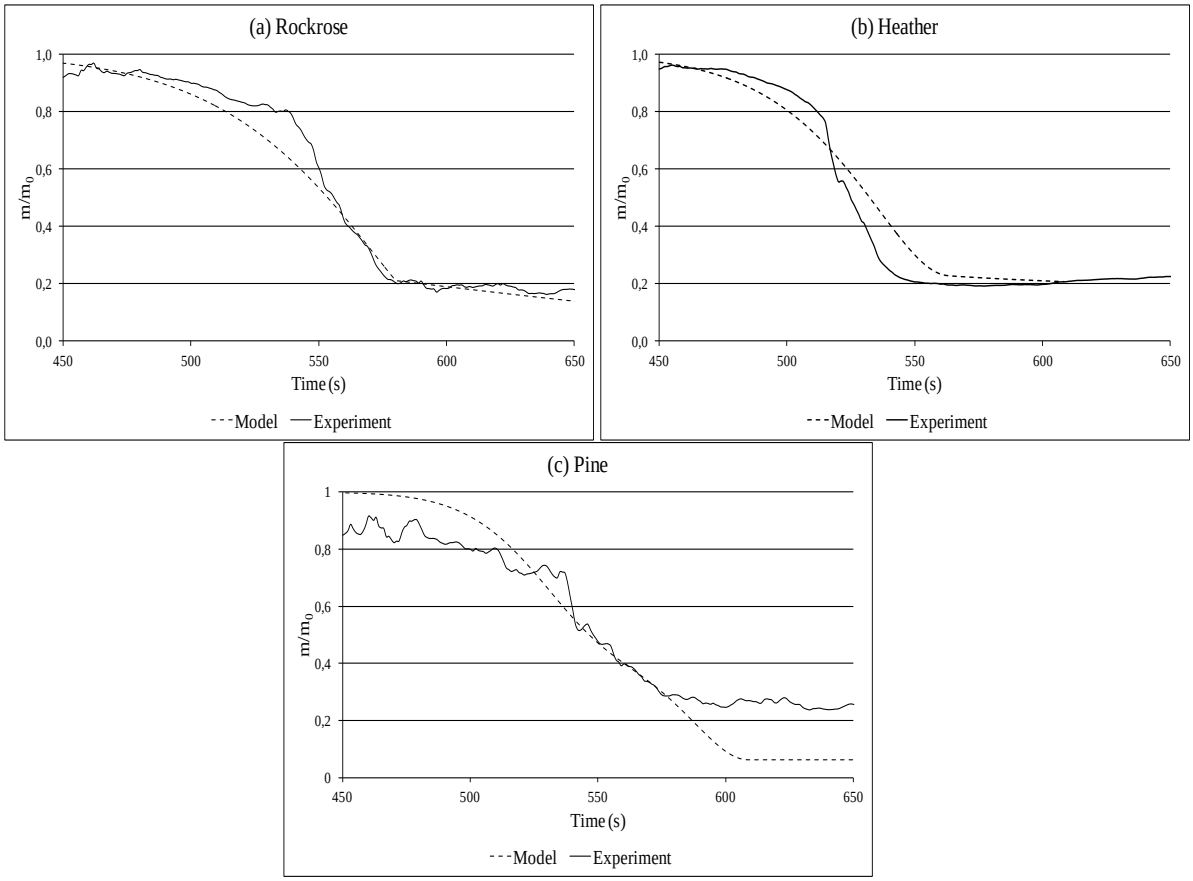

Figure 7. Experimental (solid line) and modeled (dashed line) mass loss for (a) Rockrose, (b) Heather and (c) Pine.

In a general point of view, the simulations have a good agreement with the experimental mass loss rate even if some differences appear (as attempt). For the Rockrose, the model do not match accurately in the range of $0.85 > m/m_0 > 0.60$ probably because the mechanisms of initiation and preheating are more complex than a simple Arrhenius equation of order n. Concerning the Heather, experiments exhibit an accelerate degradation process which can be explain by the very fine structure of this specie with branches of 2 mm. Conversely, Pine has a structure which is constituted by a single branch with a diameter of 6 mm. This thickness of sample involves an incomplete degradation.

Conclusion

A differential mass loss prototype has been designed with the aim to validate kinetic models adapted to field scale. This is the first time that the kinetics of decomposition of solid fuels is validated in real wildland fire condition, thus helping to a reliable characterization of a source term.
The prototype has been tested with 3 species in different conditions of fuel bed loads. Kinetic model previously tested on TGA data seems to well fit the experimental results obtained at field-scale.
The kinetic validity of the schemes is then exported outside the TGA. It is also found that the kinetic scheme with 2-steps gives a good agreement but flawed predictions are occasioned by the natural physiology of the samples (thickness, size of leaves and branches). In fact the initiation step of preheating is strongly related to the physiology. Future works will focus on the integration of the thickness in the model as an inhibitor parameter.

Abstract
Idealized FIRETEC grassfire simulations were used to study some of the roles that three-dimensional aspects of coupled atmosphere/fire interactions play on fire behavior. Domains of various widths that were periodic in the cross-stream direction, simulating an infinite-length fireline, were used to isolate local fireline-scale three-dimensional effects. Two-dimensional vertical plane (zero width) simulations were performed for comparison. Idealized finite-length fire simulations were used to study the larger fire-scale three-dimensional effects.
In the infinitely long simulations the fireline remains fairly straight on a macroscale while significant heterogeneities develop along the fireline at fireline-scales. These simulations suggest that the nature of atmosphere–fire coupling and these heterogeneities are influenced by wind speed. At low wind speed, the spread rate is not significantly affected by the width of the domain (for domains greater than 10 m wide). For higher wind speeds, the flank of the simulated firelines is fingered and the front of the fireline exhibits lobes. The average spread rates vary by approximately 20% for the different domain widths.
In the finite-length fireline simulations, the fireline shape was fairly parabolic and the headfire rate of spread (ROS) increased with wind speed and length of ignition line. The curvature of the fire was also influenced by the length of the ignition line. The indrafts of the headfire and flanking fire lines compete for upstream wind. For wider fires, the separation between the flanking fire lines is larger and more of the upstream wind is able to reach the headfire. These finite-length simulations also suggest that there might be an overall negative pressure gradient from upwind of the fireline to downwind of the fireline near the ground. This pressure gradient is believed to be tied to the penetration of wind through the fireline and the convective heating of unburned fuel.
Streamwise-vorticity pairs contribute to the heterogeneous appearance of the fire front by feeding upward momentum in the location where towers are seen on the fireline and thrusting hot gases through the fireline and down to the unburned fuel in the troughs between the firelines. These streamwise vorticies have also been recognized in the periodic infinite length and finite-length simulated firelines as well as laboratory tests.
In the two-dimensional simulations with wind speeds above 3 m/s, one major effect of the two-dimensional restrictions is to preclude the nominally streamwise-vorticity structures from forming upstream of the fireline. This thus diminishes the ability of the wind to mix through the heated plume and entrain hot gases down into the fuels ahead of the fire.
These simulations suggest that caution should be used when attempting to use one or two-dimensional models to simulate wildland fires. These simulations also suggest the significant value of experiments in which details of both flow and fire dynamics can be studied at scales ranging from fireline scale to overall fire geometry scales in order to better understand fire behavior. The hypothesis generated here can help provide insight in support of experimental design and analysis.

Keywords*: coupled fire/atmosphere, FIRETEC, grassfire, wildfire behaviour, vorticity, vortex*

Introduction

A variety of wildfire models have been developed in recent years to predict wildfire behavior, assess wildfire risk or simply gain insight into cause and effect relationships and the sensitivity of wildfires

to their environment. Some of the models are empirical-based, while others are process-model based so they can be used to explicitly simulate some of the processes that control wildfire behavior. In order to reduce complexity or save computational cost, some researchers have tried to develop wildfire behavior models using one- or two-dimensional formulations. In the case of empirical models, local fire-line scale three-dimensional effects can be inherently represented through extensive data collection in ensembles of experiments. However, without a good understanding of the phenomenology driving multi-scale fire dynamics, it is very difficult for these types of models to capture the larger fire-scale three-dimensional effects caused by fireline shape or end effects due to the complexity and number of experiments and/or field observations required to parameterize these effects over the possible size and shape of fires in various weather and topographic conditions. Some researchers have attempted to use computational fluid dynamics techniques to explore fire behavior using a two-dimensional x–z plane, where x is the direction of the wind and spread and z is the vertical direction. Unfortunately, these approaches inherently neglect three-dimensional features of wildfire behavior due to the combination of the two-dimensional formulation and process-based approach.

While the potential benefits of physics-based modeling includes the ability to look at the interplay between processes and explore various cause and effect relationships in fire, this approach has the downside of omitting those processes that are not resolved or explicitly modeled as unresolved processes. In two-dimensional approaches, fluctuations in the third direction are omitted unless explicitly modeled by sub-grid parameterizations. However, such parameterizations have not yet been adequately developed for wildfire behavior. Better understanding of three-dimensional aspects of coupled fire/atmosphere interactions could suggest new ways to represent the effects of three-dimensionality without explicitly resolving them by providing insight into the relative sensitivity of fire behavior to key variables, suggesting functional forms and reducing the number of parameters that must be obtained from experiments. Canfield *et al*. (2014) considered this three-dimensionality in two size-based categories: local fireline-scale aspects such as fireline undulations, which were the main focus of Linn *et al*. (2012), and larger fire-scale aspects such as fire shape.

In order to understand the implications of omitting these aspects of fire behavior, a three-dimensional physics-based simulation tool was used to explore the significance of local fireline-scale heterogeneities (Linn *et al*. 2012) as well as larger fire-scale three-dimensionality (Canfield *et al*. 2014) of coupled fire/atmosphere fireline dynamics. These explorations are intended to compliment experiments by feeding the development of new hypotheses and additional mechanistic perspectives that are very difficult to isolate in experiments.

2. Methods

Idealized simulations with a physics-based fire/atmosphere model, FIRETEC, were used to explore the impacts of the local three-dimensionality of coupled fire/atmosphere interactions on fire behavior (Linn *et al*. 2012). FIRETEC (Linn, 1997; Linn, 2002, Linn and Cunningham, 2005) was developed as an attempt to represent multi-phase chemistry and physics in a bulk sense by resolving quantities at approximately meter-scale. FIRETEC is coupled to a fully compressible, non-hydrostatic, atmospheric-dynamics model, HIGRAD (Reisner *et al*., 2000), that was specifically designed to operate at higher resolution as compared to traditional mesoscale models.

In all of the simulations described in this paper, the grid spacing in both of the horizontal directions is uniform and equal to 2 m. The grid spacing in the vertical direction is nonuniform, with a value of approximately 1.5 m near the ground increasing to about 30 m at the top of the domain (z = 615 m). The fuel bed load is specified to be similar to tall grass of height 0.7 m, with a load of 0.7 kg m^{-2}, contained within the first grid cell above the ground. Within the fuel bed, the surface area per unit volume is specified as 4000 m^{-1}.

In order to isolate local fireline-scale three-dimensionality from larger three-dimensionality such as fireline curvature and end effects, a series of simulations were performed using periodic boundary

conditions in the cross-stream direction (Figure 1) (Linn *et al*, 2012). Fires were uniformly ignited over the cross-stream width of several domain sizes: 10, 20, 40, 80, and 160 m. Since the domains were periodic in the cross-stream direction, these fires could be considered infinite in length with some periodic restrictions on them. In order to further isolate the effects of fire/atmosphere coupling from ambient upstream turbulence or the effects of eterogeneous vegetation, these idealized scenarios included homogeneous grass fuels with no cross-stream or time-dependent ambient wind variations at the domain boundary 100 m upwind of the fire. Two-dimensional, vertical plane (zero crossstream width) simulations were performed with the same model for comparison. Simulations with six different ambient wind speeds - 1 m s^{-1}, 3 m s^{-1}, 6 m s^{-1}, 9 m s^{-1}, 12 m s^{-1}, and 15 m s^{-1} - were performed for each of the two-dimensional and three-dimensional periodic scenarios.

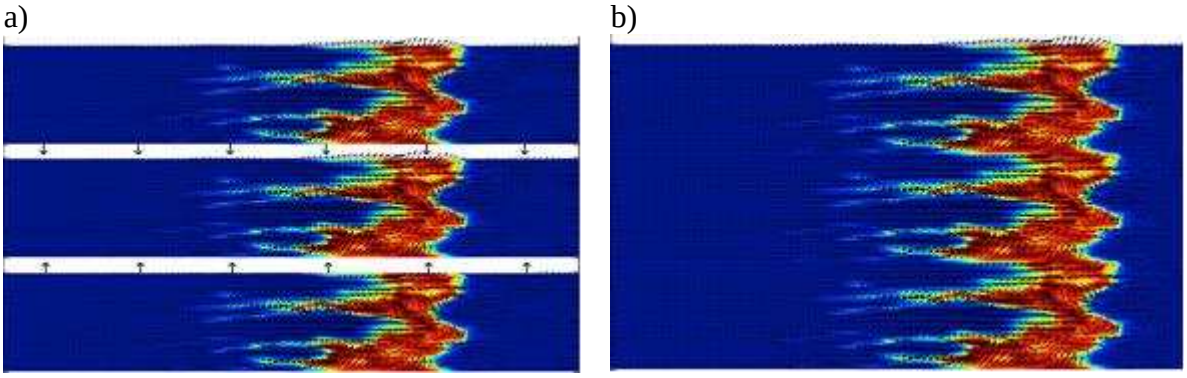

Figure 1. Top down view of 6 m s-1 wind 40 m wide fire simulation a) (in red dotted box) and the use of periodic boundary conditions to conceptually approximate an infinite-length fireline a) and b). In these images the colors indicate gas temperatures (Dark Blue is 300 K and red is greater than 1100K.) These images show the fingering behind the fireline and lobes in front of the fireline. This structure was ftypical for the infinite fireline simulations with 6 m s-1 and stronger winds.

Idealized FIRETEC simulations were also used to study the interactions between fireline shape and rate of spread (Canfield *et al*., 2014). Idealizations/simplifications similar to the infinite fireline approach described above were used except that these fires were finite in length and not periodic in the span-wise direction. These simulations, which were performed with ambient wind speeds of 3 m s^{-1} and 6 m s^{-1}, included finite-length ignition lines ranging from 20 to 400 m in length. In these simulations, the lateral boundary conditions were at least 100 m away from the ends of the ignition line. The winds at the boundaries were relaxed to the upstream flow velocity profile.

Results

All of the infinite-length simulations that were periodic in the stream-wise direction (Linn *et al*., 2012) showed some heterogeneity in the crossstream direction, even though the upstream winds, fuel, and ignition were uniform in this direction. This series of simulations suggest that the nature of atmosphere/fire coupling and the variability along the length of the fireline are influenced by wind speed. At low wind speed, variation along the length of the fireline exists but the fireline remains fairly straight and the spread rate is not significantly affected by the width of the domain (for domains greater than 10 m wide) for the duration of the simulations. For higher wind speeds, the upwind side of the simulated firelines are fingered and the downstream edge of the firelines exhibit lobes. The average spread rates vary by approximately 20% for the different domain widths (Table 1). This may indicate that the variety of sizes of atmosphere–fire structures influence spread rates and become affected by periodic domain constraints as the domain gets smaller. At higher ambient wind speeds, the structure of the wind and temperature fields also show evidence of streamwise vorticity.

Table 1. Rates of spread for periodic infinite-length fireline simulations of various widths and various wind speeds (measured 10 m above ground) (Linn et al., 2012).

Wind Speed U_{10} (m s^{-1})	2D	10 m	20 m	40 m	80 m	160 m
1	.57	.25	.23	.22	.22	.22
3	1.10	1.33	1.35	1.25	1.18	1.14
6	1.24	2.15	2.27	2.14	1.91	1.92
9	.77	2.23	2.81	2.41	2.49	2.28
12	.76	2.67	3.14	2.96	2.94	3.01
15	1.63	3.17	3.31	3.56	3.47	3.44

In the periodic infinite-length simulations, rate of spread increases with wind speed as seen in previous investigations with this model (Linn and Cunningham, 2005) as well as other numerical works and observations. The magnitudes of the spread rates for the periodic simulations were in general larger than those seen in the Linn and Cunningham (2005) finite-length fireline simulations. This result suggests a reduction of rate of spread due to fire-scale three-dimensional features such as end effects and fireline curvature that were present in the Linn and Cunningham (2005) simulations.
In the finite-length fireline simulations (Canfield *et al*., 2014) the fires did not stay relatively straight as they did in the periodic simulations (Figure 2). Instead, they took on a shape that was parabolic-like. In these simulations, rate of spread increased with wind speed and length of ignition line (Table 2) as expected and shown by observations (Cheney *et al*., 1993) and previous numerical studies (Linn and Cunningham, 2005; Mell *et al*., 2007). Flanking fire behavior was also influenced by ignition line length. As a result, fireline shape was affected by ignition line length.

Table 2. Rates of spread for finite-length fireline simulations of various widths and 3 m s^{-1} and 6 m s^{-1} wind speeds (measured 10 m above ground) (Canfield et al., 2012).

Wind Speed U_{10} (m s^{-1})	20 m Ignition line	100 m Ignition line	200 m Ignition line	400 m Ignition line
3	.20	0.68	1.10	1.15
6	.27	1.19	1.45	1.75

Three-dimensional effects at fireline scales

A predominant feature of both the relatively straight periodic infinite-length and the curved finite-length firelines is the presence of stream-wise vorticies that originate well behind the fireline and extend into the fireline itself. Such structures have also been identified in laboratory experiments at the USDA Missoula Fire Lab and are believed to be very important to the spread of fires. These stream-wise vorticies form alternating pairs and occasionally combine into larger vorticies. The development and strengthening of these vorticies is linked to the buoyancy of the sustained burning, which itself is heterogeneous in the crosswind direction. These pairs contribute to the heterogeneous appearance of the heading-fire front by feeding upward momentum in the location where flaming towers are seen on the fireline. The helical nature of the vortices thrust hot gases through the fireline and down to the unburned fuel in the troughs between the towers (Figure 3).

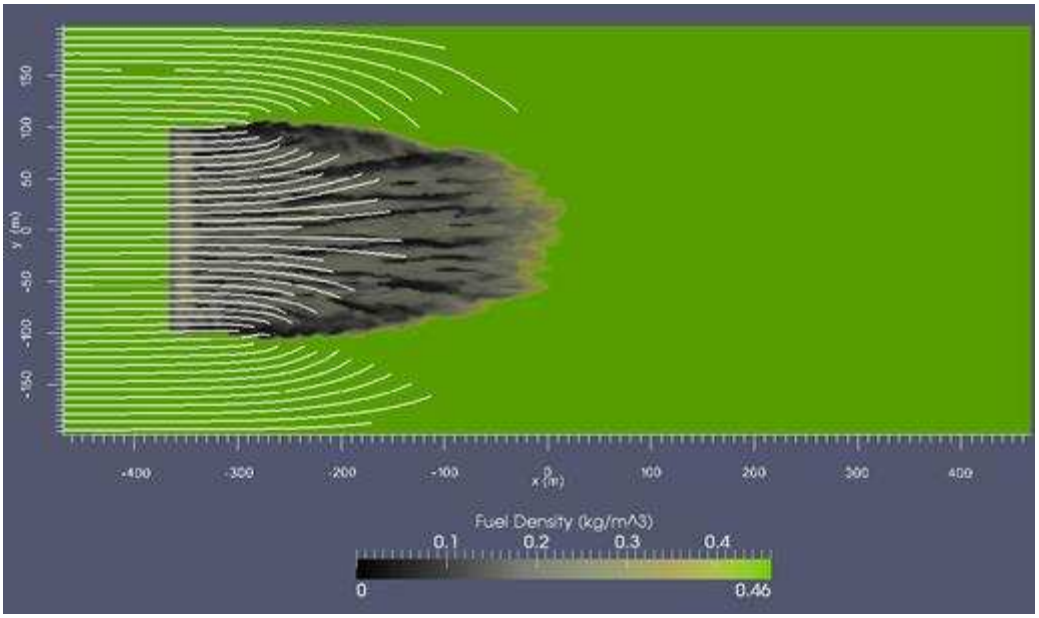

Figure 2. Top down view of 6 m s^{-1} wind 200 m-ignition fire. This image illustrates the parabolic shape of the progressing fire and the white streamlines illustrate the interaction between the upstream air flow and the competing indrafts of the flanking and heading firelines

In the two-dimensional simulations there were no cross-stream variations. These scenarios are more representative of a fire burning between two very-close plates of glass with wind blowing between them than they are of a two-dimensional slice through an infinitely long fireline. With ambient wind speeds of 1 m s^{-1}, the general structure of the plume appeared similar to those seen in the 1 m s^{-1} three-dimensional periodic simulation, but the spread rate was more than twice as fast as in the three-dimensional simulations. For wind speeds above 3 m s^{-1}, a significant effect of the two-dimensional restrictions was to preclude stream-wise and vertically oriented vortex structures. These structures occurred and proved to be important in the three-dimensional calculations, but are prevented in two-dimensional calculations because they require heterogeneity in the cross-stream direction. The elimination of the three-dimensional vorticity under two-dimensional constraints diminishes the ability of the wind to mix through the heated plume and entrain hot gases down into the fuels ahead of the fire. This causes a much slower spread rate in the two-dimensional simulations compared to the periodic three-dimensional simulations for ambient winds of 6 m s^{-1} and higher.

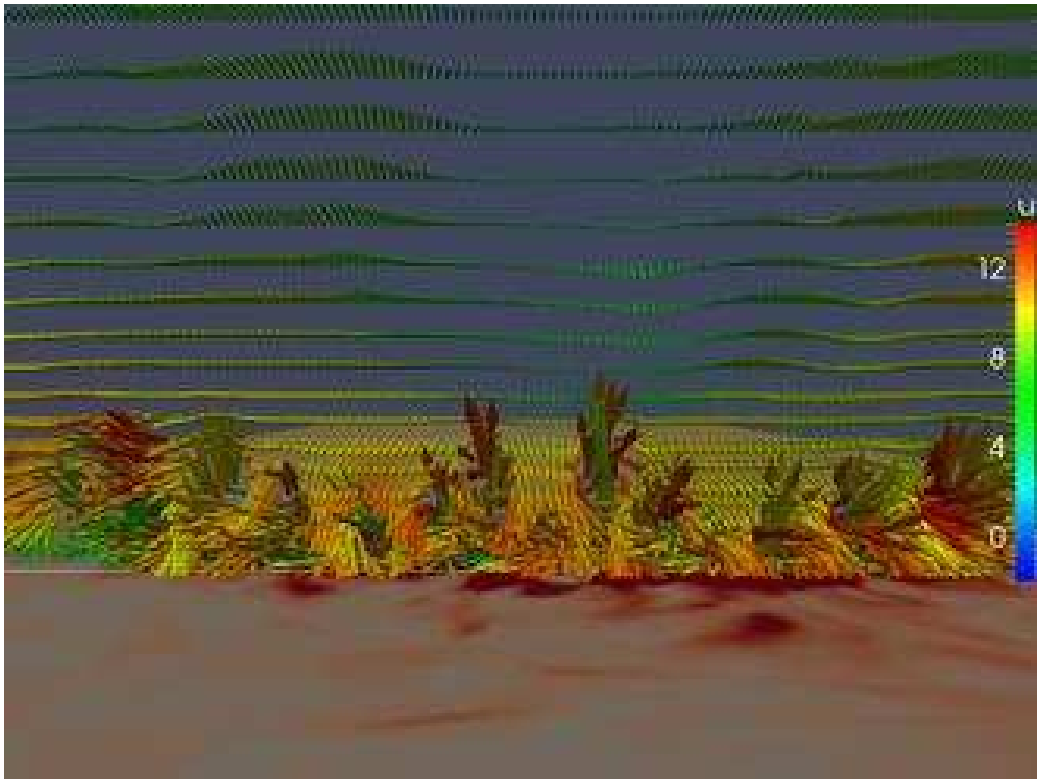

Figure 3 – Head on FIRETEC simulation of finite-length fireline (looking from in front of the fire as it approaches). This image illustrates the significance of the heterogeneity along the fireline in the cross-stream direction (left and right in the image). The fuel surface is colored by convective heating of the fuel where red is heating and blue is cooling. The vectors are in a y-z plane extending vertically above the white line and the vectors are colored by stream-wise velocity and scaled by total velocity

1.2. Three-dimensional effects at fire scales

In the finite-length fireline simulations, the curvature of the fireline and ability for winds to move around the fire lead to different fire behaviour than seen in the infinite-length fire scenarios. These differences are exacerbated by a couple of three-dimensional fire-scale interactions between the fire and the atmosphere. The head and flanking sections of the fire influence each other through their fire-induced indrafts. Indrafts from the flanking portions of the fireline compete with each other for the supply of upstream wind. For example, flanking portions of the fire draw from the airflow upstream, leaving a reduced amount of stream-wise wind to push the head fire forward and thus slowing down the forward spread rate. For wider fires, the separation between the flanking fires is large enough that competition between flanking fires is a non-issue. In scenarios where the flanking portions of the fire are relatively short compared to the length of the head fire, the wind can more effectively reach the headfire and transport hot gases to the unburned fuel in front of the fire. Similarly, as the competition between flanking fire and headfire sections of the fireline decreases, the wind arriving at the inside of the flanking fire sections can increase, enabling more effective heat transfer to the unburned fuel on the flanks as well. The competition between the indrafts of flanking and head fire and the net impacts on spread rate should be investigated experimentally in the future, as it has the potential to tie observable fireline geometry characteristics to corrections for rate of spread calculations.

The idealized finite-length grass fire simulations also suggest that there might be an overall negative pressure gradient from upwind of the fireline to downwind of the fireline. This pressure gradient may affect the penetration of wind through the fireline and the convective heating of unburned fuel. The magnitude of the effective pressure gradient across the fireline is influenced by the upstream in-draft competition between flanking and headfires. These firelines did not extend across the entire domain

and air was free to move around them, unlike in the periodic infinite-length simulations described above where air cannot move around the firelines. The wind flow around the fires in the finite-fire simulations alters the upstream to downstream pressure gradient and therefore can contribute to the differences in spread rate between the infinite firelines and the finite length firelines. This effect contributes to the difference between the finite-length firelines and infinite-length fires where the firelines become much deeper (in the streamwise direction) firelines and have larger rates of spread. In the periodic infinite-fireline scenarios, the larger pressure gradient across the firelines and inability of the winds to move around the fireline increase the flow through the fireline and the heat transfer to the unburned fuel in front of the fire.

Conclusions

This work suggests ways that the three-dimensionality of coupled fire/atmosphere behavior at a variety of scales affect fireline dynamics. The three-dimensional phenomena outlined here (described in detail in Canfield *et al*., 2014 and Linn *et al*., 2012) provide the basis for hypotheses that need to be tested in laboratory and field experiments. The three-dimensionality of the fire/atmosphere interaction also has significant implications for measurement strategies in such experiments. The analysis of any point measurements should include both knowledge of the position of the measurement with respect to the shape of the fireline as well as the context of the measurement with respect to the towers and troughs of the fireline itself.

These simulations suggest that caution be taken when attempting to use a two-dimensional assumption for wildland fire spread modelling. This is especially important when attempting to interpret results in the context of a process-based model such as that of Linn (1997), where the two-dimensional nature of the calculations are believed to have significant impacts on the simulated fire behavior. Care should be taken to account for the combined impacts of the variations in the flow field and plume structure in the third dimension. It is possible that the effects of local three-dimensionality could be represented in a manner similar to how turbulence kinetic energy is modelled without actually resolving the velocity fluctuations; however, this is not a trivial task and has not been accomplished to date. Such advances will likely come from a combination of modelling, laboratory experiments and field observations.

Abstract
The validation of physical models of fire spread requires comparing simulated results and experimental observation. Fire tests conducted at laboratory scale are appropriate to measure the finest physical mechanisms that cannot be recorded at field scale. However, particular attention must be paid concerning the influence of the experimental configuration on the fire and the way to take them into account for the simulation. Indeed, one must be sure that the main effects due to the experimental device and design are well reproduced by the models before to investigate the validation of such model by comparison with thermodynamics quantities measured. In this paper a methodology is proposed to be able to test a physical model against experiments conducted in a Large Scale Heat Release calorimeter. The hood effects as well as the ignition are investigated with WFDS, a physical model of wildland fire.

Keywords*: Calorimetry measurements, 3D numerical simulation, WFDS, fire behaviour*

Introduction

The use of physically-based wildland fire models for research purposes has increased in this last decade both due to their potential to capture the basic physical processes regardless of the scale (Porterie *et al*., 2005, Mell *et al*. 2007), and due to the growing improvements offered by computational resources. These models have been assessed at different scales but their validation is still ongoing. Laboratory-scale experiments can provide an important source of data for validating physically-based models at this particular scale. However, laboratory fires are relatively low intensity fires and their behaviour is related to the experimental configuration (e.g. experimental methodologies and design, characteristics of the experimental device, etc.). So, when using laboratory experimental data to validate physically-based models, this aspect should be carefully taken into account in order to avoid misleading conclusions.
Figure 1 depicts the different aspects that must be considered to ideally compare the simulation results provided by a given model with experimental observations done at laboratory scale. Depending on the experimental configuration, the design and device parameters might be different. With regard to the experimental design parameters, we can consider that fuel load and slope are common parameters frequently used by many investigators (Dupuy 1995, Viegas 2004, Tihay 2012). Although the range of variation for these parameters might be different from one author to the other, they can be easily (and implicitly) taken into account by physical models. Another important parameter concerning the experimental design is the ignition pattern. Different ignition types (linear or point) and methods can be found in literature. For linear ignition, Viegas *et al*. (2004) use one or more threads of wool soaked in a mixture of petrol and fuel oil. The threads are located at the edge of the fuel bed and ignited with matches. A linear flame is obtained along the thread in 5s. Santoni *et al*. (2010) spread a line of alcohol (4 to 6 ml) linearly on the fuel with a pipette and use a flame torch to ensure quasi-instantaneous ignition along one edge of the fuel. Although for such ignition patterns the fire will spread similarly under no slope condition, conversely ignition condition might affect the spreading for canyon

configuration for instance. Hence providing a numerical ignition close to the experimental one is of interest for the test of physical models. Some parameters that can also affect the spreading of fire are related to experimental device used. For instance the physical properties of the bench substrate are not thermally negligible (Dupuy, 1995). The thermal conductivity of a metallic bench (Viegas, 2004) for instance is different from an air-entrained concrete plate (Santoni *et al*, 2010). Thus heat transfer between the fuel bed and the bench must be taken into account. Another parameter that can affect fire spreading is the use of an exhaust system. Santoni *et al*. (2010) used such type of system to investigate the heat release rate (HRR) of spreading fires by collecting the smoke released during fire spread. By measuring the consumption of oxygen it is possible to derive the HRR. In previous works we investigated the HRR, the radiant and convective fraction of energy release by fire under slope and no slope conditions (Tihay *et al*., 2012). Those results can be used to validate physical models of fire spread. However the exhaust system has to be taken into account in the numerical study since the air entrainment near the fire can slightly be modified by the extraction system for low intensity fires. Finally, besides experimental design and experimental device parameters that must be accounted for, the numerical computational parameters (grid size sensitivity, parallelisation,) are of primarily importance. The size of the mesh must be fine enough to couple with both combustion of gases and heat transfer within the fuel bed.

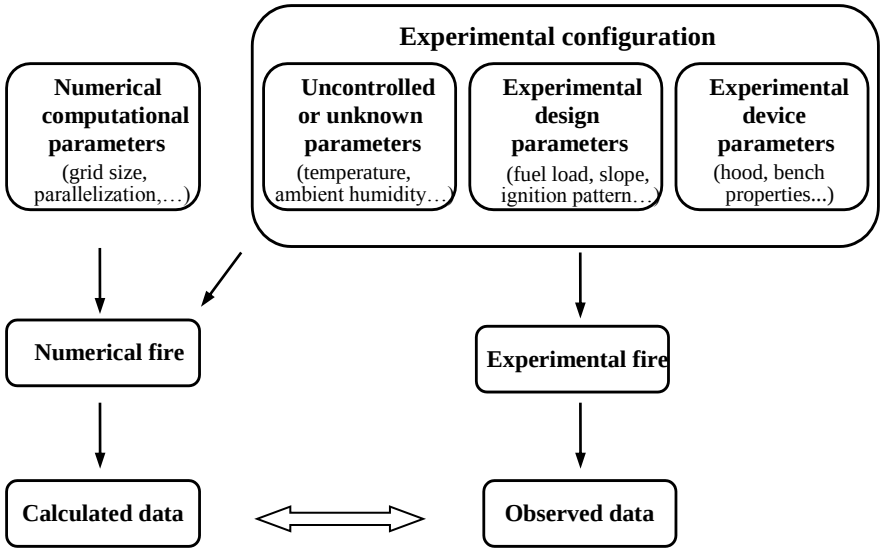

Figure 1. Diagram of the influence of the experimental conditions on numerical and experimental fires

In this paper the use of a physically-based model to simulate spreading fires in a large-scale heat release calorimeter is addressed, paying special attention to the influence of the experimental configuration. The study has been focused on two parameters which could have a major role in the behaviour of numerical fires; this is the hood extraction system and the ignition method. The experimental configuration is first depicted. Then some experimental results are provided to detail the quantities of interest to be modeled. The numerical model is presented in the fourth section. It is the *Wildland urban interface Fire Dynamics Simulator* – WFDS (Mell *et al*., 2007; Mell *et al*., 2009) developed by the National Institute of Standards and Technology (NIST) and the US Forest Service. The air flow in the hood is then studied as well as the numerical ignition. A grid sensitivity analysis is performed for the flow to reach a compromise between precision and simulation time.

Experimental configuration

The fire spread experiments were conducted by using a 1 MW Large Scale Heat Release rate apparatus (LSHR). Fire tests were performed on a 2 m long and 2 m wide combustion table located under a 3 m × 3 m hood with a 1 m^3/s extraction system (Figure 2). Two thermocouples (48 cm spaced) recorded the temperature of the combustion gases in the exhaust smoke duct. The bench was located on a load cell (sampling rate 1 Hz and 1 g accuracy) in order to record the mass loss over time during the fire spread across a fuel bed. Needles of *Pinus pinaster* were distributed uniformly on the table in order to obtain homogenous fuel beds of 1 m width and 2m long that occupy only the central part of the table. Particular attention was paid to the preparation of the fuel bed. Different fuel loads were tested: 0.6, 0.9 and 1.2 kg/m^2 that correspond respectively to fuel beds height of 4 cm and 6 cm for the highest loads. At least four repetitions were carried out for each fuel load.

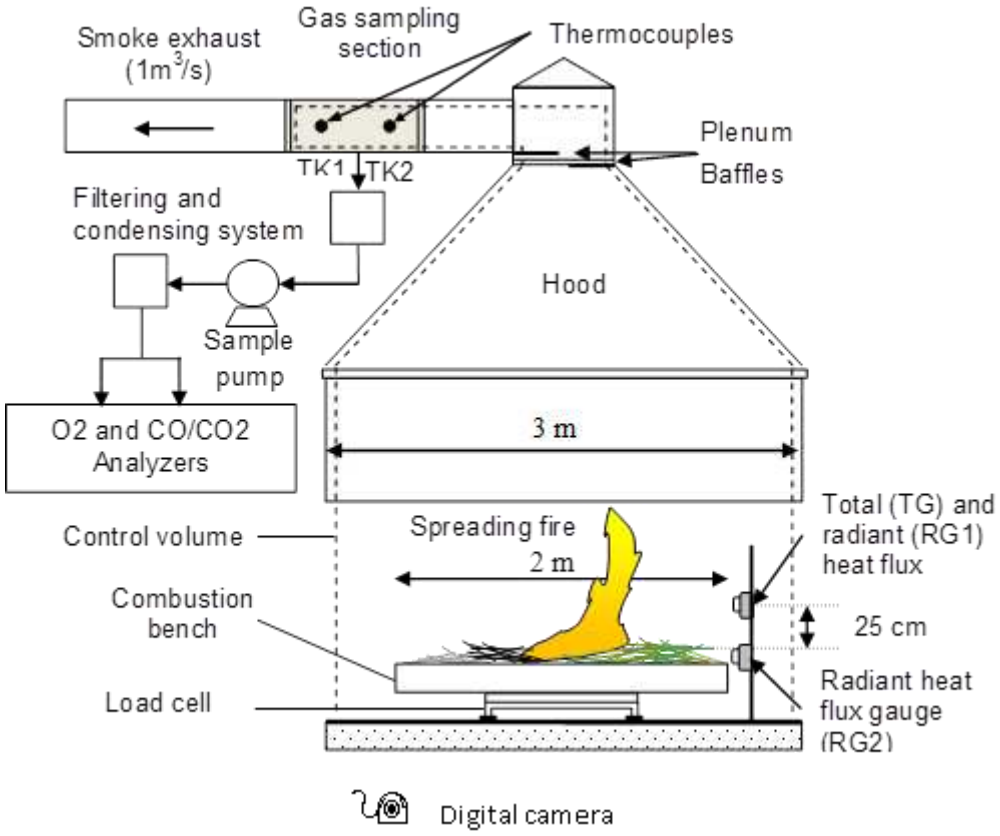

Figure 2. Large Scale Heat Release apparatus used for the fire tests

The net heat of combustion, the surface to volume ratio and density of the particles were $\Delta H_{c,needles}$ = 20313 kJ/kg, σ = 3057 /m and ρ = 511 kg/m^3 respectively. The net heat of combustion was derived from the gross heat of combustion measured in an oxygen bomb calorimeter following the standard AFNOR NF EN 14918. The needles were oven dried at 60°C for 24 hours. The resulting moisture content was between 3-5%. To ensure fast and linear ignition, a small amount of alcohol and a flame torch were used. The fire tests were conducted without wind under slope angles of 0° and 20°. The rate of spread was deduced from the position of the fire over time every 0.25 m. Three heat flux gauges (Medtherm Corporation) were placed at the end of the experimental bench, in the centre of the bed (see Figure 2 for no slope fire). The total heat flux gauge (TG) and a radiant heat flux gauge (RG1) were oriented towards the flame and located 0.20 m above the bed. The second radiant heat flux gauge (RG2) was located at the end of the combustion bench, at mid height of the fuel layer in order to measure radiation from the bed (Figure 2).

HRR measurement and main experimental results

The experiment performed allowed us measuring an important quantity of data: fire front geometry (flame height, flame angle), rate of spread, heat release rate (HRR), burning rate, convective and radiant fraction, radiant heat flux. However for the purpose of this study we solely consider the HRR as it is among the most important parameter for understanding combustion process and fire characteristics (Babrauskas and Peacock, 1992). The measurement of exhaust flow velocity and gas volume fractions were used to determine the heat release rate (HRR) based on the formulation derived by Parker (1992). The heat release rate is given by the oxygen molar flow rate:

$$HRR = E\left(\dot{n}_{O_2}^{\circ} - \dot{n}_{O_2}\right)W_{O_2} \tag{1}$$

where $\dot{n}_{O_2}^{\circ}$ and $\dot{n}_{O_2}$ represent respectively the molar flow rates of O_2 in incoming air and in the exhaust duct and W_{O_2} is the molecular weight of oxygen. The volume flow rate of incoming air, referred to standard conditions is:

$$\dot{V}_a = \frac{\dot{n}_{O_2}^{\circ}}{X_{O_2}^{\circ}}\frac{W_{air}}{\rho_0} \tag{2}$$

where $X_{O_2}^{\circ}$ is the molar fraction of O_2 in incoming air and W_{air} is the molecular weight of dry air at 25 °C and 1 atm. The oxygen depletion factor is introduced for convenience. It is given by:

$$\phi = \frac{\dot{n}_{O_2}^{\circ} - \dot{n}_{O_2}}{\dot{n}_{O_2}^{\circ}} \tag{3}$$

Combining Eq. (1) - (3), one obtains the HRR, $\dot{q}$:

$$\dot{q} = \frac{E\rho_0 W_{O_2}}{W_{air}} X_{O_2}^{\circ}\phi\dot{V}_a \tag{4}$$

Gases are measured on a dry basis since the analyzers cannot handle wet mixtures. Thus, the mole fraction of gases in air is derived from the analyzers' measurement and from air humidity. For instance, the mole fraction of oxygen in air is given by:

$$X_{O_2} = \left(1 - X_{H_2O}\right)X_{O_2}^{a} \tag{5}$$

where superscript *a* denotes the mole fraction in the analyzers. Unfortunately, in an open system, not the incoming air flow rate $\dot{V}_a$ but the flow rate in the exhaust duct $\dot{V}_s$ is measured. A relationship between $\dot{V}_a$ and $\dot{V}_s$ is obtained and after some development (Parker, 1992), the HRR is given by the three following relations:

$$\dot{q} = \frac{E\rho_0 W_{O_2}}{W_{air}}\left(1 - X_{H_2O}^{\circ}\right)X_{O_2}^{a\circ}\dot{V}_{s,298}\left[\frac{\phi}{(1-\phi)+\alpha.\phi}\right] \tag{6}$$

$$\dot{V}_{s,298} = 22.4A\frac{k_t}{k_p}\sqrt{\frac{\Delta P}{T_S}} \tag{7}$$

$$\phi = \frac{X_{O_2}^{a^\circ}\left(1 - X_{CO_2}^{a}\right) - X_{O_2}^{a}\left(1 - X_{CO_2}^{a^\circ}\right)}{X_{O_2}^{a^\circ}\left(1 - X_{CO_2}^{a} - X_{O_2}^{a}\right)} \quad (8)$$

X denotes the molar fraction and ρ_0 is the density of dry air at 298K and 1 atm. $\dot{V}_{s,298}$ is the standard flow rate in the exhaust duct. α is the expansion factor for the fraction of the air that was depleted of its oxygen. The superscript ° is for the incoming air. A is the cross sectional area of the duct, k_t is a constant determined via a propane burner calibration, k_p=1.108 for a bi-directional probe, ΔP is the pressure drop across the bi-directional probe and T_s is the gas temperature in the duct.
Instantaneous heat release rates (HRR) measured during the fire tests are displayed in Figure 3 for fuel loads of 0.6, 0.9 and 1.2 kg/m² and no slope. For experiments performed without slope, a quasi-steady state was reached for all fuel loads. The flameout occurred earlier for higher fuel load due to the increase in the rate of spread. The average HRR were computed during the quasi-steady state. The average heat release rates were 41, 87 and 130 kW for the 0.6 to 0.9 and 1.2 kg/m² fuel load, respectively. The greater the fuel load, the greater the heat release rate. The mean values increased by a factor of 2.1 and 3.2 with increasing the fuel load by a factor of 1.5 and 2. The total heat released (THR) was obtained by integration of the HRR curves during the whole experiment. The average total heat released were 22, 33 and 44 MJ for the 0.6, 0.9 and 1.2 kg/m² fuel load, respectively. The total heat released depends also linearly on the load.

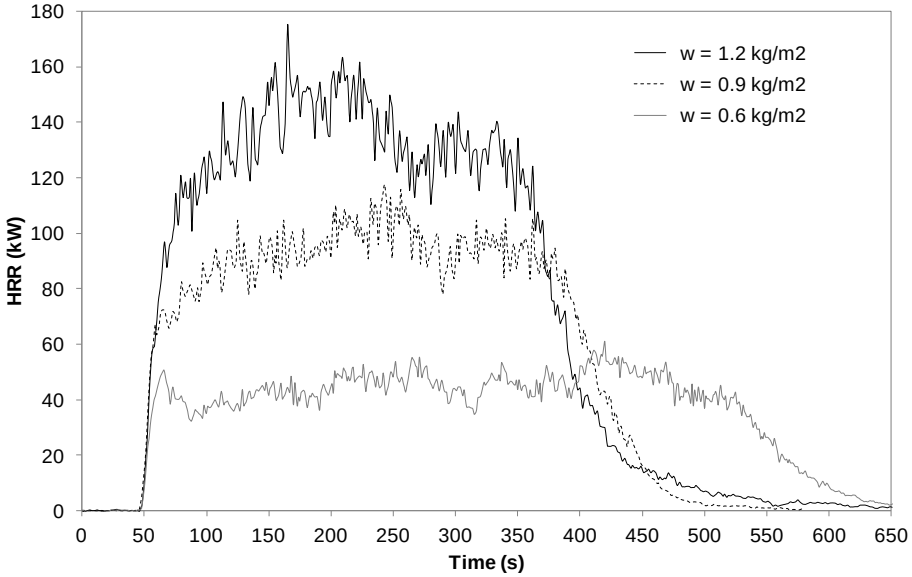

Figure 3 –Heat release rate versus time for fuel load of 0.6, 0.9 and 1.2 kg/m²

Numerical model

The numerical approach, called WFDS for WUI Fire Dynamics Simulator, is an extension of the capabilities of the FDS (Fire Dynamics Simulator) to outdoor fire spread and smoke transport problems that include vegetative and structural fuels and complex terrain. FDS is a fire behaviour model developed by NIST in cooperation with VTT Technical Research Center of Finland, industry, and academics (Mc Grattan *et al*., 2013a). The methods of computational fluid dynamics (CFD) are used to solve the three-dimensional time-dependent equations governing fluid motion, combustion, and heat transfer. The numerical model is based on the large-eddy simulation (LES) approach and provides a time-dependent, coarse-grained numerical solution to the governing transport equations for mass,

momentum, and energy. There are currently two ways of representing vegetative fuel in WFDS. One is restricted to surface fuels (Mell *et al*., 2007). It is called the boundary fuel model. The other, called the fuel element model can be used for raised or surface fuels but requires more spatial resolution (Mell *et al*., 2009). The interested reader is referred to Mell *et al*. (2009) for an extended presentation of WFDS and its capabilities. In the present work, we use the fuel element model to represent the vegetation. We assume that the litter is composed of thermally thin fuel elements. The needles of *Pinus Pinaster* are sufficiently small in size (e.g., branches <1.85 mm in diameter) that the heat transfer is not resolved within the core of each needle on the computational grids used here (2 cm). This is similar to other modelling approaches (Porterie *et al*., 2005). Both convective and radiative heat transfer between the gas phase and the vegetation is accounted for, as is the drag of the vegetation on the airflow. In the modelling approach used here, the temperature equation for the fuel bed is solved assuming a two stage endothermic decomposition process of water evaporation followed by solid fuel pyrolysis. The grid size (2 cm) inside the vegetation litter was evaluated as a fraction of a length scale representative of the radiative heat transfer $\delta_R = 4/(\beta\sigma)$ which constitutes one of the most important modes of heat transfer contributing in many situations to the propagation of the fire. β represents the compactness of the litter. Its value was 0.029 for the fuel loads of 0.6 and 0.9 kg/m^2 and 0.039 for the fuel load of 1.2 kg/m^2. The values of δ_R are respectively 4.4 cm for the fuel loads of 0.6 and 0.9 kg/m^2 and 3.3 cm for the fuel load of 1.2 kg/m^2. Simulations were run with an Intel Xeon cluster whose nodes consists of two 8-core Intel Xeon E5-2650 CPUs running at 2.0 GHz with 32 GB of main memory.

Sensitivity analysis and ignition method

5.1. Sensitivity analysis of the flow in the hood

As detailed previously, calorimetric calculations are based on the measurement of oxygen consumption. A hood extraction system collects the gases released from the combustion, hence this system induces an air flow. Validating a physical model of vegetation requires thus being capable to capture the flow within the hood that could influence the spreading of the fire. In other words, before to test the model against experimental results one must verify previously that it is able to represent the flow without fire, since the flow field could have an influence for fire tests with the smallest fuel load. Indeed, for the load value as 0.6 kg/m^2, the fire front is not regular and it seems formed of an ensemble of individual flamelet. It is not the case for the highest fuel load (0.9 kg/m^2 and 1.2 kg/m^2) for which the fire front is like a wall of flame spreading towards the unburned fuel. To study the flow we have first considered the whole laboratory of experimentation with the LSHR inside as well as the different vents. Figure 3 depicts the laboratory simulated with WFDS.

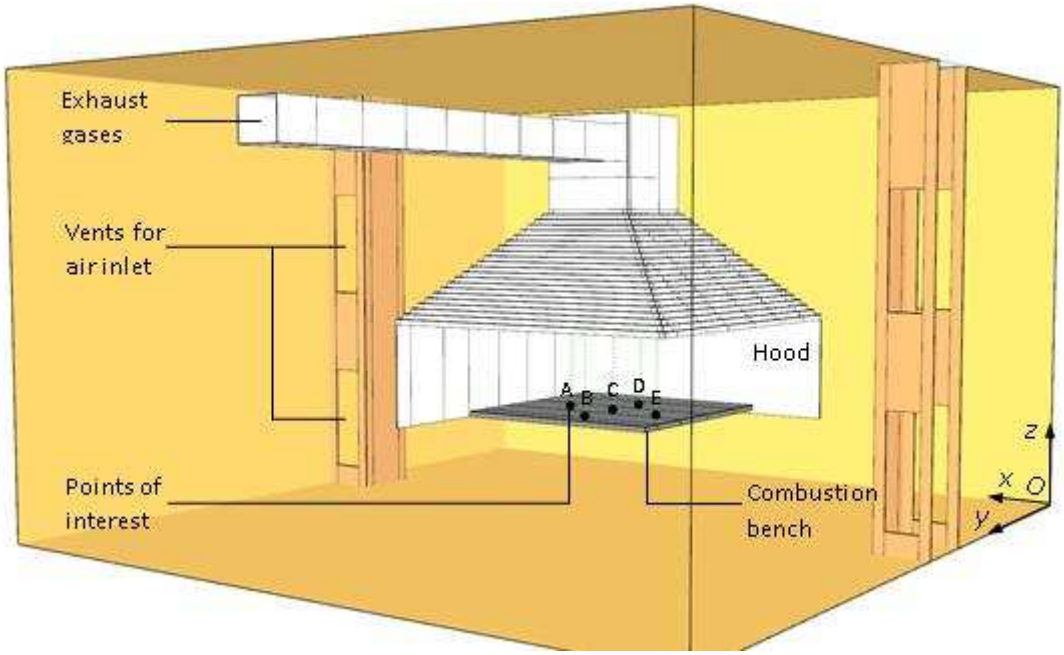

Figure 4. Laboratory with LSHR and vents.

We can see that the domain of calculation is much larger than the LSHR hood where the fire tests were performed. However, before to reduce the size of the calculation domain (to the size of the control volume of the hood as shown in figure 1 for instance) it is important as a first step to conduct a sensitivity analysis with the actual dimension of the experimental laboratory whose dimensions are 6.6 m long, 6.4 m large and 4.4 m high.

Sensitivity analysis

A sensitivity analysis has been performed to find out the more appropriate grid resolution to capture the flow dynamics behavior within the hood. Although the mesh size inside the vegetation is governed by the radiant heat transfer through the fuel bed, conversely a measure of how well the flow field is resolved in the gas phase above the fuel (for simulations involving buoyant plumes) is usually given by the non-dimensional expression $z_c / \delta x$ (Mc Grattan *et al*., 2013b)

$$z_c = \left(\frac{\dot{q}}{\rho_\infty c_p T_\infty \sqrt{g}} \right)^{2/5} \tag{9}$$

where z_c is a characteristic fire scale, δx is the nominal size of a mesh cell and $\rho_\infty = 1.2$ kg/m^3 , $c_p = 1000$ J/(kg.K) and $T_\infty = 293$ K are respectively the density, specific heat and temperature of ambient air. The $z_c / \delta x$ values have to range from 4 to 16 (Mc Grattan *et al*., 2013b). In our case, since the fire is spreading as a line, the characteristic length scale $z_{c,line}$ for a line plume is given by:

$$z_{c,line} = \left(\frac{\dot{q}'}{\rho_\infty c_p T_\infty \sqrt{g}} \right)^{2/3} \tag{10}$$

where $\dot{q}'$ represents the fire line intensity, i.e. the energy release rate per unit length of the fire (Quintiere, 2006). Since the fire front remains quasi-linear during the fire tests, the fire line intensity is equivalent to the HRR: 41, 87 and 130 kW respectively for fuel loads of 0.6, 0.9 and 1.2 kg/m². We obtain $z_{c,line}$ values of 0.11, 0.18 and 0.24 m respectively for the 0.6 to 0.9 and 1.2 kg/m² fuel loads. For these fuel loads, the mesh size δx must respectively be lower than 2.8, 4.6 and 6 cm.

As a first stage, our sensitivity analysis is based on the study of the flow in the hood without the fire. The following mesh sizes were used: 2.5 cm, 5 cm and 10 cm called respectively grid 1, grid 2 and grid 3 in the following. The reason is that away from the fire, the mesh size can be coarse and having mesh size greater than the sizes mentioned previously can provide computational time saving without altering the resolution of the fire region for which the grid has to be finer (less than 2.8, 4.6 and 6 cm for the 0.6 to 0.9 and 1.2 kg/m² fuel loads). For the sensitivity analysis, we will consider 5 positions of interest on the bench on combustion (Figure 4): point C is at the center of the table and points A, B, D and E are positioned 0.5 m aside. The global velocity and the velocity components of the flow will be considered as a function of height above these 5 positions. The interval (Fig 4) between each point along height depends on the mesh size. The total velocity (and deviation) with height are displayed in figure 5 above positions A and C as example. The results presented are representative of simulations obtained at location B, E and F. The better agreement between grid 1 and 2 was obtained at position A while position C is representative of the worst agreement between simulations results obtained with both grids. Figure 5 shows that the values of the total velocity obtained with grid 2 are near to the simulation of reference performed with grid 1. We observe also that grid 3 fails to reproduce the tendency of the variation of the velocity with height observed for grid 1 and 2. The small differences observed between the results obtained with grid 1 and grids 2 suggest that a mesh size of 2.5 cm is sufficient to get convergence in the case of a non reacting flow. Another point that deserves mention is the comparison of inflow at the vent of the domain. The mass balance was checked for the three grids, but we observe that the inflow is very different for grid 3. In that case, a greater amount of air comes into the domain and then flow out at the vent denoting an important recirculation that was very low for grid 1 and grid 2. All these results show that a mesh size of 10 cm is not capable to accurately represent the flow in the hood and in the laboratory.

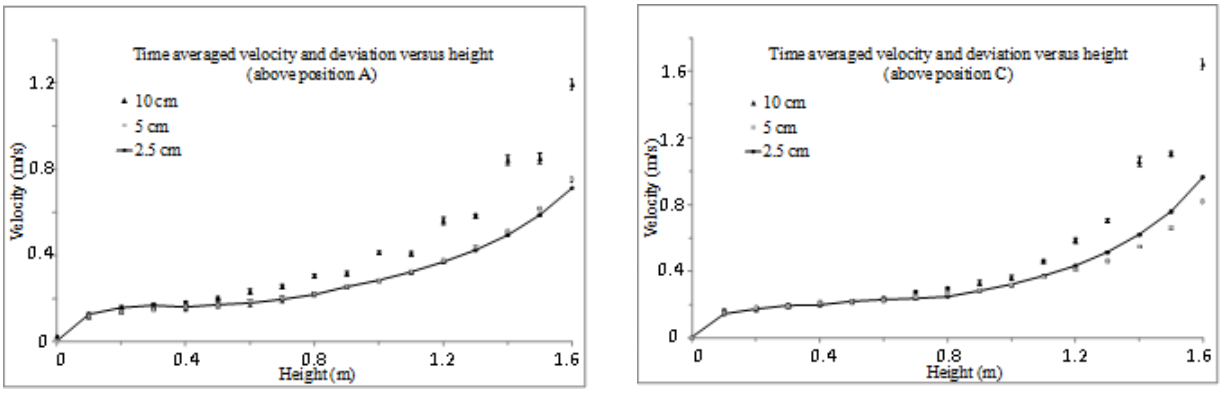

Figure 5. Time averaged velocity and standard deviation versus height in the hood for the large calculation domain (laboratory) above position A and C for the different grids

The quality of a particular simulation is most directly tied to the grid resolution. In order to measure this quality, the fraction of unresolved kinetic energy called the measure of turbulence resolution (MTR) was examined (Mc Grattan *et al*., 2013b). The MTR is similar to the Pope (2004) criterion. The MTR was calculated at each point above the positions of interests as depicted in figure 4. Then the time average of MTR was calculated at each point along height. And finally the mean of these values was calculated versus height above the five positions of interest. Figure 6 displays the results of the mean time averaged MTR along height for the different grid tested. According to Mc Grattan *et al*. (2013b), maintaining mean values of MTR near 0.2 provides satisfactory results (simulation results within experimental error bounds) for mean velocities and species concentrations in non reacting, buoyant plumes. Hence figure 6 shows that grid 1 and grid 2 are convenient for this criterion while grid 3 is not suitable.

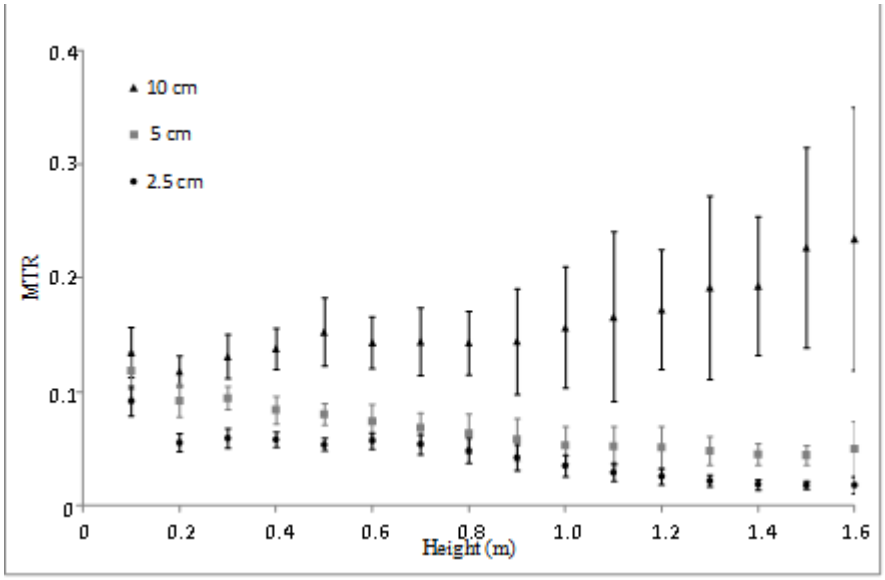

Figure 6. Measure of mean turbulence resolution with standard deviation for the different grids.

Size of the calculation domain and time saving

The size of the calculation domain is an important factor that affect greatly the calculation time. The greater the domain is the larger the time of simulation is. As an example, the simulation time performed per day for the flow is given in table 1 for the mesh sizes of 2.5, 5 and 10 cm (grids 1, 2 and 3). Different domains of calculation have been studied and the simulated results have been compared as previously, attempting to reach a compromise between the precision of the results and the simulation time. Two domains are discussed hereafter. The first one is a little bit larger than the hood (50 cm larger in all direction). It is called 'LSHR and vicinity'. The second one is limited to the size of the hood (see control volume in figure 1). It is called LSHR.

Table 1. Calculation time for the different grids

	Grid 1	Grid 2	Grid 3	Grid 4
Domain	Laboratory	Laboratory	Laboratory	LSHR
Mesh size (cm)	2.5	5	10	2 and 4
Number of mesh	11 489 280	1 436 160	179 520	2 707 200
Number of processor	14	1	1	14
Calculation time (sec/day)	13	29	883	72

In order to optimize the different requirements of the grid (in the litter and in the flame), the mesh size was fixed to 2 cm in the litter, above it and below it (under the bench). A coarse mesh size of 4 cm was used elsewhere in the calculation domain since as seen previously grid 2 (5 cm size) was enough convenient for the flow. We have chosen 4 cm since it is not allowed with FDS to align meshes with size of 2 cm and 5 cm (Mc Grattan *et al*., 2013a). The simulation of the flow done with these domains was compared to a simulation of reference performed with the large domain (see Figure 2) for which a mesh size of 2 cm was used in the hood and 4 cm elsewhere in the domain to be coherent with the mesh of the small domains.

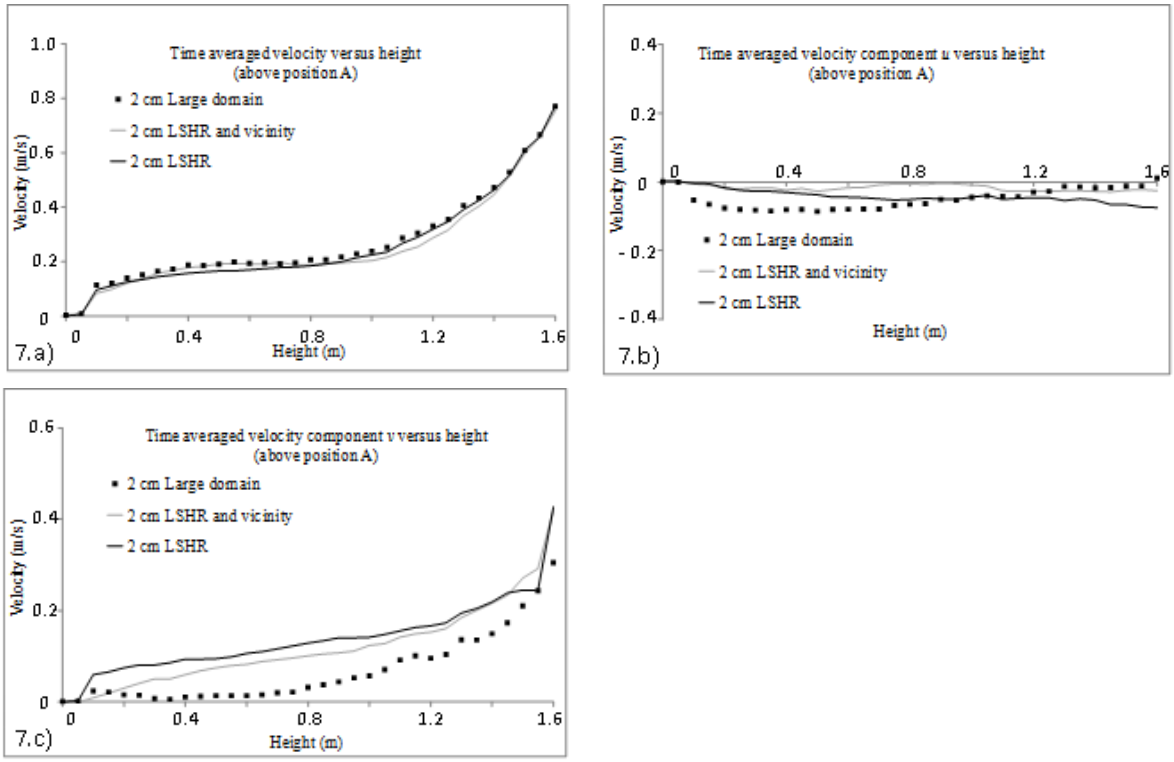

Figure 7. Simulation of the velocity in the hood of the LSHR: comparison between the large calculation domain and the domains limited to the hood and to the hood vicinity: a) global velocity, b) component u, c) component v, d) component w.

Figure 7 shows the time averaged velocity versus height above position A and the time averaged of the three components of the velocity *u*, *v* and *w* along respectively the axis *Ox*, *Oy* and *Oz* as depicted in Fig 2, for the three calculation domain. We observe that for the different positions along the height the three calculation domain provide similar results for the three components of velocity. The LSHR domain is however in better agreement with the large domain than the 'LSHR with vicinity' domain for component *w*. We can note that the values of components *u* is almost zero along the height and simulation results obtained with both domains can be considered in agreement for *u*. The main difference between the small domains and the large one is visible for component *v* which is overestimated with the small domains. However, we can observe that the tendency of components *v* which increases with height is rendered by the simulation performed with the small domains. Here also, the difference between the results of both small domains is negligible. Similar results were obtained along height for points located above the positions B, C, D and E. We can conclude that both small domains are equivalent to simulate the flow by comparison with the simulations performed with the large domain.

5.2. **Ignition method**

Concerning the ignition method, experimental fires were ignited by using a small amount of ethanol and a flame torch to ensure a fast and linear ignition of the fuel beds. The fires were ignited along the entire width of the fuel bed by using between 4 and 6 ml of alcohol. Figure 8 displays a zoom of figure 3 to focus on the HRR just at the ignition. 4 ml were used to ignite the fire tests with fuel load of 0.6 kg/m² while 6 ml were used to ignite fire tests with higher fuel load.

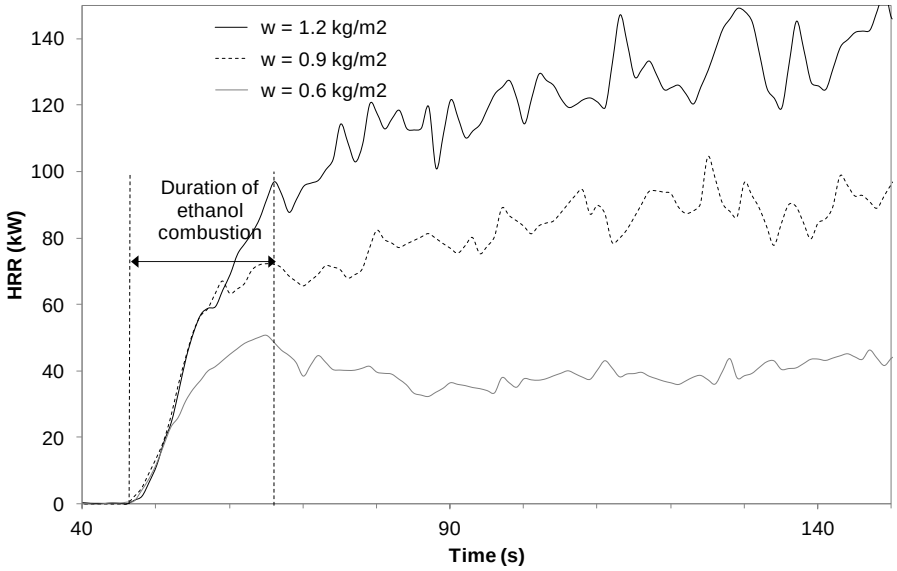

Figure 8 –Heat release rate at the ignition for fuel load of 0.6, 0.9 and 1.2 kg/m²

A study has been performed to investigate the duration time of ethanol burning when it is spread on the combustion bench without the vegetation. We measured this time (see Figure 8) in order to determine the mass of needles burned with ethanol during the ignition, $m_{needles}$:

$$m_{needles} = \frac{\int_0^{t_{ig}} \dot{q}\, dt - V_{ethanol} \times \Delta H_{c,ethanol}}{\Delta H_{c,needles}}$$

where t_{ig} represents the duration of ignition, $V_{ethanol}$ is the volume of ethanol used to ignite the vegetation and $\Delta H_{c,ethanol} = 21300$ kJ/L is the net heat of combustion of ethanol. The mass of needles involved in the ignition has been estimated to 20 g, 32 g and 35 g respectively for the fuel load of 0.6, 0.9 and 1.2 kg/m². The mass of needles used for 0.9 and 1.2 kg/m² are very close because the same quantity of ethanol was used for both fuel loads.

WFDS offers different options to simulate an ignition source that have been tested to reproduce the experimental ignition. Two different numerical methods to ignite the fuel bed have been compared in order to assess their ability to reproduce our experimental ignition in terms of heat release rate. The first method considers a linear strip of a given width located at the edge of the combustion bench for which the HRR per unit area is fixed during a time interval corresponding to the duration of the ignition. With this method and given the mass of fuel involved in ignition a strip of one meter long and 4 cm wide was considered. Although the calculated width was slightly lower than 4 cm, this dimension was chosen to be in agreement with the mesh size (2 cm) within the fuel bed. The HRR per unit area was set to 1100 kW/m^2 for the fuel load of 0.9 kg/m². The strip of ignition was applied during 18 s. It should be noted that the fuel bed length was shorten of 4 cm in order to avoid superimposing the needles and the strip that can be viewed as a burner located in front of the fuel bed. The second method consists of fixing the temperature of an ignitor at 1000°C. The ignitor is 4 cm wide and one meter long. Its height is equal to the fuel bed height. The ignitor is like a set of particle with porosity equal to the porosity of the fuel bed. It is located in front of the fuel bed. The simulated results of HRR for both methods of ignition were very similar. A point that deserves mention is the necessary time required "before to ignite the numerical fire". Even though the time for the flow to reach a quasi-stationary regime is not a problem for experimental fires since the hood is turned on a long time before ignition, it is the case for numerical fires. Indeed, the numerical ignition has to take place once a "quasi-

stationary flow regime" is established. This time is about 60 s for the LSHR domain of calculation and for a fuel load of 0.9 kg/m². Ignition before this time (that is to say during the transient flow regime) might result in a perturbation of the fire line that subsequently affects the spreading of the fire front over time (see Figs. 9a and 9b). In that case, the perturbation of the ignition is due to the flow that is not stabilized and introduces some dissymmetry before a given time that depends on the configuration (height of the fuel bed,…).

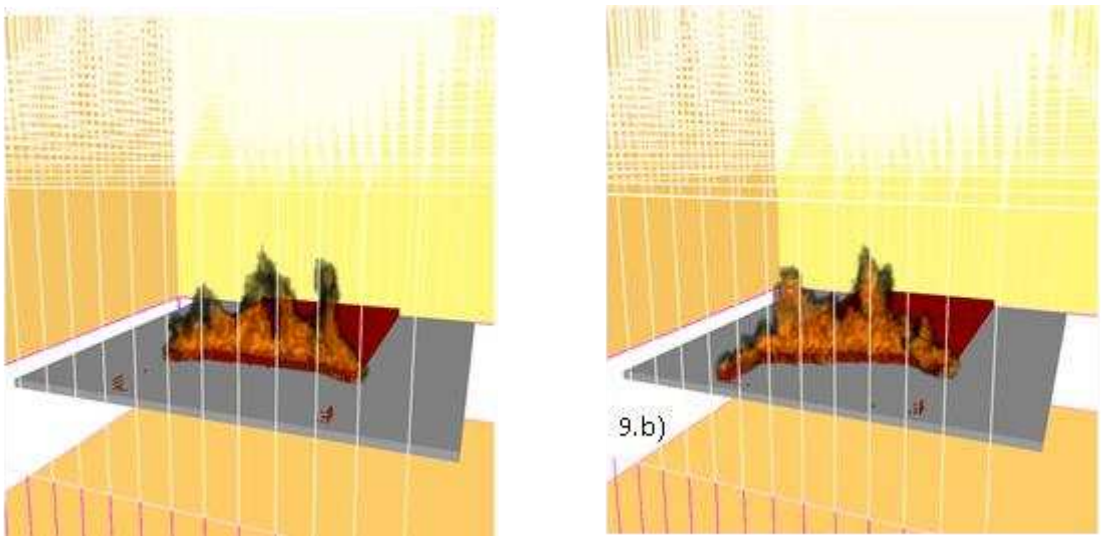

Figure 9. Influence of ignition time on the fire front shape for a fuel load of 0.9 kg/m²: a) numerical ignitions performed after stabilisation of the flow, b) numerical ignition performed before stabilisation of the flow

Conclusion and prospects

Physical model of fire spread are very promising to represent the behavior of wildland fires at a scale useful for risk assessment and fire safety concerns. The aim of our ongoing study is twofold. We propose a set of experimental data that can be used to validate physical model based on thermodynamics quantity of interest. Secondly we propose a methodology to validate such models paying attention to the influence of the experimental conditions that can affect the comparison between numerical and experimental fires. We focused on two parameters which could have a major role in the behaviour of numerical fires: the hood extraction system and the ignition method. This paper represents the first step of our work. Further studies will be devoted to the following activity: measurements of flow velocity within the hood will be done to assess the accuracy of WFDS to represent the flow with no fire. Secondly a full study will be performed to test WFDS against the set of data obtained from experiments conducted with the calorimeter for fire spreading under both slope and no slope condition for the different fuel loads: HRR, mass burning rate, radiant heat flux and exhaust gas composition. The role of the char during the process of spreading will be particularly investigated.

Abstract

In order to better understand the dynamics of fire-atmosphere interactions and the role of micrometeorology on fire behaviour the FireFlux campaign was conducted in 2006 on a coastal tall-grass prairie in southeast Texas, USA. The FireFlux campaign dataset has become the international standard for evaluating coupled fire-atmosphere model systems. While FireFlux is one of the most comprehensive field campaigns to date, the dataset does have some major limitations especially the lack of sufficient measurements of fire spread and fire behaviour properties. In order to overcome this, a new, more comprehensive field experiment, called FireFlux II, was conducted on 30 January 2013. This paper will address the experimental design and preliminary results. The experiment was designed to allow an intense head fire to burn directly through an extensive instrumentation array including fixed 42-m and three 10-m micrometeorological towers (Figure 2). The fuels consist of a mixture of native grasses.Each tower was equipped with a variety of sensors, including 3D sonic anemometers, pressure sensors, heat flux radiometers, and an array of fine-wire thermocouples to measure plume temperatures. The experiment was carried out under red flag warning conditions with strong winds of 8 m s-1 and relative humidity of approximately 24%. Instrumentation also included a scanning Doppler wind lidar, microwave temperature profiler, radiosonde balloons for upper-air soundings, a full suite of air quality instrumentation located downwind, and multiple ground and tower mounted infrared and visible video cameras. In addition, the fire spread was monitored from the air using helicopter mounted infrared and visible video cameras. Because the experiment was designed to be conducted under a north wind, the timing of the experimental period only allowed for a northwest wind. This required the instrumentation array to be moved in order to document the fire spread and was a limitation to the experiment. Preliminary results showed that the fire spread rate was ~1.5-2.5 m s-1 for the head fire while the flanks spread at 0.7 m s-1. The surface pressure field indicated that a low-pressure region formed downwind of the advancing fire front. The observations from the 42-m tower show that the strongest fire-induced winds occur a the surface in the cross-wind direction.

Keywords*: Grass fire, field experiment, fire-atmosphere interactions, micrometeorology, fire-induced winds*

Introduction

Studies on the fine-scale structure of fire-atmosphere interactions and fire behaviour have been based mostly on numerical simulations using coupled fire-atmosphere models (Clark *et al*. 1996; Mell *et al*. 2009; Linn and Cunningham 2005; Kochanski *et al*. 2013; Fillipi *et al*. 2013) and few field campaigns (Cheney *et al*. 1999; Clements *et al*. 2007). To better understand the dynamics of fire-atmosphere

interactions and the role of micrometeorology on fire behaviour, the FireFlux campaign was conducted in 2006 on a coastal tall-grass prairie in southeast Texas, USA (Clements *et al*. 2007, 2008). The FireFlux campaign dataset has become an international standard for evaluating coupled fire-atmosphere model systems. While FireFlux is one of the most comprehensive field campaigns to date, the dataset does have major limitations, especially the lack of sufficient measurements of fire spread and fire behaviour properties. In order to overcome these limitations, a new and more comprehensive field experiment, called FireFlux II, was conducted on 30 January 2013. This paper will address the experimental design and preliminary results.

Experimental Design and Instruments

The FireFlux II (FF2) field campaign was conducted at same plot as FireFlux at the University of Houston Coastal Center in Texas, USA, on 30 January 2013. The experiment was designed to allow for an intense head fire to burn directly through an extensive instrumentation array that included four meteorological towers, one fixed 42-m tower and three 10-m towers (Figure 1). The towers were equipped with a variety of sensors (Table 1), including three-dimensional sonic anemometers, pressure sensors, heat flux radiometers, and an array of fine-wire thermocouples to measure plume temperatures. Also located within the prairie were two interspersed grids of 28 surface thermocouples, buried underground, 18 pressure sensors positioned ~3.0 m above the burn plot, and 8 fire behaviour sensor packages that measured flame temperature, heat fluxes and gas velocities ~1 m AGL.
A key platform and instrumentation suite deployed during FF2 was the California State University-Mobile Atmospheric Profiling System (CSU-MAPS) (Clements and Oliphant 2014). The CSU-MAPS includes a truck mounted scanning Doppler wind lidar and a microwave profiling radiometer used to continuously measure background and plume thermodynamic and kinematic properties throughout the experimental period. The Doppler lidar provided high-resolution measurements of smoke plume aerosol backscatter intensity and radial wind velocities across the plot and around the fire front. The lidar has a range gate resolution of 18 m and the temperature profiler has a vertical resolution that scales with height, with a finer resolution of 50 m within the boundary layer. The CSU-MAPS also includes a mobile, trailer-mounted 32 m meteorological tower that is equipped with 5 levels of 2-d sonic anemometers and thermistor/hygristor sensors. In addition, a radiosonde system was used for an in-situ upper-air sounding taken just before ignition. Emissions and air chemistry were measured with a full suite of gas and particle samplers located downwind of the experimental plot (Figure 1). Multiple ground and tower mounted infrared and visible video cameras were used for measuring fire behaviour properties. In addition, the fire spread was monitored from the air using helicopter mounted infrared and visible video cameras. Table 1 provides a detailed description of meteorological instruments used during the experiment.

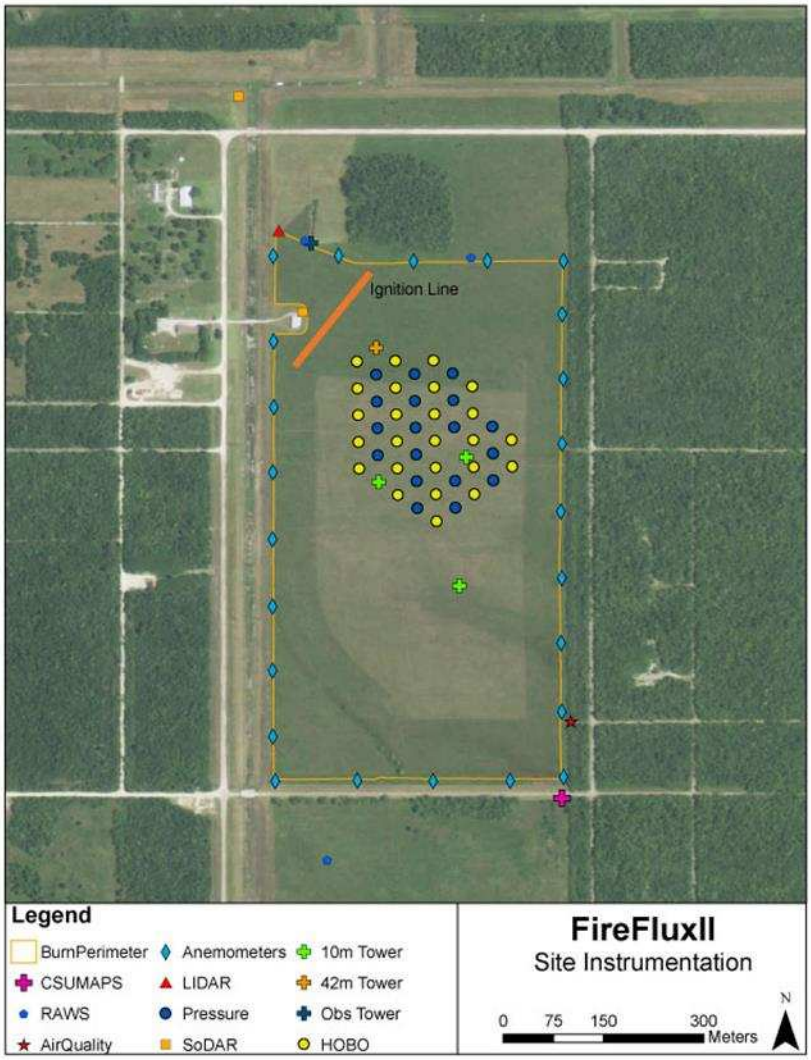

Figure 1. A map of the experimental setup during FireFlux II conducted on 30 Jan 2013.

Site description

The experimental plot was a natural tall-grass, of 155 acres (0.63 km^2) in size. The fuels consisted of a mixture of native grasses, including big bluestem (*Andropogon gerardi*), little bluestem (*Schizachyrium scoparium*), and long spike tridens (*Tridens strictus*). Fuel loading calculations were made from 20 destructive sampling plots. The average fuel loading for the experimental unit was 2.88 tons $acre^{-1}$.

The experiment was to be conducted under a north wind. However, synoptic conditions, as well as the timing of the experimental period, only allowed for a northwest wind as the best scenario. The decision was made to take advantage of the lesser than ideal conditions. WRF-SFire simulations (Mandel *et al*. 2012, Kochanski *et al*. 2013) were conducted to confirm the idealized fire spread under a northwest wind and based on these simulations, the instrumentation array was reconfigured just 24 hours prior to ignition. The reconfiguration was aimed to provide the most efficient experimental configuration for capturing the expected fire spread and maximize the number of instruments in the path of the fire.

Fuel moistures

Fuel moisture calculations were made from 20 different sampling plots. Three different sample types were collected 30 minutes prior to ignition: upper level grass (UL), lower level grass (LL), and forb (a herbaceous flowering plant). The boundary between the two grass layers was assessed based on the visual center of the mass height of the grass. Table 2 describes the moisture content percentages in detail.

Preliminary Results

Synoptic environment

The ignition occurred at 15:04 (CST) local time on 30 January 2013 and was associated with a post-frontal environment. The month of January was associated with above average precipitation and weak frontal systems, limiting ideal experimental conditions that required strong post-frontal northerly winds. Due to the excessive rain, soil conditions were wet with some regions of standing water within the experimental plot. A cold frontal passage the previous night created a strong northwesterly surface flow in excess of 8 m s-1, with gusts up to 12 m s-1, as well as a relative humidity of approximately 24% at the time of ignition (Figure 2). These conditions led to a red flag warning to be issued by the National Weather Service for the day of the experiment. A radiosonde launched 40 minutes prior to the ignition shows that the daytime boundary layer associated with a shallow superadiabatic surface layer and nearly adiabatic to slightly stable above the surface layer up to a capping inversion at nearly 2000 m aloft. The upper-level winds transition to strong westerly flow from the more northwesterly at the surface (Figure 3).

Preliminary spread analysis

The fire quickly spread from its ignition to the southeast side of the plot in 4 min while the flank continued to spread to the south end of the experimental plot. Using the ground based temperature loggers (Fig 4) to determine the fire front position, the fire spread rate was calculated to be ~1.5-2.5 m s^{-1} for the head fire while the flanks spread at 0.7 m s^{-1}.

Sample Type	Sample Size (n)	Mean (in %)	Median (in %)	Confidence Level (95%)	Standard Error	Standard Deviation
UL Grass	5	8.49	9.05	1.01	0.52	1.15
LL Grass	10	18.14	17.17	2.00	1.02	3.22
Forb	5	16.07	9.56	12.77	6.51	14.57

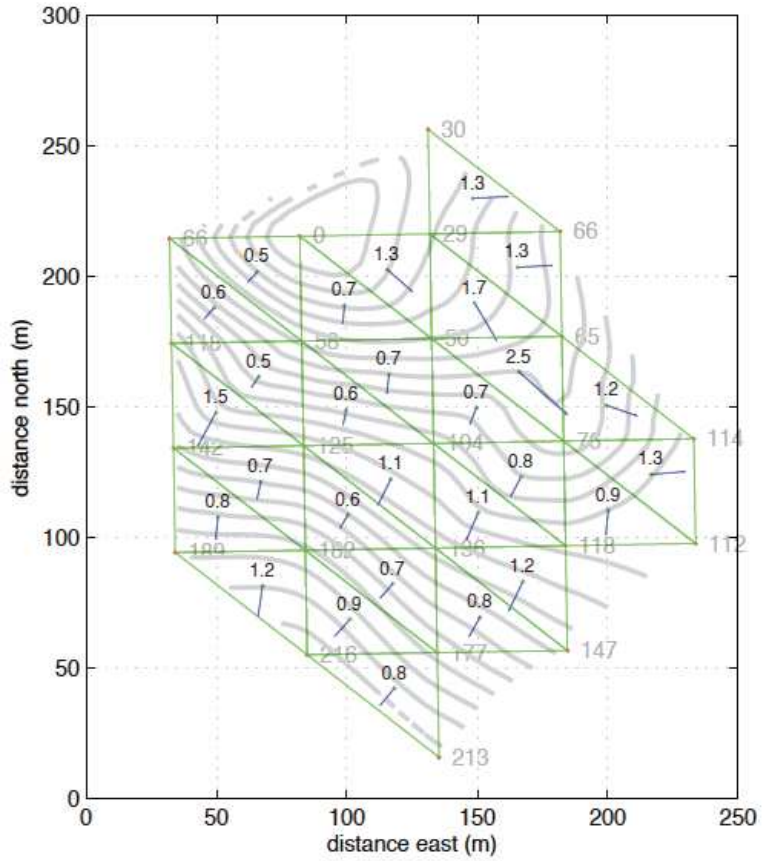

Figure 4. Rate of Spread vector calculation made from 28 ground thermocouples. Arrival times (s) at each HOBO, isochrones at 10-s intervals, ROS vectors, and ROS speed. (m/s).

3.3. In situ tower observations

Wind and temperature observations made from the 42 m tower are shown in Figure 5 for each measurement level. The time series shows little variability in the u-component wind, which is the streamwise component velocity, except for a slight decrease in velocity at the 20 m height just before the fire passes the tower. However, in the crosswind, v-component, the winds change from 2 m s-1 to nearly 6 m s-1 at 6 m AGL. Similar structure was observed at 10 m AGL, but not as large in magnitude (Figure 5). These observations indicate that the strongest fire-induced circulations occur at the surface near the fire front while above the fire, the ambient winds have a more pronounced effect on the plume, as indicated by the 20 m wind speed not changing from ambient. This fire-induced shear layer, where the surface winds accelerate and shift in direction at the fire front, can potentially increase turbulence generation near the surface potentially impacting fire behaviour.

The fire front passage is indicated by the sharp increase in temperature in Figure 5 (lowest panel) where maximum temperatures reached ~150 °C. At this same period, maxima in vertical velocities occurred at each level of the tower associated with the updraft of the plume. The maximum-recorded velocity was 8 m s^{-1} at the 20 m AGL level while at 10 m AGL the maximum updraft velocity was approximately 4 m s^{-1}.

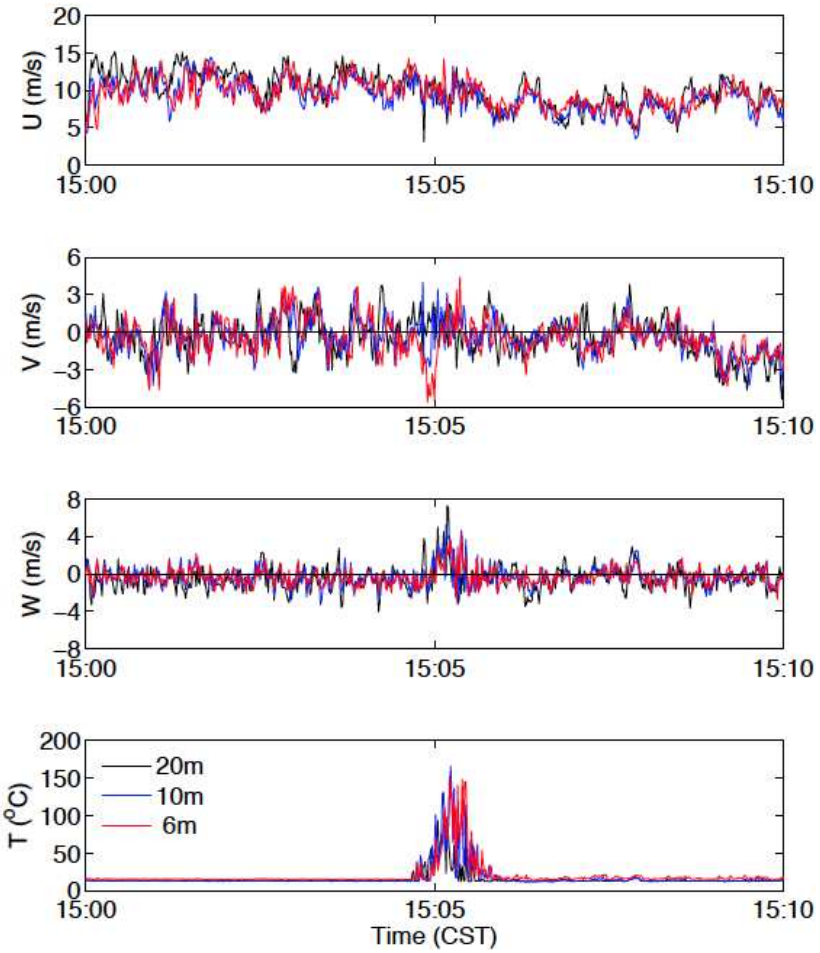

Figure 5. Time series of winds (u,v,w) and plume temperatures (T) during fire front passage (1505 CST) at the 42 m tower. Top panel is the u-component of velocity rotated into mean wind, v-componet is the cross-wise wind, w velocity is vertical component. Temperatures are taken from Sonic anemometers.

3.4. Photogrammetric analysis

For FireFlux II, photogrammetric analysis techniques were implemented in order to identify the fire spread rates for the head and flank fires. The technique, previously applied to fire front passage studies in controlled environments (Pastor et. al 2006), uses georectified high-definition and infrared imagery from a helicopter, correlated with georeferenced Plan Position Indicator (PPI) Doppler lidar scans, tower data, and perimeter anemometer plots, to create a comprehensive view of the wind field of the burn plot. In addition, georectifiying the helicopter high definition and infrared imagery to the prairie also allows for fire front tracing, providing an alternative method to calculating fire spread rates.
Preliminary photogrammetric analysis shows the progression of the fire as it burned across the prairie (Figure 6). Figure 6a, at ignition time, shows strong winds in excess of 10 m s-1 from 300 degrees, consistent with data from the perimeter anemometers, SoDARs, and tower data. Figure 6b, at approximately 86s after ignition, shows the development of the smoke plume moving with the wind

as the fire passes through the main tower, as seen by the black backscatter intensity contours. The smoke created by the backing fire along the edge of ignition also appears. Lidar data immediately downwind of the smoke plume contains errors, likely due to the lidar beam's inability to penetrate past the smoke. Figures 6c and 6d show the continued progress of the smoke plume over the prairie as the fire develops. Fire spread rate calculations using the georeferenced helicopter imagery shows a head fire spread rate of ~1.3-1.5 m s^{-1} and flank fire spread rate of ~0.5-0.7 m s^{-1}, which correlates well with the rate of spread calculations taken from the in ground temperature sensors (Figure 4). However, the error in this technique increased approximately 160 seconds into the burn, due to the change in the helicopter's altitude and angle in relation to the surface, skewing the error.

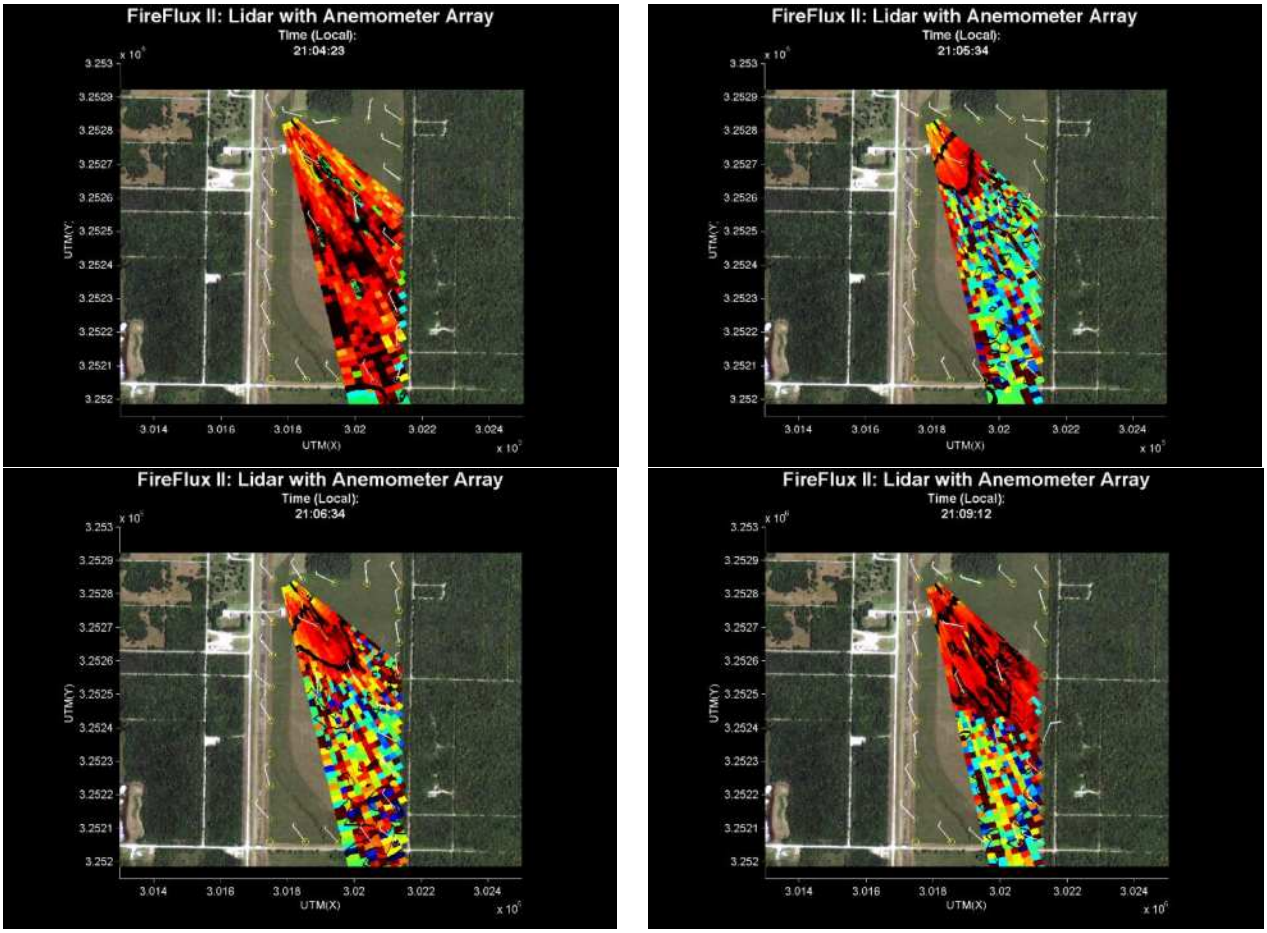

Figure 6. Time series of georectified images from FireFlux II, with Doppler lidar imagery superimposed over perimeter anemometer wind barbs. Black lines within the lidar scan designate the location of the smoke plume.

Conclusions

Analysis on the FireFlux II dataset is ongoing, and the work presented is a preliminary assessment of the potential for the data. The goal of improving upon the limitations of the original FireFlux field campaign is attained, as FireFlux II provides several methods for measuring fire spread rate and fire behaviour properties. Preliminary photogrammetric analysis gives a reliable method for calculating spread rate, coinciding well with values attained from ground thermocouple vector calculations. Future work in this area involves using the photogrammetric analysis method in the vertical, by correlating range height indicator (RHI) Doppler lidar scans to photography of the smoke plume, in order to further study the spread rate of the fire, as well as smoke plume dynamics. Data collected from pressure

sensors located within the experimental plot also shows promise in uncovering more information on pressure perturbations at the fire front.

Additionally, the FireFlux II dataset reinforces information gained in the original FireFlux campaign, providing more vertical wind and temperature measurements within the prairie with more in situ tower measurements. With these supporting datasets, we hope to build a more robust data library for model validation and more in depth fire-atmosphere interaction study.

Acknowledgements

This experiment would not have been possible without help and management from the following individuals and agencies. The Texas A & M Forest Service is thanked for conducting the burn operations. We want to thank the Rich Gray and his team for managing the burn operations, Dave Popoff from Galveston County Emergency Management for helping organizing county operations and personnel, Capt. Todd Weidman from La Margue Fire Dept for logistics and providing his staff of fire fighters, Prof. Steve Pennings and Tim Becker of the University of Houston Coastal Center for the research permit and help with all the logistics at the site, Paul Sopko (USFS), Ben Hornsby (USFS), Joe Restaino (USFS), and Dianne Hall (SJSU) for help with field sampling and setup, and Kent Prochazka (NWS Houston) for the fire weather forecasts. This research was funded by grants from the National Science Foundation (AGS-1151930) and Joint Fire Science Program (#11-2-1-11).

Abstract
A phenomenon known as the 'Spring Dip' in conifer live foliar moisture content (LFMC) has been documented and monitored for decades. This period also corresponds with intense crownfire activity in areas dominated by *Pinus resinosa* (Red pine) or *Pinus banksiana* (Jack pine). Despite a long-standing tradition of measuring LFMC during the dip period, the drivers of these variations have been the source of much speculation but little investigation and the actual causes of foliar flammability change have received even less attention. Here we assess the seasonal drivers of LFMC variations and their impact on foliar flammability. Foliar samples were collected for an entire year from both Red pine and Jack pine at a site in Central Wisconsin. New and previous year's foliage were sampled separately when both were present. From these samples, we determined LFMC, foliar chemistry and foliar density. We also ignited samples in an open flame burner to assess seasonal changes in their flammability. We verified that there is indeed a drop in the foliar moisture content during the spring. However, foliar density changes explained 96.7% of the variation in LFMC across both species and both needle age categories. These density changes were driven by an accumulation of starch and sugar in the previous year's foliage, most likely as a result of the onset of photosynthesis in the spring. Foliar starch, sugar and crude fat content explained 86.4% of the variation in foliar density. Foliar flammability followed the same trend as LFMC, reaching its period of highest flammability during the time of the lowest LFMC. However, these changes were strongly related to changes in foliar density, where density explained 51% and 77.4% of the variations in foliar flammability. Our results challenge the assumption that live conifer foliage flammability is limited by its water content and this study has led to a new theory of the factors that dominate live fuel flammability.

Introduction

Jack pine (*Pinus banksiana*) and Red pine (*Pinus resinosa*) are distributed throughout much of the high latitude and temperate North American forests and collectively they cover parts of eleven states and eight Canadian provinces. Wildfires are an integral component of their ecology (Ahlgren and Ahlgren 1960). Fires that occur in these areas can vary from low intensity surface fire to high intensity crown fires. Fire severity significantly affects the ecological succession and subsequent distribution of these trees throughout the boreal region (Arseneault 2001). It is therefore important to develop a complete understanding of the factors that drive fire severity in these forests.
Fire behavior in these forests is a crucial component of the development of management strategies for these species (Johnson and Miyanishi 1995). Successful prediction of fire behavior in these stands has been the source of much investigation (Quintilio *et al*. 1977, Stocks 1987, 1989, Stocks *et al*. 2004). Both weather and fuel conditions can significantly influence fire behavior in these stands. Strong winds and dry conditions lead to intense fires that spread rapidly. Fuel factors such as the crown base height, canopy bulk density and foliar moisture content are important determinants of their fire behavior (Van

Wagner 1977, 1993). Variations in crown base height and canopy bulk density happen slowly as stands develop over time, while foliar moisture content can vary significantly throughout the season. As such, foliar moisture content has the largest potential to alter the potential fire behavior of Jack pine and Red pine stands throughout the year.

A phenomenon known as the 'spring dip' in foliar moisture content has been extensively documented (Van Wagner 1967, 1974, Chrosciewicz 1986). It describes a seasonal decline in the foliar moisture before new needle flushing and a subsequent increase in moisture content thereafter. This period of low foliar moisture content corresponds with an increase in crown fire likelihood. While the phenomenon itself has been adequately described, the causes of the dip, and subsequently their potential impact on fire behavior, have not been adequately explored. One difficulty with evaluating seasonal changes in foliar moisture content is that they are driven by a combination of both changes in leaf water content and dry mass. Little (1970) suggests that a similar observed dip in foliar moisture of balsam fir (Abies balsamea), was attributed at least in part to a change in foliar carbohydrates. A complete examination of the seasonal dynamics of foliar moisture content and their influence on crown flammability must then examine changes in foliar dry matter composition as well as changes in foliar water content.

Here we present a study aimed at characterizing the seasonal changes in foliar chemistry during a period the 'spring dip'. We sample current and past year's foliage from mature Red pine and Jack pine trees at varying intervals for an entire year. We measure foliar moisture content, foliar density, chemical composition and each sample is also combusted on an open flame burner to measure their seasonal changes in flammability. We use this extensive dataset to explore the inter-relationships between measured foliar moisture content, foliar water content, foliar dry matter variations and their influence on ignitability.

Methods

Jack pine and Red pine sampling sites were located ~ 0.6 km apart in northern Adams County in central Wisconsin, USA, approximately 10 miles south of the city of Wisconsin Rapids. The red pine collection site is at N44° 14' 33", W89° 49' 44". The jack pine site is at N44° 14' 4", W89° 48' 54". Elevation at both locations is 873 feet. Topography at both sites is level to gently rolling on well-drained Plainfield Sand soils of glacial outwash origin. The area is part of a broad sand plain bisected by the Wisconsin River as it crosses the central part of the state.

The soils and topography of the area have made it prime landscape for growth of vast commercial plantations of red pine (*Pinus resinosa*), interspersed with natural forest cover of jack pine (*P. banksiana*) and "scrub" oak (*Quercus ellipsoidalis, Q. palustris, Q. alba, Q. velutina*). The lands are also ideal for residential, agricultural and recreational development, with numerous homes and cabins dotting the landscape and the major community of Rome (over 3500 homes) located within three miles to the south and southeast of the sampling site.

The landscape has experienced frequent fires of both natural and human origin throughout its history, including the pre-settlement period. It has also seen some of the largest and most destructive fires in Wisconsin during the post WWII era, the most recent being the 3400-acre Cottonville Fire of 2005. The red pine sample site itself is a plantation re-established after a forest fire that occurred in 1995, while the jack pine samples were taken from volunteers found in a separate, younger red pine plantation established after a commercial harvest of an oak/jack pine stand in 2000.

Needles were collected in both "new" (current year growth) and "old" (previous two growth seasons combined) age classes for both red and jack pine. Jack pine samples were collected in metal sampling tins, while larger plastic containers were used for the longer red pine needles. Containers were kept sealed during transport to a lab at the Wisconsin Department of Natural Resources (WDNR) office in Wisconsin Rapids. In the lab, the samples from each species/age class were divided into three subsets. Two subsets were designated for chemical and flammability analysis and were packaged for overnight

shipping to AgriAnalysis for chemical testing and to the US Forest Service Fire Lab in Missoula, Montana. From the third subset, five fascicles of varying size were selected for determination of needle density while the rest of the subset was used for bulk measurement of live foliar moisture content (LFMC). Fresh weights were measured to the nearest milligram for both the fascicles and bulk samples were obtained and the volume of the fascicles was determined using an Ohaus density apparatus. Fascicle and bulk samples were then dried overnight in at 85°C and measured to obtain dry weights, after which all weight measurements were brought together for final calculations of needle density and LFMC. LFMC was converted from a dry weight basis to a wet weight basis to standardize the scales between the foliar chemistry and moisture content measure using the following equation:

$$M_{wb} = (LFMC * 100 / (100 + LFMC)) \quad \textbf{Equation 1}$$

Samples were ignited using an open-flame burner. The apparatus was built specifically for the rapid heating and ignition of live fuel samples and is composed of a pre-mixed propane, a sample holder and timer (**Erro! A origem da referência não foi encontrada.**). Flow rates were set at 0.48 mol/min for fuel and 6.47 mol/min for air. This yields a rich flame that is partially pre-mixed and partially diffuse, yet creates a flame that is very similar to wildland flames and a convective heating environment that is conducive to very rapid heating. Samples were introduced to the flame by the sample holder where they were immersed in flame and their time-to-ignition was recorded as the point where flames were visibly attached to the surface of the sample.

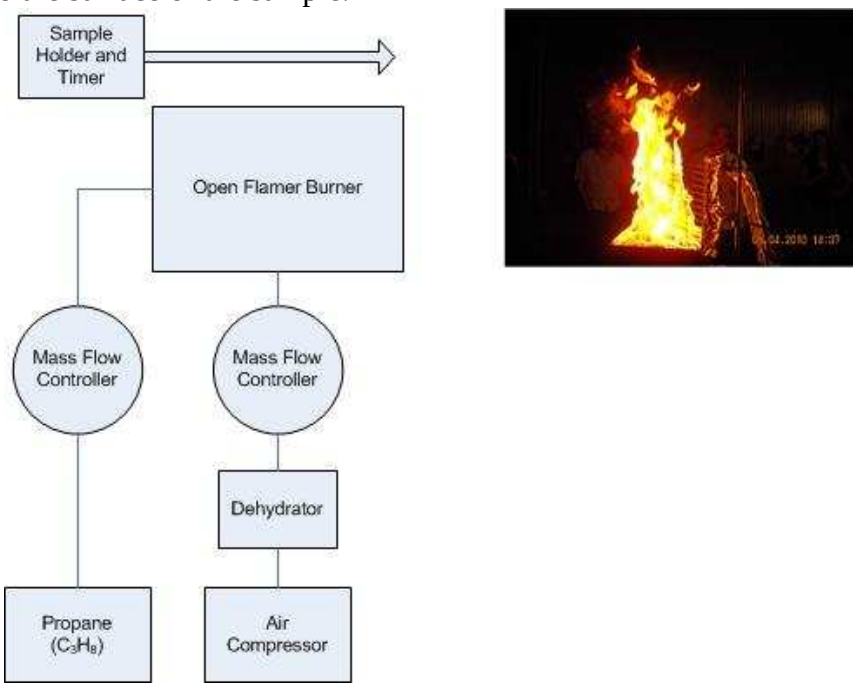

Figure 1. Flow diagram of the open-flame igniter apparatus.

Results

Live foliar moisture content (LFMC) seasonal trends followed patterns similar to those reported by Van Wagner (Van Wagner 1967) (Figure 2). Dormant foliar moisture contents for previous year's needles of red pine (*Pinus resinosa*) and jack pine (*Pinus banksiana*) were high for both species. Red pine needle moisture was 114.3% on March 29th, 2013 and 120.6% for jack pine but both dropped precipitously starting in about April and recovered completely by August (Figure 2). The lowest recorded LFMC recorded for red pine (82.0%) occurred on June 3rd, 2013 and the lowest LFMC for jack pine (91.5%) occurred on May 13th, 2013, representing a 29% and 26% reduction in LFMC during the 'Spring Dip' for Red pine and Jack pine respectively. LFMC recovery coincided with new needle

emergence in mid-June (Figure2). New needle LFMC was >250% for both species and declined rapidly during needle development (Figure 2).

Foliar chemistry varied substantially between needle age classes but was similar between species (**Erro! A origem da referência não foi encontrada.**). The strongest variations were observed in starch concentrations of old needles in both species, while crude fat and sugar content of new needles continued to rise after emergence signally foliar chemical changes due to needle hardening. Starch concentrations of old needles rose from zero to 14.4% and 11.8% of dry weight for Red pine and Jack pine respectively. Both crude fat and sugar content of new needles more than doubled over the study period.

Foliar density tracked seasonal changes in foliar chemistry. Density of old needles increased during the 'spring dip' period reaching a seasonal maximum value of 0.52 g/cm^3 and 0.497 g/cm^3 for Red pine and Jack pine respectively (**Erro! A origem da referência não foi encontrada.**). Density of old needles for both species increased by more than 20% during the dip period. Starch, sugar and crude fat content of needles explained 86.2% of the variations in foliar density across both species and needle ages (**Erro! A origem da referência não foi encontrada.**). Foliar density exhibited a linear relationship with foliar moisture content and it explained 96.7% of the variation, when foliar moisture content was translated from a dry weight to a wet weight basis (Equation 1).

Foliar density also explained much of the variation in time to ignition of both species. Density was most related to Jack pine flammability where it explained 77.4% of the variation in time to ignition, while density explained 51% of the variation in time to ignition for Red pine across both needle ages.

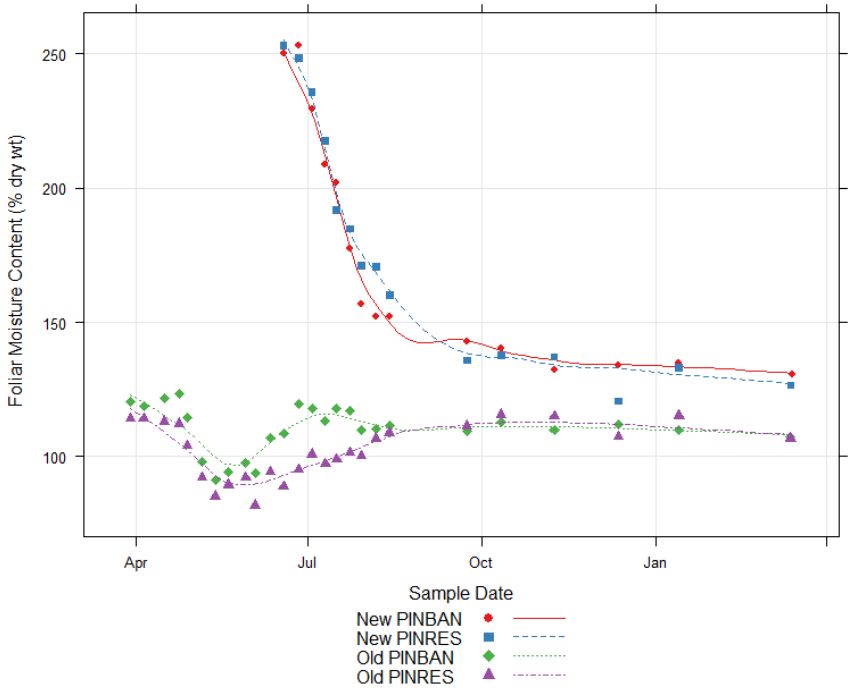

Figure 2. Seasonal variations in live foliar moisture content for Red pine and Jack pine from April 2013 - April 2014. Seasonal low LFMC values were observed in old needs of both species during the 'spring dip' period and the highest recorded values were observed in new needles. By the end of the study period, old and new needles had similar foliar moisture contents but new needle moisture contents were consistently higher for both species.

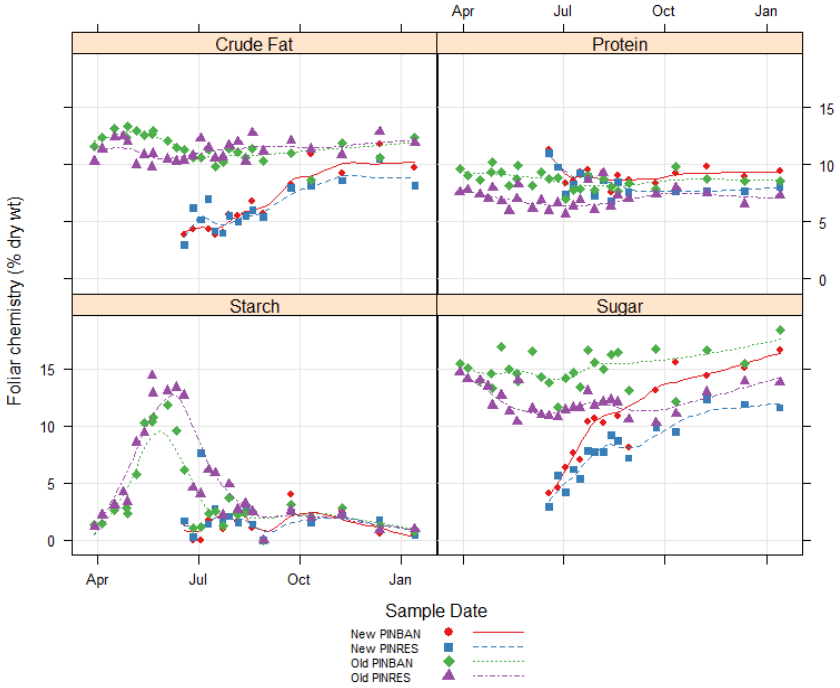

Figure 3. Seasonal variations in live foliar chemistry for Red pine and Jack pine from April 2013 - April 2014. Crude fat was lowest in new needles of both species and increased during needle development. Needle starch content showed over a ten-fold increase during the spring, increasing from 0% during dormancy to 14.4% and 11.8% for Red pine and Jack pine respectively just prior to new needle emergence. Additionally, sugar content of new needles increased during needle development but protein was similar between needle ages and species.

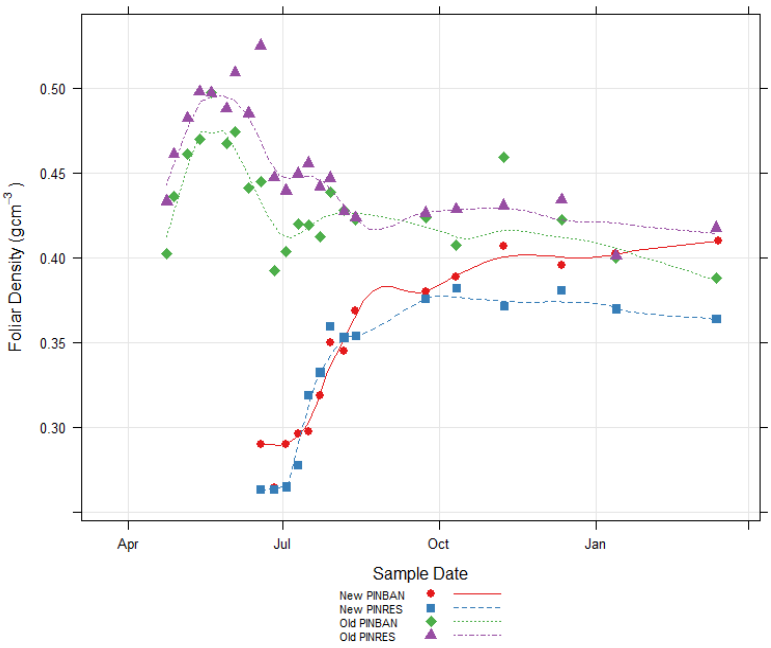

Figure 4. Seasonal changes in the foliar density of old and new Jack pine and Red pine needles from April 2013 to April 2014. Highest needle densities for old needles of both species occurred during the spring while lowest densities observed for both species occurred just after bud break as new needles emerged. New needle density increased as needles matured, while old needle density decreased over that period.

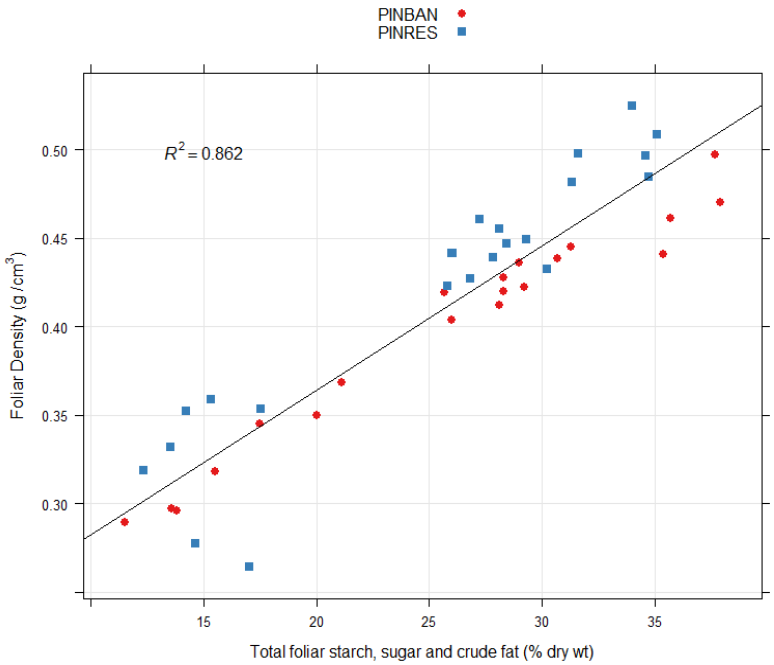

Figure 5. Relationship between total foliar starch, sugar and crude fat concentrations (as a percentage of total dry matter) and foliar density. These variables explained 86.2% of the variation in foliar density across both species and both age classes suggesting that seasonal variations in foliar density are primarily dependent on carbon dynamics (starch and sugar) and needle development (crude fat).

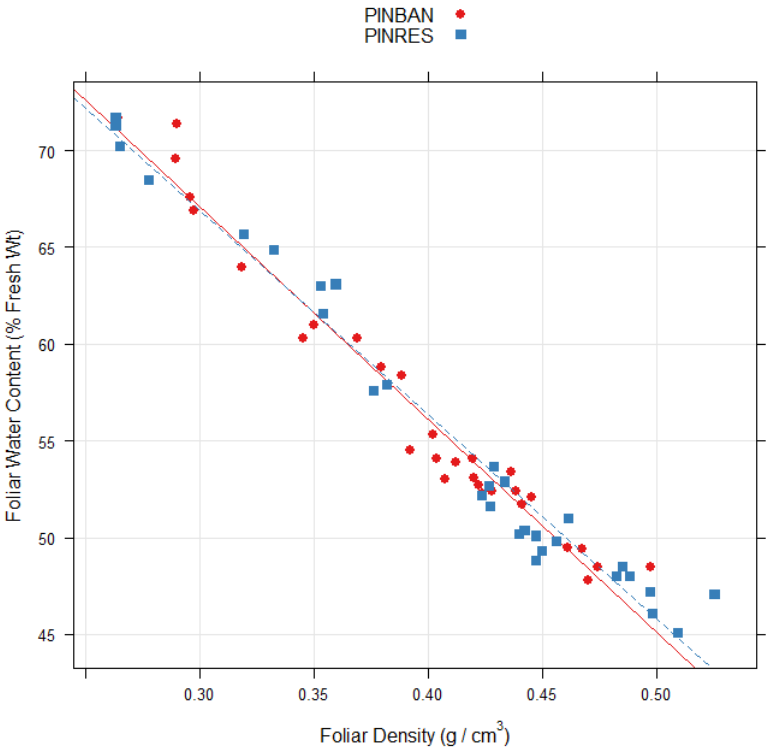

Figure 6. Relationship between total foliar density and foliar water content (% fresh wt). Foliar density explained 96% of the variation in foliar water content across both species and needle ages.

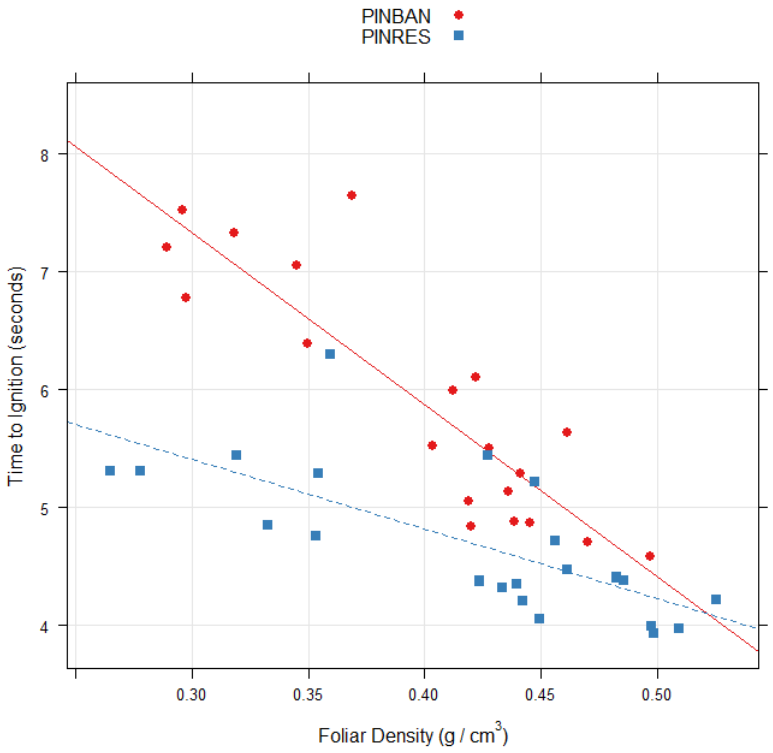

Figure 7. Relationship between foliar density and time to ignition for Red pine (PINRES) and Jack pine (PINBAN). Foliar density explained 51% of the variations in time to ignition for Red pine and 77.4% of the variation in time to ignition for Jack pine.

Discussion

Foliar moisture content has long been assumed to relate to red pine and jack pine flammability but little work has explained the interactive drivers that influence their seasonal changes. Our study has shown that foliar moisture content variations are a direct result of seasonal changes in foliar chemistry, not moisture content variations, which is consistent with previous findings (Little 1970). These chemical changes are reflected in seasonal changes in foliar density and subsequent changes in seasonal foliar flammability.

Foliar moisture content variations coincided with the onset of photosynthesis and the accumulation of carbon compounds prior to the flushing of new needles. During the early season, once trees have broken dormancy, we observed large increases in stored starch prior to the immergence of new foliage (**Erro! A origem da referência não foi encontrada.**). Once new needles emerged, that stored starch was depleted because during needle development, carbon is translocated from old needles to new needles (Gordon and Larson 1968). New needles also have a high demand for carbohydrates during their early development and they only export carbon to other parts of plant several weeks after they are fully developed (Ericsson 1978). Ultimately, photosynthesis is the main driver of the spring dip and the plant-level carbon cycle determines the apparent moisture content of the foliage but these changes could be affecting foliar flammability in ways that have not been previously considered.

It is conceivable that while the apparent moisture content of foliage varies substantially throughout the season, the absolute water content of the foliage could stay relatively constant. If this were the case, it would imply that the true seasonal drivers in foliar flammability lie not in changes in the water content of the foliage but in the chemical changes that compose the foliage. These chemical compounds might alter how rapidly needles can ignite. We noted strong seasonal changes in starch content of old foliage

during the dip. Starch and sugar compose over 28% of the dry weight of foliage yet they have never been considered as driving components of wildland fires. Generally, time-to-ignition is positively related to density (Incropera and DeWitt 2002). However, we found that these two quantities were negatively related, suggested that the drivers of the density increase, were more easily volatilized and thus lead to faster ignition, despite their contribution to particle density. Sugar, starch and crude fat should be studied further to determine whether or not they appreciably alter foliage ignitability.
This is the first study to combine moisture content, chemistry, density and ignition testing during the "Spring Dip" period. We have revealed some previously undiscovered linkages that could change how we assess live fuel flammability in the future. This new knowledge may lead to better tools to help fire managers assess crown fire potential in these dynamic forests.

Abstract

The topographic features influences fire regime and fire behavior jointly with the remaining environmental variables. The fire regime characteristics can vary due to fine scale topography and variation in stand history according to topographic features. The fire often influences severity with smaller areas of high severity on lower mesic slopes and larger areas on upper xeric slopes. Several researches confirm the severity of wildland fire. Topographic variables were relatively more important predictors of severe fire than either climate or weather variables. Predictability of severe fire was consistently lower during years with widespread fires, suggesting that local control exerted by topography may be overwhelmed by regional climatic controls when fires burn in dry conditions. This was an indoor study conducted at Forest Fire Laboratory, of Departamento de Engenharia Florestal, Universidade Federal de Viçosa (DEF/UFV), Minas Gerais State, Brazil. It was used a combustion table apparatus with a dispositive to simulate six slopes (0º, 5º, 15º, 25º, 35º and 45º). It was measured the flame length to correlate with the fire line intensity. Five replications were used for each slope, both in uphill as the downhill. The fuel bed was formed by a grass Melinis minutiflora Beauv. common in Brazilian grassland. The average values of dry fuel load for each slope were 0.561 kg, uniformly distributed on a platform area of 1.0 x 1.0 meter. The fire line intensity was calculated according to Byram (1969). The relative humidity mean in the downhill and uphill burn day was 48.8% and 57.8% respectively. The result showed that there was increases in the fire line intensity when compared downhill with the uphill slope from range 5 to 45 degrees. The increase was 2.7 times higher in the 45-degree slope compared with the lowest slope. This study will establish a factor for increasing the height of the flames and the fire intensity increased as the surface slope. In all replicates of downhill burning was observed a shorter length of the flames at the beginning and the end portion of plot while on uphill the flame length was shorter only on last plot portion. The flame length was a crescent relationship from 0 until 45 slope degree, represented by Y=1.1136+0.0675X-0.0012X2, with a R2 of 0.9362 for uphill and a polynomial representation of Y=1.0923X + 0.101X – 0.0046X2 - 5E-05X3 with a R2 of 0.8304 for downhill.

Keywords*: slope effect; flame length; fire spread; fire behavior*

Introduction

The great wildfires are occurring on all parts of the world, according to their regional climatic conditions. The relationships between mankind activities and the environment are heavily documented due to the influence of the climatic variations on the human welfare overtime. On the last years we are observing a great demand for food given the population growth requiring the expansion of agricultural areas and a necessary and periodical management of the soil which the fire has been an important tool (JUSTINO *et al*., 2011). Although the fire has been used by man since the remote times, is now growing concern over its use due to the change in the structure of farms, climate and greenhouse gas emissions. These conditions are producing great changes on the landscape and resulting in large accumulations of fuel. In fact, in different parts of the world and by different reasons the amount of fuel has risen considerably and there has been a consequent increase in the number of fires and land burnt each year as reported by Miller *et al*. (2012), Pausas (2012), Pausas (2004), Soares and Batista (2007), Beautling (2009). Miller *et al*. (2012) further state that recent research has indicated an increasing in worldwide fire size, large fires are becoming more frequent, and in at least some locations

percentage of high-severity fire is also increasing. These changes in the contemporary fire regime are largely attributed to changing climate, land management practices, including suppression of fires and abandonment of rural areas.

The topographic features besides others parameters environmental influences the fire regime and fire behavior jointly with the remaining variables that characterize the environment. According Miler *et al*. (2011), the fire regime concept was developed to provide a framework for investigating differences in the way fire influences ecosystems. The fire regime characteristics can vary due to fine scale topography and variation in stand history. These researchers conclude that topographic features however, often influence severity with smaller areas of high severity on lower, mesic slopes and larger areas on upper, xeric slopes.

The environmental complexity leads to different situations and makes not all fire is equal; fire-caused change or fire severity can vary considerably and decisively influences the effects resulting like evolved species largely with low to moderate-severity fire, and those post-fire landscapes are characterized by survival of fire-tolerant and large-diameter individuals. Severe fires kill and consume large amounts of above and belowground biomass and affect soils, resulting in long-lasting consequences for vegetation, aquatic ecosystem productivity and diversity, and other ecosystem properties (DILLON *et al*., 2011). However, in many respects, Dillon *et al*. (2011) confirm it is the severity of wildland fire, rather than whether or not a location burned that has greatest effect on ecological processes. Topographic variables were relatively more important predictors of severe fire occurrence than either climate or weather variables. Predictability of severe fire was consistently lower during years with widespread fires, suggesting that local control exerted by topography may be overwhelmed by regional climatic controls when fires burn in dry conditions.

Fire behavior probabilities are different from each other because they depend on spatial and temporal factors controlling fire growth. That is, the likelihood of fire burning a specific area is dependent on ignitions occurring off-site and the fuels, topography, weather, and relative fire direction allowing each fire to reach that location. The results shown by Mistry and Berardi (2005) indicated that there is a higher probability of fire entry from particular border regions as a result of the fuel characteristics.Wind speed greatly increased the spread and extent of fire. According to Miller *et al*. (2011), species compositions vary widely, influenced by precipitation, topography, and substrate, producing different severity degree.

Moreover, studies have shown that fire is part of several ecosystems on the world. It can be used as a tool land management like a prescribed or controlled burning (RIBEIRO, 2009) and can be used safely to achieve different objectives of land management. Biswell (1989) make several recommendations to describe an area to be burn and the mainly one are the topographic features. The combustion process and fire behavior are complex as well as being compounded by variations caused during the burning that are difficult to predict.

The fuel used in this work was the Millinis minutiflora Beauv. an 1 hr time lag fuel.

The aim of this study was to assess the influence of slope steepness in fire line intensity and flame length in an indoor condition using the Melinis minutiflora Beauv. as a fire bed with no wind flow, and known conditions of fuel moisture and fuel load.

2. Materials and methods

This was an indoor study conducted at Forest Fire Laboratory, of Department of Forest Engineering, Federal University of Viçosa (DEF/UFV), Minas Gerais State, Brazil. It was used an apparatus named combustion table (Figure 1) with a dispositive to simulate the slope steepness in the desired angles and the flame length.

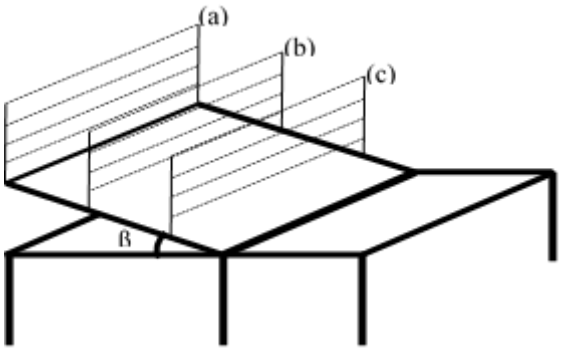

Figure 1. Schematic drawing of the combustion table

The angles ß tested were 0º, 5º, 15º, 25º, 35º and 45º and the flame length was measured from three devices (a,b,c) through the cotton yarns vertically distant every 0.25 m. Five replications were used for each angle, both in uphill as the downhill which were burned on different days.
The fuel bed was formed by a grass Mellinis minutiflora Beauv. Its power heat was determined in the Panels and Wood Energy Laboratory, Department of Forestry Engineering, DEF/UFV finding 4,186 kcal. The relative humidity of the testing room and the fuel humidity throughout the day 1 (uphill) and the day 2 (downhill) are shown in Tabel 1.

Table 1. Relative humidity and fuel humidity on day 1 (uphill) and day 2 (downhill) of burn.

Uphill			Downhill		
Day time (h)	Relative humidity (%)	Fuel humidity (%)	Day time (h)	Relative humidity (%)	Fuel humidity (%)
9:00	43	10,20	9:00	76	20,28
11:00	52	9,20	11:00	75	16,47
13:00	51	10,34	13:00	52	18,58
15:00	52	6,05	15:00	43	19,69
17:00	43	7,65	17:00	42	18,64

The average values of dry fuel load for each angle tested are shown in Table 2. Before each burning the fuel load was uniformly distributed on an platform area of 1.0 x 1.0 meter (Figure 1).

Table 2. Dry fuel load (kg) for each slope.

Uphill		Downhill	
Slope (degree)	Fuel load (kg)	Slope (degree)	Fuel load (kg)
0º	0.545	0º	0.545
5º	0.557	5º	0.508
15º	0.554	15º	0.525
25º	0.577	25º	0.498
35º	0.567	35º	0.511
45º	0.569	45º	0.513

The fire line intensity was calculated by Byram (1969) equation:

$$I = H.w.r$$

where,

I = fire line intensity (kcal/m/s);
H = heat power (kcal);
w = fuel load (kg);
r = fire spread (m/s).

It was measured after each burning the flames length, the burning time, the rate of fire spread and burning intensity by Byram (1969). The analyzes were carried out with the StatGraphic statistical package to determine the correlation between the flames length and burn intensity, the gradient increase in intensity with slop increasing and to establish a propagation factor in accordance with the slope for the fuel type studied.

Results and discussions

The media and standard deviations values of fire line intensity (Figure 2 and 3) recorded small burning values for both slopes. This was expected because the burning was conducted indoor or without the influence of wind besides the controlled conditions of humidity and fuel load. However, they show a significant difference between the two types of burn. The uphill burning recorded higher and increasingly values between the flat condition (0°) and the largest slope (45º). The highest intensity of burning was recorded for the 45° uphill and was about three times higher than the intensity recorded for the 45°downhill. This confirms the expected scattering flames towards the uphill or the effect of topography behavior.

It is clear that the fire behavior has a strong influence of the fire speed in the absence of others variables. In this study both the heat value as fuel load did not vary. The highest fire speed attained was for the 45º uphill and it was 4.5 times higher than the highest speed reported for the downhill.

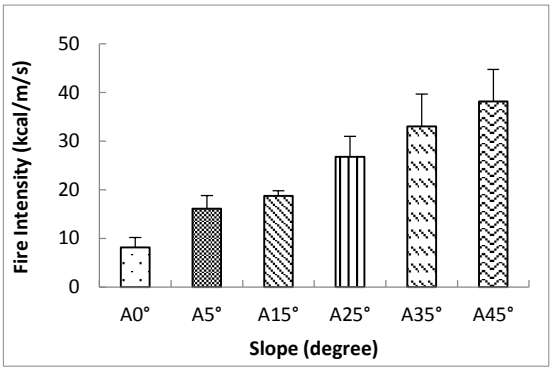

Figure 2. Uphill burning

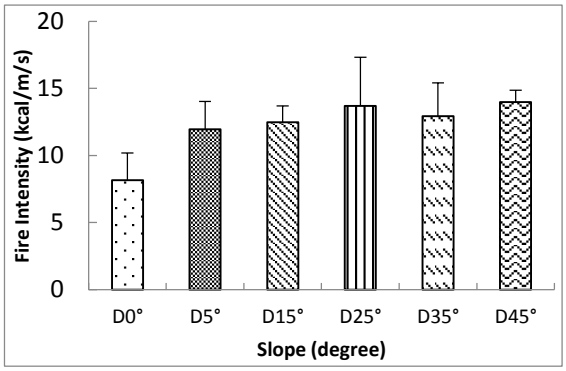

Figure 3. Downhill burning

The relationship between the different levels of slope and the fire line intensity (Figure 4 and 5) showed a better fit of the mathematical model for the firing in the uphill. This relationship was almost direct to which a rectilinear model was fitted.

This profile of fire behavior in uphill is well within the expected. However, in the downhill burning the fire behavior was not the same. The mathematical model fitted was a second degree polynomial equation. In addition, the adjusted model showed a lesser coefficient than the uphill model.

The Figure 5 shows a trend of reduced intensity as the line of fire approaches the lower portion of the burning area. This can be explained by the fact that the fuel load is practically in the end and a less heat flow is produced.

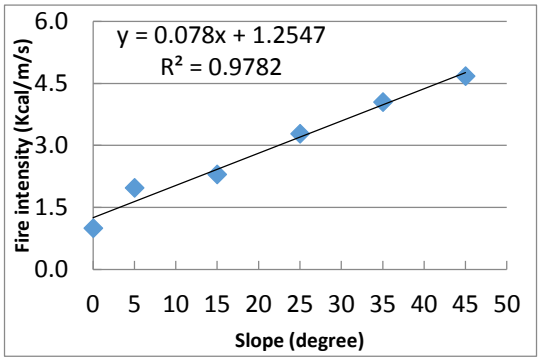

Figure 4. Uphill burning

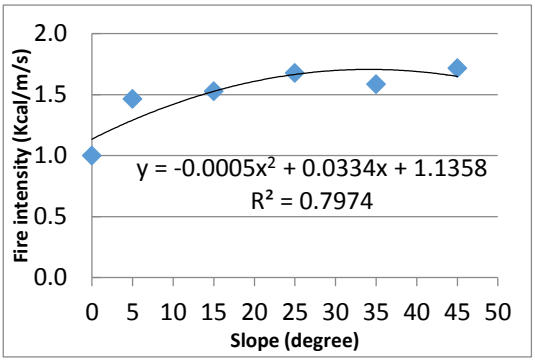

Figure 5. Downhill burning

As noted in other studies, there is a direct relationship between The fire line intensity and the flame length. However, this behavior varies according to other environmental variables and the direction of fire. Burning in the uphill (Figure 6) tends to have a direct relationship with exponential trend. The flames tend to have greater length in relation to the downhill fire and increase in length with increasing slope. However, when reaching the top portion of the flame length decreases by the fact reduce the fuel to be burned and the headwind on the opposite side of the burning surface.
Burning in the uphill shows a different behavior in relation to downhill. Upon reaching the end of the burning surface, the smaller slope, the flames become smaller, probably no more upward flow of warm air and there is no more fuel to be burned.

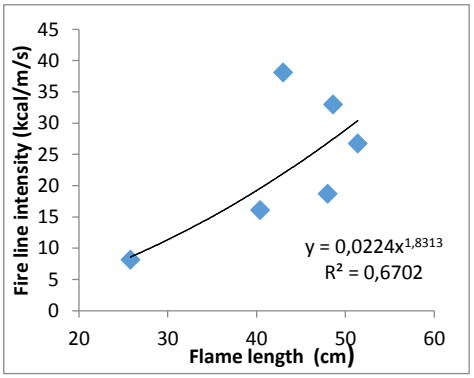

Figure 6. Uphill burning

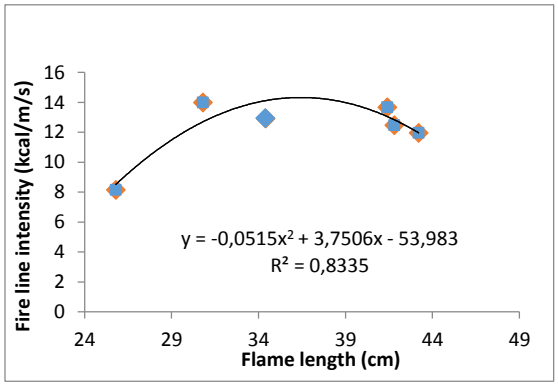

Figure 7. Downhill burning

3. Conclusion

It can be concluded that in the absence of any other variables such as fuel moisture, prevailing winds, different loads and fuel type the slope of the relief has a strong influence on fire behavior. In natural conditions this variables can have an exponential influence that is very difficult to predict because the reaction of combustion promotes local modifications in the combustion area that match the variables in humidity and air flow and are difficult to measure.

Abstract
Forest fires are a recurrent disturbance in Mediterranean ecosystems, and the effect on the structure and dynamics of vegetation may depend largely on fire severity. Our knowledge of how fuel consumption in different species can be an indicator of fire severity is limited, and very few studies have covered this aspect. Our initial work hypothesis is based on the existence of different ecological severities according to each species' structural characteristics. The work aims to determine degree of severity by assessing biomass of different species consumed during a fire. Three experimental fires in Ayora (eastern Iberian Peninsula) were conducted, and subplots dominated by Rosmarinus officinalis, Quercus coccifera, Erica multiflora and Juniperus oxycedrus were selected. The soil temperature during fire was measured using thermocouples in each subplot. Average fuel consumption per species was determined by measuring the minimum diameter of the branches burned in each subplot. Our results indicate fire severity variability between species. The fuel consumption values within the subplots differed significantly between species. The largest were found for E. multiflora and R. officinalis if compared to Q. coccifera and J. oxycedrus. The temperature residence time above 40°C was very important for all species, but the longest occurred in E. multiflora and J. oxycedrus. Soil temperature and its duration were related to fuel type. The results show that fuel accumulation and its spatial distribution in the plant architecture, associated with reproductive strategy, are one of the most important traits in determining fuel consumption and soil temperature and can, therefore, play a key role in fire severity terms. These results indicate the importance of considering fuel structure and flammability of species as potential drivers of new fire regimes.

Keywords*: consumed biomass, fire ecology, fuel type, flammability, Mediterranean shrubland, severity degree*

Introduction

Fire is a recurrent natural disturbance in Mediterranean ecosystems which drives the dynamics of many plant communities (Naveh, 1975; Trabaud, 1980; Gill *et al*., 1981; Pyne, 1995; Baeza *et al*., 2006; Santana *et al*., 2011). However, the level of severity affecting an area depends on the parameters defining the fire regime, such as: extent, frequency, recurrence period, seasonality and intensity of fires. These parameters have been discussed in several papers, but very few have attempted to relate the effects of fire on vegetation by taking into account fire severity (Pérez and Moreno, 1998; Key and Benson, 2005; Lentile *et al.*, 2006; Keely, 2009).
The effects of fire variability on the ecosystem may depend on canopy's dominant species; in particular, the structural characteristics of fuels can modulate the effects on the ecosystem. Availability of fire-prone fuel is determined by its flammability; this property varies from one species to another, and is determined by the interaction of different structural attributes (Cornelissen *et al*., 2003; Alessio *et al*., 2008). Differences in dead twigs retention (Zedler, 1995; Schwilk, 2003; de Luis *et al.*, 2004; Bond and Keeley, 2005), a property that changes with time (Baeza *et al.*, 2011), and structural differences in the arrangement of leaves and stems (van Wilgen *et al*., 1990), affect the temperatures reached during the fire and the heat they emit.
Some research has suggested that differences in fuel structural attributes between different species

induce variability in soil temperature and fuel consumption (Pérez and Moreno, 1998; Molina and Llinares, 2001; Santana *et al*., 2011). Other studies have shown relationships between post-fire regeneration strategies (seeders or resprouters) and flammability traits (Zedler *et al*., 1983; Lloret *et al*., 2003; Bond and Keeley, 2005; Saura-Mas *et al*., 2010). Therefore, further studies are required to clarify the effects of the fuel characteristics of different functional groups in relation to fire severity.
This study focused on fire severity, and specifically on the relationships between two related proxies: fuel consumption and soil temperatures. These relationships were assessed in species with different functional attributes (seeders or resprouters). Our aim was to know how fuel consumption in different species can act as a fire severity indicator.

Methods

This work was conducted in Ayora, eastern Iberian Peninsula (39 º 05'-40 º 15 'N, 0 ° 51'-1 ° 59' W). In April 2009, three plots of 33x33 m were burned. The areas were previously delimited by a 4-metre-wide fire break in which vegetation was eliminated through mechanical brushing. Experimental burnings were carried out under strict safety conditions and were monitored by forest services.
Vegetation was a shrubland dominated by seeders such as *Rosmarinus officinalis* and *Ulex parviflorus*. The resprouting species, these being *Erica multiflora, Quercus coccifera* and *Juniperus oxycedrus*, appeared between the seeder species distributed in a mosaic. This vegetation came from the regeneration of the pine forests burned in the 1979 Ayora fire, which means a vegetation age of 30.
Thirty-six subplots of 50x50 cm were randomly selected prior to the fire. A thermocouple connected to a datalogger was placed in the centre of each subplot on the soil surface, which recorded the temperature every 10 seconds. After the fires, the diameter of burned twig tips were measured for the different species in each subplot following the methodology of Moreno and Oechel (1989).
Furthermore, the average fuel consumption for each species was determined using allometric equations, which were applied to the diameters of the burned twig tips. The differences between the amounts of consumed biomass among the various species were analysed by one-way ANOVA. The residence time of temperature above 40°C was related using regressions with the terminal burned twigs diameter and consumed biomass.

Results

Biomass consumption differed among the three fires. Fire 3, with a maximum temperature of 710°C was the severest, followed by Fire 2 and Fire 1 with 676°C and 670°C, respectively.
The variability in fire severity among the different species was also observed. The highest consumptions were observed for *E. multiflora* and *R. officinalis* rather than for *Q. coccifera* and *J. oxycedrus* (Figure 1).

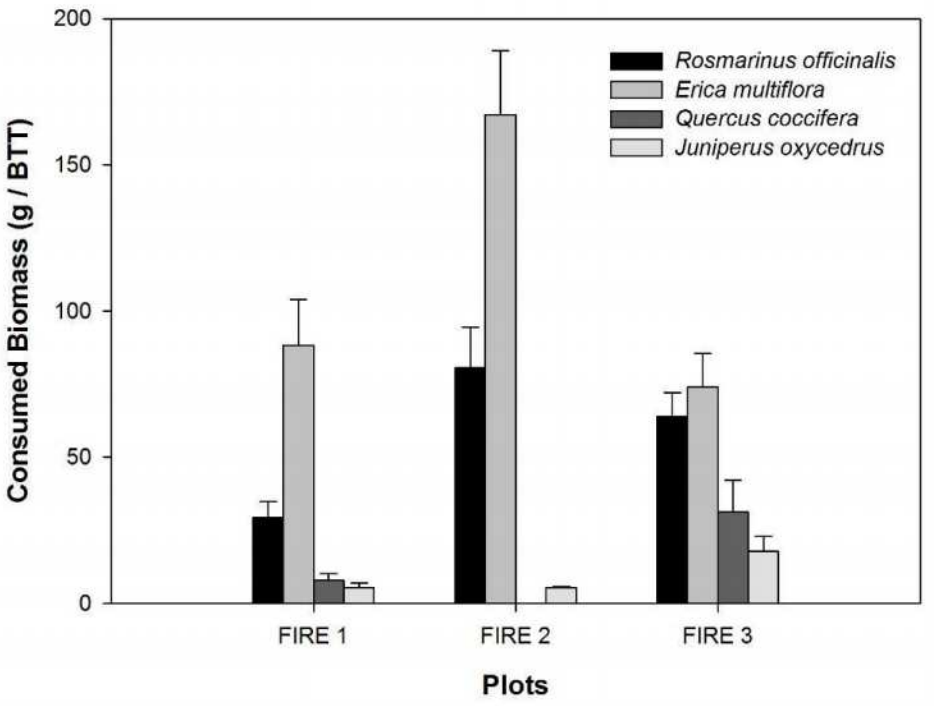

Figure 1. Consumed biomass (mean ± standard error) for the different species during each fire. (BTT: Burned Twig Tips)

The residence time of temperature above 40°C was high for all the species, and ranged between 74 and 92 minutes, but longer durations were recorded for *E. multiflora* and *J. oxycedrus* (Figure 2). Temperatures above 60°C and 80°C were of intermediate duration, and residence time was longer for *Q. coccifera*. For temperatures above 400°C, duration was relatively low (under 5 minutes) for all the species.

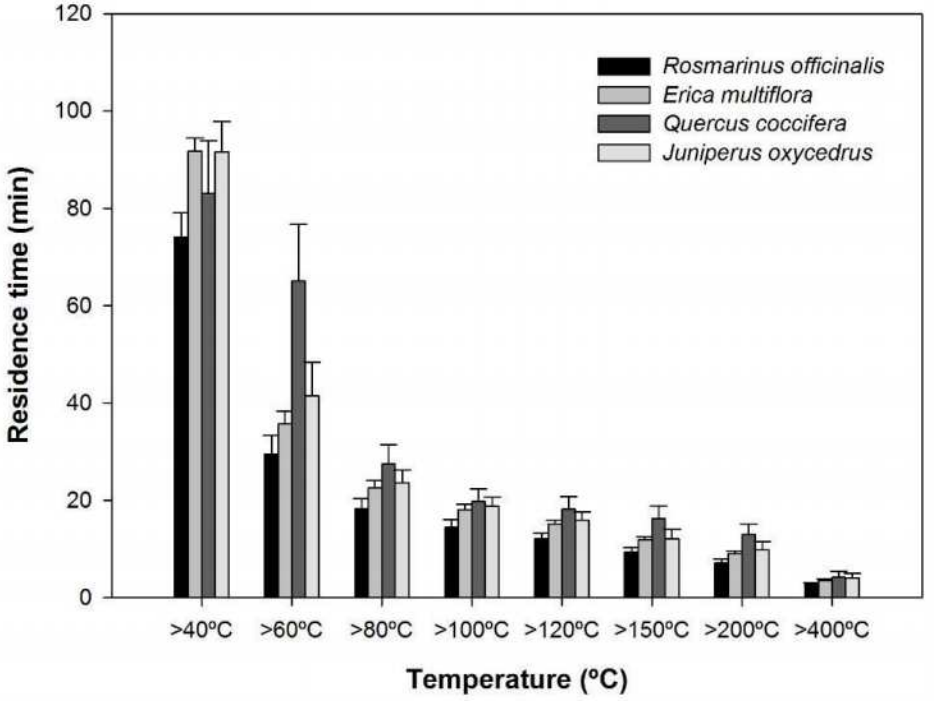

Figure 2. Residence time of temperatures at ground level (0 cm) for the different species (mean ± standard error)

The diameters of the burned twig tips and consumed biomass correlated positively with residence times of above 40°C for *R. officinalis* and *J. oxycedrus* (P <0.01; Table 1). Furthermore, the consumed biomass of *R. officinalis* correlated significantly with the residence times above 100°C and 120°C, while this effect was not observed for the consumed biomass and the diameters of terminal tips of *Q. coccifera* and *E. multiflora*.

Discussion

The present study reveals the existence of variability in fire severity between our experimental fires, even though they took place at the same time, in similar communities and under similar climatic conditions. This fact has been pointed out in other communities (Baeza, 2001). It has also been suggested that variation in vegetation moisture might be responsible for these differences (Johnson and Miyanishi, 1995). Fuel moisture content is the main factor to control the fire spread rate in controlled burnings applied to young and mature Mediterranean gorse (dominated by *Ulex parviflorus*; Baeza *et al*., 2002b). This variability is also due to the fuel characteristics of the component species and may, thus, depend on the assembly of different compositions in each plot. In fact, specific vegetation composition seems to play a decisive role in the temperatures recorded during a controlled burning in Mediterranean shrublands (De Luis *et al*., 2004).

Our study reveals that seeder species *R. officinalis* was the most flammable species in contrast to resprouter species. One exception was *E. multiflora*, which also showed high flammability. In line with this, some previous studies have correlated flammability characteristics with post-fire regeneration strategies in plants (Bond and Keeley 2005; Ojeda *et al*., 2010; Saura-Mas *et al*., 2010). Mediterranean Basin seeders grow much faster and allocate more biomass on leafs than resprouters. Seeders are mainly non-sclerophyllous and are associated with early succession stages, whereas resprouters are mainly sclerophyllous and are associated with late succession stages (Keeley, 1998; Pausas, 1999; Verdú, 2000). In fact seeders need lower temperatures to produce flame and exhibit fast combustion (Saura-Mas *et al*., 2010, Santana *et al*., 2011). However, the higher temperatures required by resprouters to initiate combustion, together their large fuel loads, can make fires not easily to extinguish (Andrews and Bevins, 2003). These preliminary results suggest that the ecosystems dominated by seeders are more prone to fire and burn more severely than those dominated by resprouting species.

Moreover, fire behaviour and its impact potential are related to the amount of accumulated fuel which, in turn, depends on the time elapsed since the last fire (Baeza *et al*., 2011). In fact, the differences observed between each species' consumed biomass are attributable to not only the structural

differences between species, but also to the retention of dead branches (Schwilk, 2003; Bond and Keeley, 2005). Our results indicate that shrub species such as *E. multiflora* and *R. officinalis* obtain much higher consumed biomass values if compared to tree or semi-tree species such as *Q. coccifera* and *J. oxycedrus*. Baeza *et al*. (2011) suggested that in advanced succession stages, shrub species like *E. multiflora* obtain higher percentages of dead fuel and dead thin twigs than other tree species such as *Q. coccifera* and *J. oxycedrus*. This suggests that the plant communities dominated by these shrub species are more likely to burn.

The fuel structure differences between species are significant in soil temperatures modulation and temperature residence times. In our study, *R. officinalis* displayed shorter temperature residence times despite its greater fuel consumption. This can be explained by its fast combustion due to a more dispersed fuel load in its structure. In contrast, the residence time was longer for resprouters with thicker fuels and larger amounts of fuel. These species require higher temperatures and longer times for the combustion of their biomass.

Indeed as has been widely documented in other fire-prone shrublands with similar fuel loads, the maximum soil temperatures and the longest residence times are significantly higher and longer, respectively, for fuels of lower height and higher bulk density (Molina and Llinares, 2001; Wright and Clarke, 2008). These results agree with other studies in conducted Mediterranean shrublands (Bradstock *et al*., 1992, 1993; Savadogo *et al*., 2006; Baeza *et al*., 2002a; Santana *et al*., 2011).

Our results show that differences in fuel accumulation among species with a different reproductive strategy, as well as their spatial distribution in the plant architecture, represent one of the most important structure features that determine fuel consumption and soil temperature. Consequently, it may play a key role in fire severity determination.

Abstract
Experiments were performed using stationary gas burners and liquid fuel-soaked wicks to study fundamental wildland fire behaviour, including unsteady flame heating. These experiments were motivated by observations of instabilities in spreading fire experiments that suggest they play a critical role in fire spread. Stationary fire experiments in forced flow and on inclined surfaces exhibited instabilities similar to those observed in spreading fires but allowed for more detailed analysis of the mechanisms responsible. Large scale inclined experiments were performed using an ethylene gas-fed burner at angles from 10 to 60 degrees. Forced flow experiments were performed on liquid-soaked wicks and small scale gas burners at wind speeds from 0.2 to 3 $\mathbf{ms^{-1}}$. Results presented include observations of the general flame structure, including streamwise streak spacing and flame fluctuation frequencies which relate to instabilities observed in large spreading experiments. A description and correlations of flame geometry, useful for predictions of wildland fire spread are also presented.

Keywords*: wildland fire, inclined flame spread, diffusion flame, flame pulsation*

Introduction

Predicting the rate of spread (ROS) of large wildland fires is of critical importance for operational firefighting, prescribed burning, and calculating future wildfire potential. Currently, most of these models are based upon correlations derived from experiments performed in the 1970's by Rothermel, Anderson and others (Finney *et al*. 2013a). While these correlations provided a "leap forward" in the prediction of a steady ROS, they failed to capture essential physics and therefore break down under extreme wind, topographic, and other conditions (Finney *et al*. 2013b). A considerable amount of effort is therefore being invested towards better understanding this fire behaviour, especially the mechanisms of heating to fuel particles. While it has proven difficult to study these phenomena in some large-scale spreading fires, a series of stationary, scaled experiments have been designed to determine the underlying physics that occur during fire spread.

Recent experiments of flame spread in discrete fuel beds have revealed the presence of buoyant instabilities which may lead to increased convective heating of fuel particles (Finney *et al*. 2013a). Unfortunately, detailed fluid dynamics and convective heating measurements in spreading fires remain difficult to capture because of the moving burning region of the fire. This is compounded by changes in the flame front and fuel burnout with time, causing non-steady burning rates and dynamic fire behaviour that require dozens of expensive, large scale fire experiments to investigate. Stationary burners have long been used to study fires in the built environment (de Ris and Orloff 1975), therefore they offer an ideal configuration to study non-steady fire effects in a thorough, statistical manner, in essence capturing a snapshot of a moving fire front. Experiments here show these stationary burning regions contain two buoyant instabilities which are similar to spreading fires, appropriately scaling with macro-features of large spreading fires, however they provide enhanced measurement capabilities (Finney *et al*. 2013a).

Motivation

Recent studies of spreading fires in the 3×3 m wind tunnel at the Missoula Fire Science Laboratory have shown coherent structures that form in the streamwise direction of the flow as well as spanwise fluctuations that propagate to the downstream edge of the flame zone contributing to fuel heating. The highly spatially-uniform fuel beds used in these experiments allowed for the observation of these structures with more repeatable results than previous efforts (Finney *et al*. 2013a). The results suggest that flame spread in fine fuel beds is driven by non-steady convective heating and intermittent flame contact on fuel particles. These heating characteristics were measured using micro thermocouple arrays and high speed video. The travelling flaming region, however, made it difficult to carefully study these properties, such as a statistical analysis of these features which appear stochastically in the flow. A technique was therefore needed that could study these new instabilities and other general structures of propagating wildfires in a small-scale configuration that can be utilized over long times.

Figure 1. Photos demonstrating the scales over which coherent streaks and flame towers have been observed. (a) Inclined gas burner, $L_f \approx 0.2$ m, (b) Comb burn experiments in 3×3 m wind tunnel, $L_f \approx 2$ m, and (c) Canadian Crown fire experiments, $L_f \approx 30$ m (Clark et al. 1999).

A stationary, non-spreading fire was chosen as it allows for a thorough statistical analysis of the flame structure. Long-duration experiments allow for a large sample size and more control over variations in experimental parameters, such as decoupling the heat-release rate of the fire from flow conditions, unachievable in spreading fires. The flame zone depth in the direction of fire spread can also be carefully adjusted via the size of the burner. High speed video and micro thermocouples are useful on these fires to reveal and track buoyant instabilities in the fire flow which resemble those appearing in spatially-uniform fuel beds. The same intermittent heating observed in the fuel bed experiments were observed in the stationary burner, but with the ability to collect a larger data set. Other modifications to the flow field, such as the incoming boundary layer thickness is also adaptable in these small scale experiments.

3. Methods

3.1. Experimental Setup

Forced-flow experiments were performed at both the USDA Forest Service's Missoula Fire Science Laboratory and a specially-designed 30 centimeter cross section wind tunnel at the University of Maryland's Fire Phenomenon Laboratory (UMD). In Missoula, a propane burner was constructed in the laboratory, using sintered metal as the porous burner surface which measured approximately 30 by 25 cm. A volumetric flow meter was used to measure the flow rate of propane gas into the burner, and experiments were conducted at fire sizes of 7.5, 10.9, and 15.1 kW. Ceramic insulation board was placed around the burner so as to make a continuous flat, inert surface to limit side-air entrainment. The apparatus was tested in a low-speed tunnel, 3×3 m cross section, at free-stream velocities of 0.22, 0.44, 0.67, 0.89, 1.11, and 1.34 ms^{-1}. Side view video was captured with a Phantom brand high-speed camera at 120 frames per second.

At UMD, a laminar wind blower was designed and built for uniform forced flow combustion experiments. The wind blower was designed to pressurize a 0.75 cubic-meter plenum box with a centrifugal fan. The flow then travels through a converging section into a 30×30 cm rectangular duct into a mesh screen and honeycomb flow straightener. The flow travels another 1.35 m in the duct resulting in a fully-developed laminar boundary layer before it is exhausted at the outlet. The velocity profile of the boundary layer was measured along the centerline of the blower above the burner surface using a hot-wire anemometer. Measurements confirmed the blower is capable of repeatedly producing precise forced flow velocities between 0.6 and 4.8 ms^{-1} with turbulence intensities less than 3% at maximum velocities.

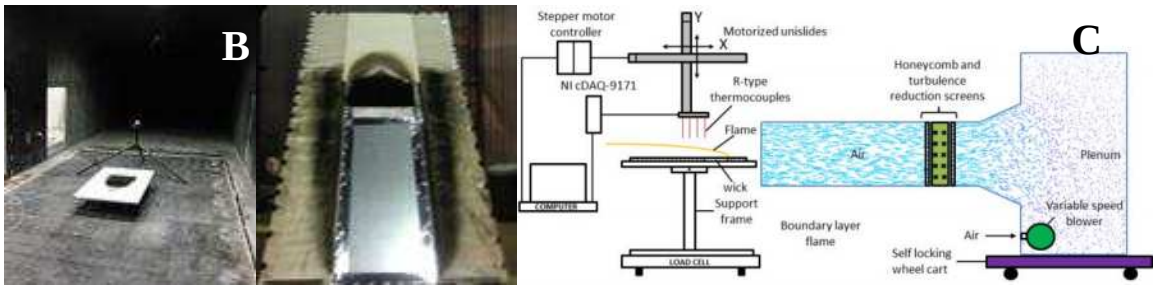

Figure 2: (A) Forced-flow gas burner in the Missoula 3×3 m wind tunnel, (B) Inclined gas burner at Missoula and (C) Forced flow configuration at UMD.

Large-scale inclined experiments were performed in Missoula on a gas burner flame wall repurposed from a vertical configuration (Jimenez *et al*. 2010). The retrofitted burner is rotatable so that experiments could be performed at inclination angles between 0 and 90 degrees relative to the ground. The width of the burner was 0.595 meters and the total burner surface height was 1.83 meters. To produce a line fire, sections of the burner were sealed so that gas flowed out of a ceramic plenum only above the exposed burner surface. The width of the line fire was fixed, based on the flame wall, but the depth of the burning region was changed between experiments by extending the amount of burner surface covered. Non-combustible surfaces were also attached to the top and sides of the flame wall in order to extend its length and width, minimizing side-air entrainment. Sidewalls were also considered for use, however it was found that at this scale such walls would induce the trench effect, drastically increasing flame lengths and flame attachment somewhat different than the open-fire behaviour trying to be studied here (Atkinson *et al*. 1995). A flush transition from the burner to the attachment section was ensured. Similar to vertical flame wall experiments (Finney *et al*. 2010), the burner was first purged with nitrogen and ethylene fuel was then introduced at a rate specified by the mass flow controller. Once the flame was fully developed across the exposed burner area, the flow of nitrogen was cut off.

3.2. Instrumentation

High-speed videography was used to capture digital images of the flame in all configurations from both the side and top view (Figure 1and 2). The side view camera was a Phantom, recording at 120 frames per second and a 1920×1080 pixel resolution, mounted on a tripod and tilted to give a parallel view of the flame relative to the attachment surface. The top-view camera was a high-speed Casio EFX-1, recording at 120 frames per second at a 640×480 pixel resolution, mounted on a tripod mounted to the bottom of the flame wall. This allowed for observation of the flame from the upstream edge at approximately a 45 degree angle. Micro-thermocouple arrays, similar to those used in spreading fire experiments (Finney *et al*. 2013a), were also placed downstream along the centerline of

the burner, raised 1 centimetre above the inert "unburnt fuel" surface with a spacing of 2 cm between thermocouples. Temperature measurements were sampled at a frequency of 120 Hertz.

Results

4.1. Mechanisms of Instability

In both spreading, forced flow (wind-driven) fires and stationary forced flow and inclined (sloped) experiments two dominant instabilities were observed. The first consisted of streamwise streaks, appearing as flame peaks and troughs when observed parallel to the direction of external flow (Figure 3). These structures resemble counter-rotating vortex pairs (Taylor-Görtler vortices) which form over concave surfaces (Saric 1994). The significance of these structures is that they splay flames downward into the fuel-bed, adding heating to the fuel surface that increases rates of flame spread. Similar structures have been observed in experiments on inclined heated surfaces with correspondingly increased rates of heat transfer noted (Jeschke and Beer 2001)**.** In stationary burner experiments, flame attachment was seen to occur downstream of the burner in both forced flow and inclined experiments, facilitating heating of "unburnt" fuel and thus simulating flame spread. Within this attachment region the flame front was also observed to pulse or burst further downstream, extending the direct flame contact zone with the unburnt fuel surface far beyond the mean flame front. The frequency of these observed pulsations were then extracted from oscillations of the flame location within this attachment region. This behavior is important as it could be similar to heating of fuel particles by direct flame contact which may be responsible for flame spread, as observed in larger scale experiments (Finney *et al*. 2013a).

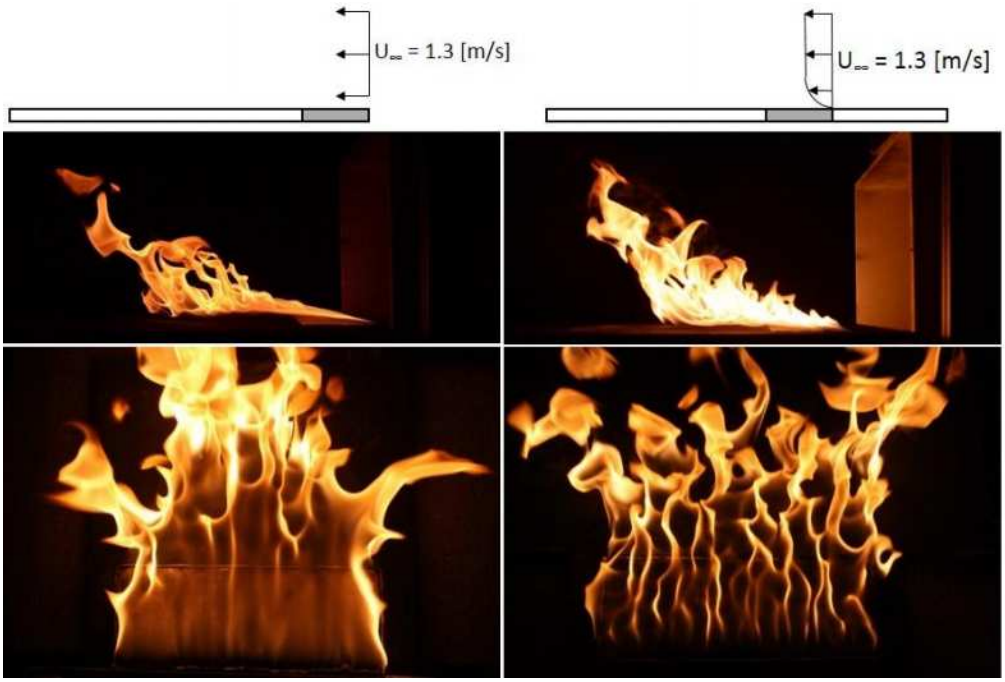

Figure 3. Boundary layer effects on a stationary wind-blown fire. (Left) No boundary layer development surface, i.e. placed directly in the free-stream flow. (Right) 25 cm boundary layer development surface (boundary layer thickness ≈ 2 cm). The fuel source was a heptane-soaked wick and an inert surface was placed downstream for all experiments to observe attachment of the flame.

In order to investigate the mechanisms responsible for these instabilities, experiments were conducted on UMD's forced flow burner apparatus to see what flow configurations were necessary for the formation of streamwise streaks. After a series of experiments, it was found that the length of the flat, inert surface leading into the flame significantly modified observed structures in the flow. A 30 cm wide, 12 cm deep porous ceramic wick was soaked with heptane and ignited in a 1.3 ms^{-1} flow with

two different leading edge conditions. First, the wick was placed directly in the free stream flow, allowing for negligible boundary layer development. Second, the wick was placed parallel to the surface of the wind tunnel, providing an 8 cm boundary layer development length. Figure 3illustrates this effect with two different configurations. The difference in the flames is striking, the uniform flow generated flame with no boundary layer development has almost no observable streaks, with a flatter, more laminar appearance (left-hand side of Figure 3). The flame with the boundary layer, however, forms strikingly coherent streaks which periodically force the flames closer to the fuel surface (troughs) or further into the air (peaks) along the width of the burner. Analysis of the two configurations utilizing methods described in the proceeding sections also showed that the boundary-layer configuration results in higher burning rates (0.8 g/s vs. 0.3 g/s), measured by a load cell and higher flame fluctuation frequencies than the uniform-flow configuration (7.3 Hz vs. 3.5 Hz). Therefore, the formation of streaks appears to be important in understanding downstream heating and thus fire spread.

4.2. Streamwise Streak Analysis

Streamwise streaks were observed to originate at the base of flames where any boundary layer development was present, whether that development occurred due to external forced flows or entrainment into the flame on inclined experiments. Streaks are observable due to up wash regions (peaks) where flames illuminate the structure. In order to further understand the instability which modifies the spacing between these streaks, measurements of the streak spacing were taken under a wide variety of flow configurations. High speed video taken from the top of the experiments was used to determine this average streak spacing 1 cm from the base of the flame.

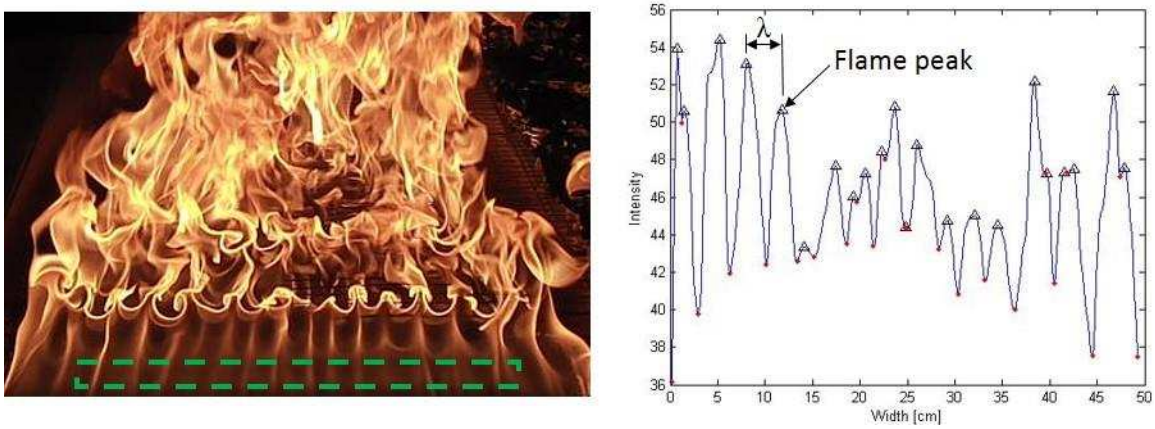

Figure 4. Streak analysis method for stationary gas burners. (Left) Top-view image from the Missoula inclined experiment, with a crop box region identified by dashed green lines. (Right) Smoothed intensity plot across the width of the burner, with local maximums marked as black triangles, representing the flame upwash peak.

The video was loaded into MATLAB and decomposed into individual frames. The region-of-interest started at the base of the flame across the width of the burner. For image analysis, the region was cropped one centimeter from the base of the burner in the flow direction. The intensity for each pixel column in the region-of-interest is averaged and the intensity across the width of the burner smoothed. The local maximums in intensity were determined to be a streak in the flow, and the spacing between the streaks determined for each image (Figure 4). Streak spacings for each experiment were then plotted on a histogram, fit to a log-normal distribution and the peak was used to scale the spacing between streaks for experiments (Figure 5).

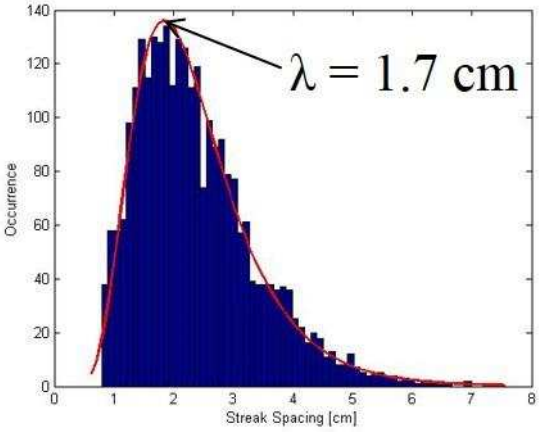

Figure 5. Probability distribution function (PDF) of streak spacing for a single experiment. The vertical axis represents the frequency of occurrence and the horizontal access the streak spacing observed. The red line indicates a log-normal distribution fit to the observed PDF.

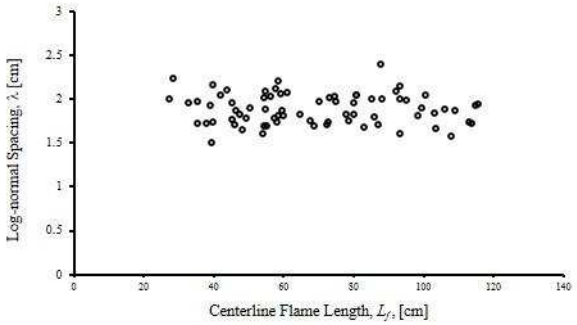

Figure 6. Maximum log-normal streak spacing, λ, remains relatively constant for small scale stationary burner experiments.

Similar to large scale experiments (Finney *et al*. 2013a), a relationship between the streak spacing and flame length were found, shown in Figure 6. This relationship appears nearly linear here over the limited test conditions, however if plotted against large-scale data (Finney *et al*. 2014) a relationship between flame length and streak spacing of the form, $\boldsymbol{\lambda = 0.39 L_f + 0.34}$ is observed. While the streaks meander from side to side during tests, the uniformity of the log-normal distributions observed show that they are coherent in formation for the unique conditions of every test. Their formation requires incoming vorticity of both the boundary layer and flame to interact, forming a centrifugal instability similar to Taylor-Görtler vortex streaks. Other instabilities are also observed, especially in inclined experiments, namely span wise waves that appear on the base of the inclined burner. These are most likely Tollmien-Schlicting waves that form at the base of a boundary layer from small perturbations that slowly grow in size and play a critical role in a laminar flow's transition to turbulence (Goldstein and Hultgren 1989). In these observed boundary layers, these waves cause flames to break off into flamelets so that they are easily observable. Similar structures are also seen in larger spreading fire experiments in the 3×3 m Missoula wind tunnel (Finney *et al*. 2014). They may play a role in the formation of pulsations or bursts of flames discussed in the next section. Further research using stationary burners will explore more effective scaling techniques and ways of predicting their formation and effects.

4.3. Flame Pulsation Analysis

Pulsations, or bursts of the flame beyond the mean flame front location were observed in spreading fire experiments as well as in stationary burners (Figure 7). The flame location in stationary experiments was determined using side-view high-speed video and an array of thermocouples ahead of the burner. A region starting at the downstream edge of the burner and extending fully downstream, 1 cm above the surface was determined as a region of interest where extension of the flame would relate to flame attachment and fuel particle heating. The flame location was then determined in this region-of-interest by tracking the furthest-most downstream tip of the flame. This location fluctuated in time and it was observed that the flame would pulse downstream, "bursting" into what would be the unburned fuel region in a spreading fire experiment.

Experimental videos were loaded into a MATLAB script for analysis. The previously described region of interest was defined from the downstream edge of the burner surface to the end of the image in the downstream direction, with a height above the surface of 1 cm (see the dashed purple rectangle in Figure 7). Each image in the video was cropped to this same region-of-interest and then converted to a black and white image using the same average threshold value from the streak analysis. The attached flame location (xa) was determined as the furthest downstream pixel in the region-of-interest that satisfied the flame threshold level (Figure 7).

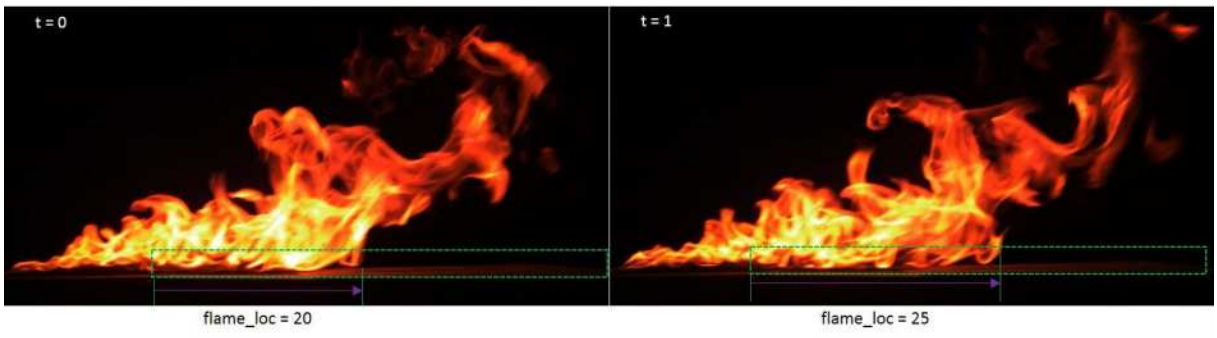

Figure 7: Flame location between two time steps in a forced flow experiment. The flame attachment location (x_a) is measured from the downstream edge of the burner to edge of the flame within the attachment region.

The flame extension downstream within the attachment region fluctuated in time, causing intermittent flame contact (Figure 8). The frequency of the flame pulsations was determined at locations on the downstream end of the burner using a variable interval time average (VITA) method (Blackwelder and Haritonidis 2006). The levels were determined at a range of locations downstream of the burner, starting at the burner edge and increasing in 1 cm increments (Figure 9). The flame position in time was compared to each of these locations and the number of occurrences was tallied. A level-crossing in the VITA technique was only considered for one direction; therefore only when the flame was previously not at a location and then at it in the next time step was it considered a crossing. The frequency for each location was then determined by dividing the number of crossings by the total number of frames analyzed, and multiplying by the frame rate of the video.

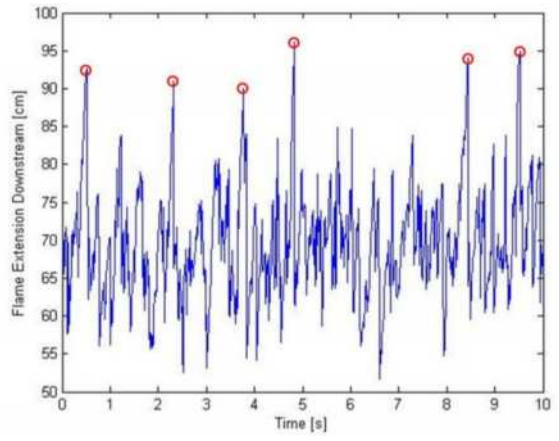

Figure 8. Flame location over time determined with high-speed videography. Flame location fluctuates around maximum frequency pulsation distance, but occasionally "bursts" further downstream (noted by red circles).

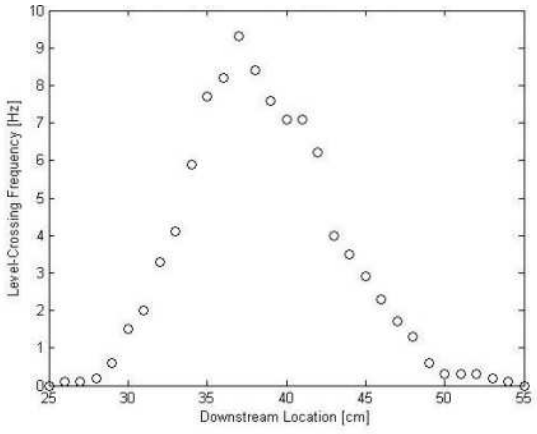

Figure 9. VITA frequency at advancing downstream locations.

In analysis of the trend of the frequency with different configurations, an analogy with pulsating pool fires was applied in the form of a Strouhal-Froude relationship. The Strouhal number, $\boldsymbol{St = fL/U}$, where *f* is the VITA frequency, *L* is a characteristic length scale and *U* is the free-stream velocity, was used to non-dimensionally relate oscillating flow mechanics to a balance of momentum and buoyancy forces. For this, the Froude number was used, $\boldsymbol{Fr = U/(gL)^2}$, where *g* is the acceleration due to gravity. Following the analysis of spreading fires (Finney *et al*. 2014), the flame length L_f was chosen as a characteristic length scale for the system, which represents the magnitude of the buoyant force. Figure 10 shows this scaling, $St = 2Fr^{-0.3}$ which is resolved from forced-flow gas burner experiments. The value of this exponent is below the value of -0.43 found in scaling for larger-scale fire spread experiments (Finney *et al*. 2014) and the -0.5 for diameter scaling of puffing in circular pool fires (Cetgen and Ahmed 1993 and Malalasekera *et al*. 1996). While the flame length may not be the most fundamental quantity for scaling analysis because of its coupling to experimental conditions, it is useful as most wildland fire spread analyses are correlated to this quantity (Byram 1959).

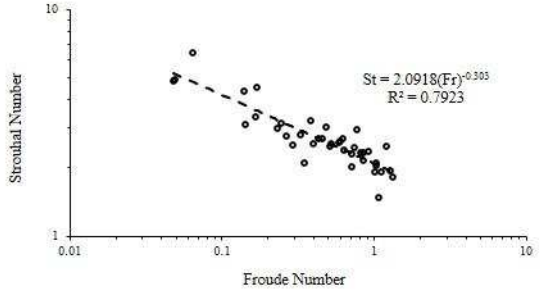

Figure 10. Strouhal-Froude scaling for stationary burners in forced-flow environment.

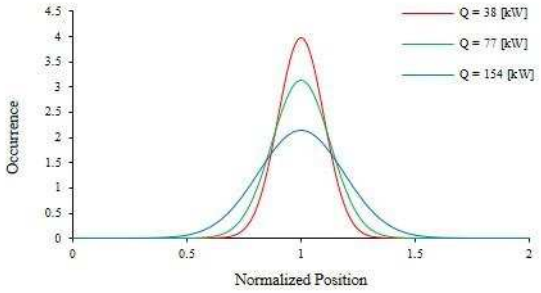

Figure 11. Probability-density function distribution of flame attachment along the free surface for three different heat-release rates (Q).

Statistical analysis of the flame position over time was also performed by producing a probability density function of the normalized flame attachment length (x_a) for different fire and flow configurations on an inclined and forced-flow gas burner. A histogram of the flame attachment length consistently shows a normal distribution of the downstream flame extension along the surface for each experiment. To compare the distribution for experiments, the attachment length was normalized with the average of the flame attachment distance in the attachment region (nominally an average flame extension along the free surface). The mean and standard deviation of the normalized flame location was then used to produce normal probability density functions, one of which is shown in Figure 11.
The representative tests shown in Figure 11 indicate increasing heat-release rates (Q = 38.6, 77.1 and 154.3 kW/m^2) of ethylene on the inclined Missoula flame wall. As the heat-release rate of the fire is increased, it is clear that the peak downstream extension of the flame resides further away from its mean position and extends further downstream more often. While other variables were compared, such as the incoming wind velocity and slope angle of inclined burners, once normalized with the flame length they were found to have little effect on the relationship shown in Figure 11. The implications of this finding are that, despite varying flow conditions and relative fire sizes (L_f), it is the overall heat-release rate of the fire that represents increasing extension of flames beyond the mean flame length into unburnt fuels. This perhaps suggests a means for correlation or future study.
Finally, an analysis was performed to investigate how far downstream of a burner a maximum VITA frequency would occur. Again, the relative fire size in terms of heat-release rates were found to best represent the variation in frequencies observed. Figure 12 shows this relationship, with the distance at which the maximum VITA frequency for a fire is observed downstream of a gas burner for various

inclined and forced-flow conditions versus a dimensionless fire size, $\boldsymbol{Q^* = Q/\left(\rho c_p T g^{1/2} L_f^{5/2}\right)}$, where $\boldsymbol{Q}$ is the heat-release rate of the fire, $\boldsymbol{\rho c_p T}$ representative gas density, specific heat and temperature, respectively, g acceleration due to gravity and $\boldsymbol{L_f}$ the flame length.

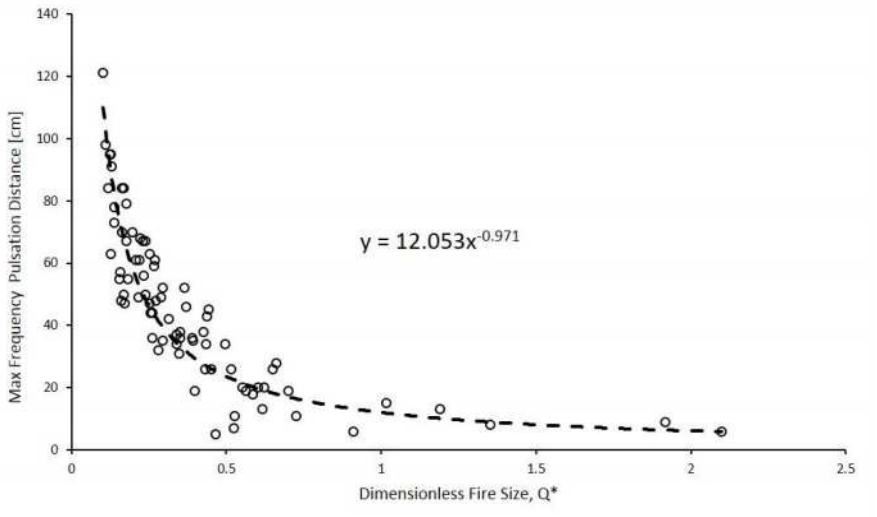

Figure 12. Max-frequency pulsation distance downstream into "unburnt fuel-bed" is considerably far for fires with low dimensionless fire size, Q*, and decreases exponentially with increasing dimensionless fire size.

4.4. Flame Geometry

Knowledge of the mean flame geometry, such as flame length, tilt angle, etc. are useful for assessing fire properties and can be easily obtained from stationary fire experiments. Measurements of the two-dimensional flame geometry were taken from side view images of the each experiment. Videos were processed into gray-scale images in MATLAB for the analysis. To determine the average flame geometry, the image was converted to RGB and all pixels with values between 0.48 and 0.52 were converted to red (Figure 13). To distinguish between flame and non-flame in the images, a thresholding tool was used on five randomly selected frames, from which a threshold was selected for the luminosity of the flame and background (non-flame). An average threshold value was then used for converting all frames in the video. Thresholding converted the gray-scale images to binary, black-and-white images, with 1 indicating flame and 0 indicating no flame. All images were then averaged.

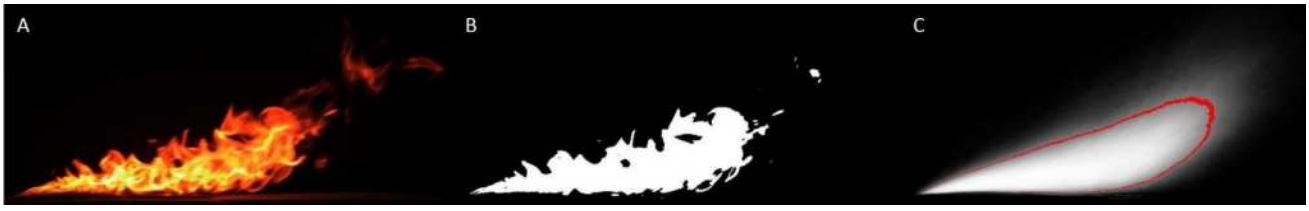

Figure 13. Image averaging technique used to determine flame geometry. (A) Still image from side-view camera (B) Black and white converted image using flame intensity threshold. (C) All black and white images averaged with pixel values between 0 and 1. A threshold line following pixels with value 0.48-0.52 are shown in red, identifying the average flame geometry.

Several flame geometry measurements were made using the average image (Figure 13 and 14). The flame tip was considered to be the highest point, furthest downstream from the burner. Flame length (L_f) was then measured from the midpoint of the burner (d/2) to the flame tip, along the centerline of the flame. The flame height (H_f) and flame extension (x_f) lengths were measured from the top of the

surface and the downstream edge of the burner to the flame tip, respectively. The attachment length (x_a) was defined as the average distance the flame extends downstream within the attachment region (denoted as a dashed box 1 cm above the attachment surface). The boundary-layer thickness incoming to the base of the burner (δ) was determined based on hot-wire anemometer measurements as 99% of the incoming free-stream fluid velocity, which compare favorably to estimates of δ using the Blasius solution (White 2011).

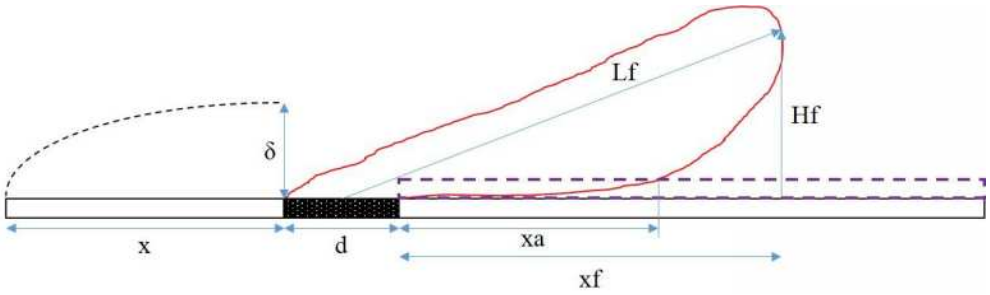

Figure 14. Physical length scales of the experiment. Independent parameters shown include the depth of the burner, d, leading edge, x, and boundary-layer thickness, δ. Dependent variables include the flame length L_f, flame height, H_f, flame length along the surface, x_f, and flame attachment length x_a.

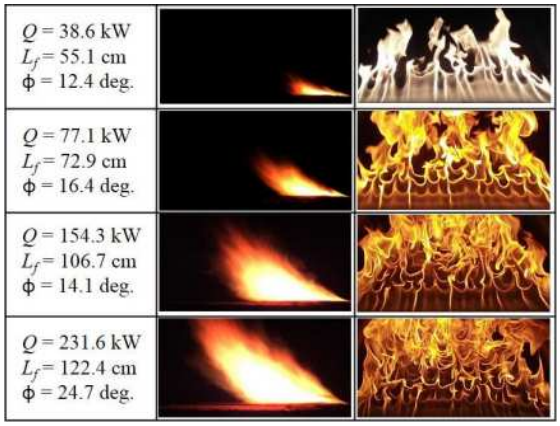

Figure 15. Variation of flame tilt angle based on heat release rate per unit length of the burner width (59.5 cm) at slope angle of 30 degrees. Burner depth = 12.7 [cm]

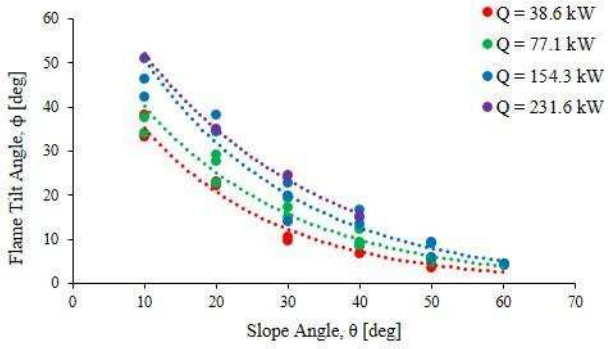

Figure 16. Flame tilt angle for several different heat-release rates (Q) on an inclined gas burner.

Figure 15 shows four representative conditions for tests on an inclined ethylene gas burner. Variations in the heat-release rate per unit length ($\dot{\boldsymbol{Q}}$), the flame length, $\boldsymbol{L_f}$ and the angle of inclination, $\boldsymbol{\phi}$ on the flame geometry are shown in both side-view and front-view images. From the side view, it can be seen that as both the angle of inclination and heat-release rate are increased, the flame length increases, however the attachment region does not experience a linear increase with flame length. The slope angle, which is representative of the attachment of the flame to the surface is shown in Figure 16. As the slope angle of the burner is increased, the flame tilt angle decreases, thereby signifying the flames becoming more and more attached to the surface of the burner. With increasing heat-release rates, it takes a greater angle of inclination for the flames to attach closer to the surface. This is expected as additional buoyant forces propel the flame upwards, compared to incoming entrained air.

A dimensionless length scale, $\boldsymbol{D^* = [\dot{Q}/(\rho c_p T g^{1/2})]^{2/5}}$ has been used in the fire research community to describe the source strength of a buoyant fire source (Quintiere 1989). This non-dimensional length

scale is given by the ratio of the fire heat release-rate $\dot{\boldsymbol{Q}}$ to the ambient air conditions $\boldsymbol{\rho c_p T}$ (density, specific heat, and temperature) and the square root of the acceleration due to gravity, all raised to the 2/5 power. The gravity term contributes to the buoyant force of the fire, and should act parallel to the line of action of the flame. To incorporate the slope angle of inclined fires, a rotated gravity vector term parallel to the inclined surface is used, given by the acceleration due to gravity time the sine of the slope angle. Flame lengths of pool fires, for instance, can be scaled with the dimensionless fire length, $\boldsymbol{D^*}$, and so with an adjusted gravity vector they should be able to as well. In Figure 17, preliminary scaling of the flame length with an adjusted gravity vector is shown to scale linearly with the centerline flame length. This suggests that the flame length for fires over sloped surfaces may be universally correlated if the correct ratios between buoyant forces and the gravity vector are taken into account.

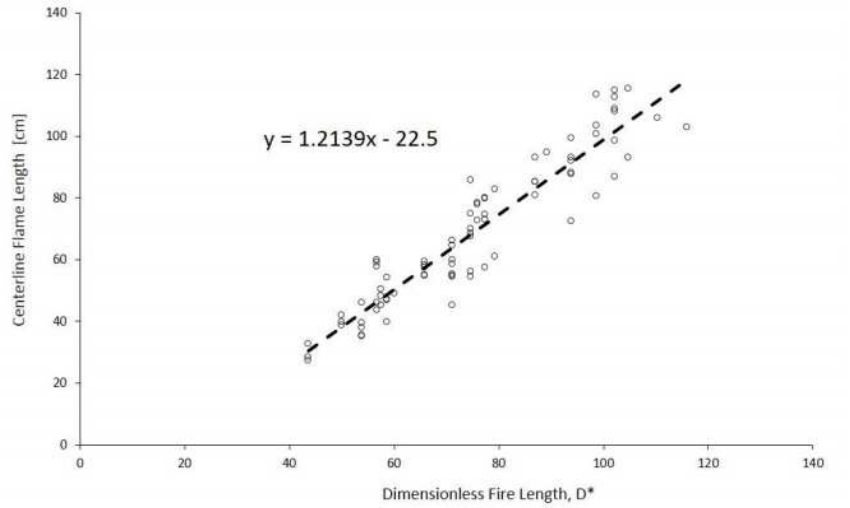

Figure 17. Relationship between centerline flame length and dimensionless fire length parameter D*, shows that for larger fires in steep slope the flame length is increases linearly.

Conclusions

This study has presented a framework for the use of stationary gas burners to study spreading wildland fire behavior, enabling measurements and analysis of key parameters related to instabilities and flame geometry that play a role in flame spread. Numerous techniques used to accomplish this are shown, as well as preliminary scaling analysis. Recently-discovered instabilities and flow structures are shown to be re-created in steady gas burners, allowing for more detailed studies, including statistical analysis made possible by the long time scales stationary flames can be created. Correlations for the mean flame geometry, such as the flame tilt angle and flame length can also be obtained by these studies with appropriate nondimensional scaling.

Abstract
The forest fire in Korea was occurred by human activities. Recently, forest fires intended to damage not only forest and related regions but also urban facilities like houses, buildings and citizens. In this study, we simulated the fires which occurred on wildland–urban interface in Pohang-Si and Ulju–Gun in spring, 2013. And we compared real damages of facilities in wildland interface with simulated damaged for applying in Korea forest environment. These results would be good reference data for the prediction about danger zone in wildland-urban interface.

Keywords*: Wildland-urban interface, forest fire simulation, FARSite , Forest fire danger zone, fire intensity*

Introduction

The forest fires in wildland-urban interface especially damaged in human and their properties. Therefore, many researchers have studied about environments in which were more danger (forest floor, topography, weather, the location of houses and etc.). And they classified with danger zone and safety zone in wildland–urban interface from forest fire. Moreover they have developed the treatment for reducing forest fire damages (the fuel treatment, the removal of flammable matter, the change of building material and etc.). In these studies, we investigated the forest fire which occurred in Pohang-Si and Ulju-gun in Korea in 2013. These fires occurred in wildland–urban interface and forest fire in Pohang-SI ignited in mainly urban area and spread in forested area. So, many houses-even 15 floors apartment-were damaged by these forest fires. Because these fire destroyed 30 buildings and facilities, we could analyzed relationships with forest fire intensity and the condition of destroy from forest fire.

Methods

We investigated damaged area for measuring and surveyed an area burned, officers and residents for estimating forest fire damages, forest fire velocities and damaged area. After field surveys, we simulated the forest fires by FARSite for obtaining a detailed forest fire damage data.…

2.1. Field survey

Field surveys were carried out from May to June on Pohang-Si and Ulju-Gun in 2013. We surveyed total burned area and damaged facilities and houses. And we investigated the topographical conditions (a degree, an aspect and an elevation) and forest floors (a density and main species) around damaged building. And we surveyed official records about these fire for getting damage data and forest fire velocities detailed. …

Forest fire Simulation

For analysis relationships with forest fire intensity and conditions around damaged buildings, we used simulation, FARSite which was developed by USDA. FARSite simulated a detailed data about forest fire intensity, burned area, forest fire velocity from topography, weather and forest species. Topographical data were acquired from D.E.M. Weather data were input by an editor contained in FARSite. Forest floor data were getting from digital forest floor map made by K.F.R.I.. These data were processed by ARCGIS 9.3 and inputted in FARSite. FARSite made many data simulated. A fireline intensity, a flame length, a time for arrival, heat per rate from forest fire and burned area were acquired

Results

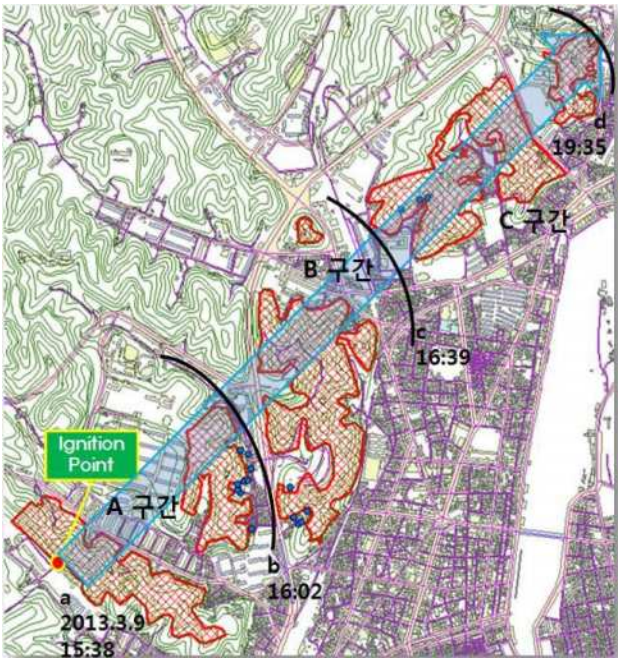

Figure 1. The result of field survey in Pohang-Si

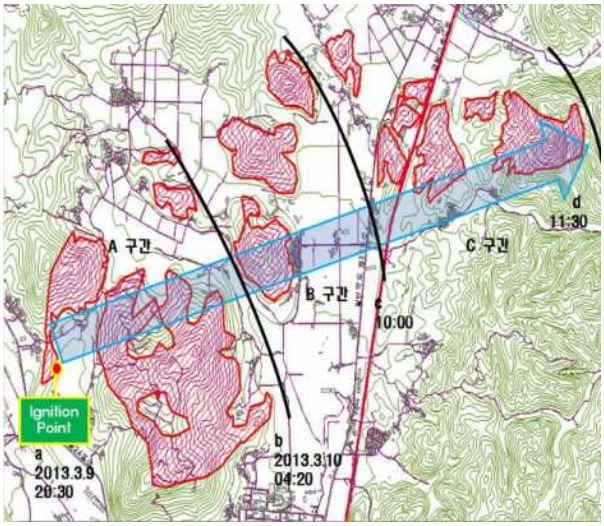

Figure 2. The result of field survey in Ulju-kun

The Pohang forest fire directly moved 3km from 20:30 P.M. 2 March and burned for 237 minutes. 79ha forested area and 110 buildings were damaged. 10 houses and one garage were destroyed wholly. The average velocity was 0.8km/hr. The Ulju forest fire directly moved 5.4km from 20:30 P.M. 9 March and burned for 900 minutes. 280ha forested area and 57 building was damaged. 15 houses and 3 buildings were destroyed wholly. The average velocity was 0.4km/hr.
The burned area from simulation was 184% larger than real burned area and the reason of this difference may be caused by forest fire attack. The average speed of spread was 0.12km/hr in simulation and 0.4km/hr in real fire. The results was similar to former simulation for Samcheok forest fire. The real fire was 3 times faster than real fire because of fuel condition maybe. The average fireline intensity from simulation of Ulju forest fire was 1,255kw/m and the average fireline intensity around destroyed building was 331.85kw/m. The average flame length from simulation of Ulju forest fire was 3.5m and the average flame length around destroyed building was 1.5m. As the results of fireline intensity and flame length were compared with U.S. Wildland-urban interface forest fire assessment guide made by N.W.C.G., this result indicate that Ulju fire was very serious state. Using these results, we analyzed and classified degree and the location of mountainous contour which divided 10class by elevation. The danger zone was classified in over 15 degree and over 3/10 location by elevation

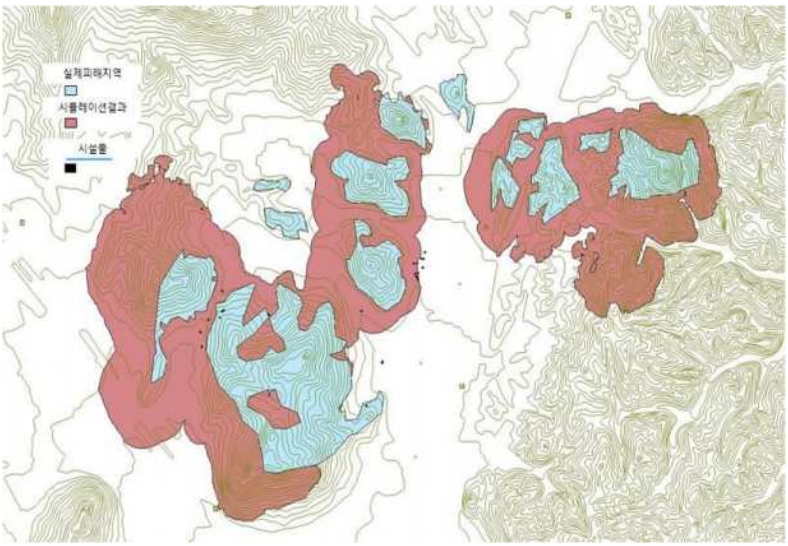

Figure 3. The comparison with simulated burned area , real burned area and locations of destroyed building

Abstract
Key to understanding fire propagation in grassland fuels is to know their annual growing cycle and the availability of biomass to be consumed by a fire. Curing is the progressive senescence and drying out of grass after flowering (annuals) or in response to drought (perennials) and is the key process transferring biomass from the live to the dead fuel component. Despite the relevance of fires in grasslands and savannah ecosystems in Australia and throughout the world, our understanding of (1) grass senescence effect on overall fuel moisture content and fuel availability, and (2) the degree of grass curing in fire behaviour, is still lacking. To investigate the effect of the curing process on grassland fire behaviour an experimental field study was conducted at two distinct locations in Victoria. Experimental burn plots size were 32 x 32 m. Simultaneous burns were conducted with one plot being fully cured (100%; control) and another being partially cured (treatment). Detailed measurements of fuel bed structure, weather variables (3D wind speed, air temperature, relative humidity and solar radiation) and fire behaviour (rate of spread, flame length, residence time and time-temperature profiles) were recorded on 52 experimental fires. The range of curing in the partially cured plots varied between approximately 35% and 90%. The range of other fire environment parameters were: 2-m wind speed: 5.4 - 20.5 km/h; ambient air temperature: 16-33 C; relative humidity: 14-40 %; Fire spread rates varied between 3.6 and 72 m/min. Preliminary analysis highlights include the observation of sustained fire spread with curing levels between 30-40% and the importance of the dead fuel component from the previous year growth to sustain propagation at these marginal conditions. The data collected is being used to reanalyze functional relationships currently used to express the effect of curing and live fuel moisture on the spread of grassland fires

Keywords*: Grass curing, grass fire behaviour, fire danger ratings*

Introduction

Key to understanding fire propagation in grassland fuels is to know their annual growing cycle and the availability of biomass to be consumed by a fire. Grassland curing is the progressive senescence and drying out of grass after flowering (annuals) or in response to drought (perennials) and is the key process transferring biomass from the live to the dead fuel component within the fuel complex. As senescing progresses, the fuel moisture content gradually decreases and the amount of dead material in the grassland increases. These changes have an important impact on fire behavior in grasslands. In Australia, where grasslands cover approximately 75% of the country, the degree of curing is used as an input into the calculation of grassfire spread and grassland fire danger ratings.

Despite the relevance of fires in grasslands and savannah ecosystems in Australia, and throughout the world, our understanding of (1) grass senescence effect on overall fuel moisture content and fuel availability, and (2) the degree of grass curing in fire behaviour, is still lacking. The ability to accurately assess the degree of curing is therefore important for fire agencies who predict fire danger throughout the fire season.

Grassland curing is a complex and dynamic process. The study examines the dynamics of grass curing levels through the grass life cycle and the relation to grassfire behaviour through the fire season. The

objective is to provide better estimates of grass curing that could be used to predict rate of spread of grassfires.

Methods

Two distinct Victoria, Australia experimental field sites, located at Wangaratta South and Wendouree, with continuous grass cover were selected for studying grass curing dynamics and grassland fire behaviour during the 2013-14 fire season (October to February). The distinct predominant grass species present at each site resulted in distinctive fuel structures. One site consisted of coarser grass and higher fuel loads than the other site which was characterized by finer grass and lower fuel loads. The differences in each site had a significant effect on fire behaviour.

Experimental burn plots size were 32 x 32 m. Simultaneous burns were conducted with one plot being fully cured (100%; control) and another being partially cured (treatment). Detailed measurements of fuel bed structure, weather variables (3D wind speed, air temperature, relative humidity and solar radiation) and fire behaviour (rate of spread, flame length, residence time and time-temperature profiles) were recorded on 52 experimental fires. The range of curing in the partially cured plots varied between approximately 35% and 90%. The range of other fire environment parameters were: 2-m wind speed: 5.4 - 20.5 km/h; ambient air temperature: 16-33 C; relative humidity: 14-40 %; Fire spread rates varied between 3.6 and 72 m/min.

Results

Preliminary analysis highlights include the observation of sustained fire spread with curing levels between 30-40% and the importance of the dead fuel component from the previous year growth to sustain propagation at these marginal conditions. The results indicate that the fire rates of spread of 40 to 60% cured can be as rapid as spread rates previously achieved by cured grasses of 60% and higher. The data collected is being used to reanalyze functional relationships currently used to express the effect of curing and live fuel moisture on the spread of grassland fires.
The results will feed into future grassland fire danger indices which contribute to the overall fire danger rating system. Accurate fire danger ratings allow fire agencies to plan for fire restrictions, resource allocation, total fire bans, fire behaviour modeling and community warnings during the fire season.

The Strouhal-Froude number scaling for wildland fire spread

Abstract
A study of wildland fires leading to a correct understanding of flame spread in wildland fire would find its foundation firmly situated on an understanding of the governing mechanisms, processes, and threshold of ignition. It is, therefore, very important for effective firefighting efforts and safety reasons to identify the roles of radiative and convective heating. Over the years, the United States Department of Agriculture (USDA) Missoula Fire Sciences Laboratory has conducted a series of experiments in their unique wind tunnel fire experimental facility. This rich database provides years of numerical data and video from burns conducted under a wide range of well-specified conditions. After identifying the need to explore the roles of both convective heat transfer and radiative heat transfer in the ignition process, the USDA's well documented line fire data provided an opportunity to observe ignition and, subsequently fire spread phenomenon, through a uniform fuel bed of laser-cut cardboard combs under controlled conditions. The goal of our study is to identify features distinguishing radiative heat transfer from convective heat transfer. The team worked to explain scaling laws, determine key parameters to support the development of scaling laws, and begin a comparison of the scaling law predictions with USDA data. When the above scaling laws are validated, it would be reasonable to design medium scale prescription fire experiments, which fall between the USDA experiments and the full scale wildland fires. Our step-by-step approach using different size scale model experiments eventually allow us to understand the governing physics that control the mechanism of flame spread through and ignition on the wildland fuel bed.

Keywords*: Scale Modelling, Scaling Laws, Fire Spread, Fuel beds, Forest Fire, Wildland Fire, Fire Behaviour*

Introduction

A correct understanding of flame spread in wildland fire would be based on governing mechanisms, processes, and thresholds of ignition. Critically, the roles of radiative and convective heating must still be discerned (Finney, Cohen, et al. 2013). Over the years, the United States Department of Agriculture (USDA) Missoula Fire Sciences Laboratory has conducted a series of experiments in their unique wind tunnel fire experimental facility. This rich database provides years of numerical data and video from burns conducted under a wide range of well-specified conditions. After identifying the need to explore the roles of both convective heat transfer and radiative heat transfer in the ignition process, the USDA's well documented line fire data provided an opportunity to observe ignition and, subsequently fire spread phenomenon, through a uniform fuel bed of laser-cut cardboard combs under controlled conditions.

The USDA Missoula Fire Sciences Laboratory and University of Kentucky Institute of Research for Technology Development (IR4TD) teams conducted two explorations to further understand ignition on a wildland fuel bed. The team first began by identifying and exploring flame behaviours in the lab environment that were previously only observed in large scale wildland fires (Finney, Forthofer, et al. 2013) (Adam, et al. 2013). The goal of our study is to identify features distinguishing radiative heat transfer from convective heat transfer. The team worked to explain scaling laws, determine key

parameters to support the development of scaling laws, and begin a comparison of the scaling law predictions with USDA data. When the above scaling laws are validated, it would be reasonable to design medium scale prescription fire experiments, which fall in size between the USDA experiments and full scale wildland fires. The USDA – University of Kentucky collaboration already produced two recent articles (Finney, Forthofer, et al. 2013) (Adam, et al. 2013), and we made further progress on the above study. In this paper we report recent field burn tests, organized by USDA Forest Service and conducted in Texas. Our step-by-step approach using different size scale model experiments will eventually allow us to understand the governing physics that control the mechanism of flame spread through and ignition on the wildland fuel bed.

Scale Modelling and Scaling Laws

University of Kentucky and USDA Forest Service in Missoula Science Laboratory have developed mutually beneficial research program to understand the mechanism of fire spread through forest fuelbeds. This paper reports one of our current progresses in this effort, namely focusing on scaling laws and scaling aspects forest fire. We begin with an excellent book: The Use of Models in Fire Research (Bert 1961). This book is the collection of sixteen different papers presented at five different sessions of the International Symposium of the same title as the book held in 1959, and commentaries are provided at the end of each session. This is a book written more than a half century ago when no computer simulation was available, but researchers' wisdom and unique insights in fire phenomena with their attempts to extract the governing physical laws which can help develop simple practical models are still valuable in the age of high speed computation, and therefore serve as an excellent reference for our forest fire research efforts.

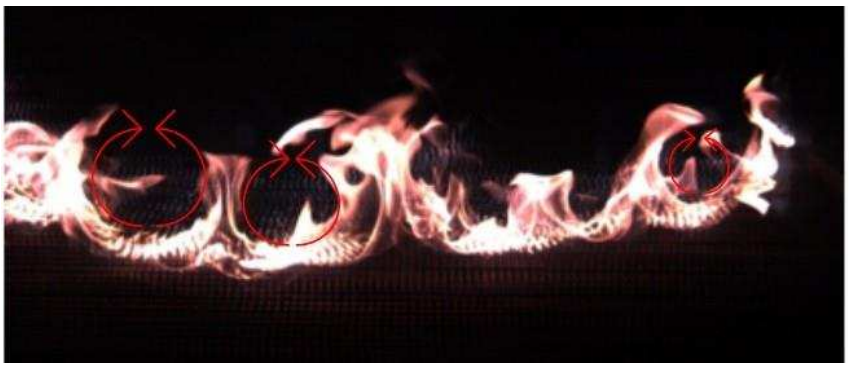

Figure 1. A high speed color photographic image of spreading flame over artificially made cardboard fuelbeds (Finney, Forthofer et al. 2013).

To continue the above book's philosophy, the USDA's Forest Service Fire Science Lab (Finney, Cohen, et al. 2013) (Finney, Forthofer, et al. 2013) made a series of unique observations on forest fires by high speed video photography and thermocouple temperature measurement techniques. These techniques are rather ordinary but their observation results are rather extra-ordinary. The following are except from Finney's observations (Finney, Cohen, et al. 2013). "A series of preliminary burns of the cardboard fuelbeds in the wind tunnel were used to refine the instrumentation. The fires were filmed with digital video cameras from the top, sides, front, back, and various oblique angles. This footage revealed two principal dynamic features of the flame zone. First the flame zone became divided in the transverse or span-wise direction into convective peaks and troughs at fairly regular spacing. The ignition interface (at the leading edge of the combustion zone) was convoluted in association with this flame structure, with a concave segment located directly beneath these peaks (Figure 1) and convex segments in the troughs. Second, the flame zone exhibited clear instabilities, which when viewed at an angle from behind and above the bed, appeared as patches originating near the rear of the burning

zone…… After reaching the ignition interface at the leading edge of the burning zone, they impinged new fuels ahead. When the flame zone was viewed normal to the stream-wise direction, eddies appeared on the upper and lower flame edges which rotated in the opposite direction. Regardless of the local geometry of the fire edge, it progressed at the same rate across the fire front." (Finney, Forthofer, et al. 2013)

Almost 30 years prior to Finney's observations, F.A. Albini (Albini 1984) made a comprehensive review on wildland fires addressing Rothermel's steady-spread model (Rothermel 1972) to predict the rate of spread of surface fire as a successful example, while describing wildland fires as poorly understood phenomena. As of today, many of the unknowns pointed out by Albini (who believed radiation as the key heat transfer mechanism for flame spread) in 1984 still remain to be unknown (for example, the role of live fuels in fire spread and the effect of wind on fire spreading behaviour). As to the wind effect, some progress has been made on fire whirl studies (Emori and Saito 1982; Chuah *et al*. 2011), while an important progress was made recently on the mechanism of fire spread (Finney, Cohen, et al. 2013) (Finney, Forthofer, et al. 2013) based on a serious of unique observations mentioned. This paper mainly focuses on the latter development (Finney, Cohen *et al*. 2013; Finney, Forthofer *et al*. 2013; Finney *et al*. 2014) which establishes a high correlation between Strouhal (St) – Froude (Fr) number based on a series of careful observations over a variety of fuel types and a wide range of size including full scale crown fires, grassland control burn experiments, large scale wood crib fires, and wind tunnel laboratory-scale fire experiments using artificial cardboard fuelbeds. In the following, we provide governing physical laws responsible for the above St-Fr correlation and possible scaling laws on fire spread.

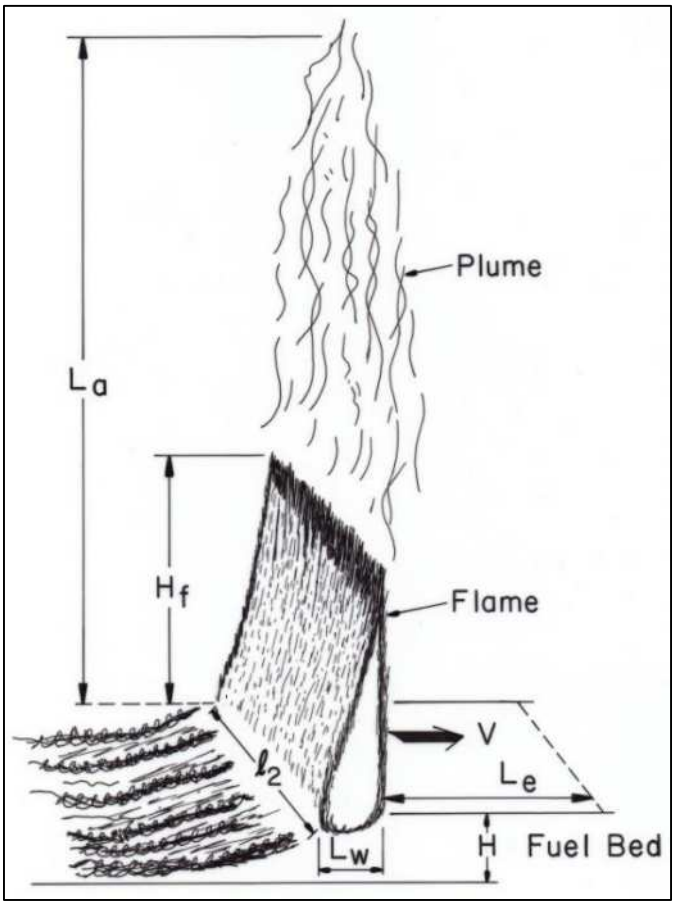

Figure 2. Schematic of one-D flame spread over fuel bed and dimensions of flame height, plume height, and fuel bed (Emori, Iguchi et al. 1988)

Here we use the law approach whose details are provided in refs (Emori and Saito 1985; Emori, Saito and Sekimoto 2000) to obtain seven independent pi-numbers from the above three different forces and five different heats. The scaling criteria demand: $\pi_i = \pi_i'$ for similarity, where $i = 1$ to 7, the left hand π_i represents a full scale scenario, and the right hand π_i' represents a corresponding scale model. Note

that the ratio of the inertial force causing vortex shedding behind a flame, $F_{i,down}$, to the inertial force of the wind, $F_{i,up}$, is unique to the current wildland fire problem, where a flame acts like a vertical solid cylinder to generate a wake in the downstream against an upcoming horizontal flow (Kuwana, et al. 2007), and pi-number constituting between heat and work done by fluid motion can be ignored. Finney *et al*. (Finney, Cohen, et al. 2013) obtained a reasonably strong St-Fr correlation, which is equivalent with the (π_2 - π_1) correlation, over wide range of experimental data including the wind tunnel fire spread experiments on cardboard fuelbeds, a full scale crown fire data, and outdoor large scale wood crib fire experiments. Using the same fuels both for the full scale and the model and assuming the same temperature at the corresponding points, the law approach can produce the following, Equation (1):

$$\phi\left[\frac{u^2}{L_w}, \frac{L_e\omega}{u}, \frac{El_2}{I}, \frac{L_aR}{I}, \frac{L_au^3}{I}\right] = 0 \qquad (1)$$

Previously Emori and Saito (1983) showed liquid pool fires to be radiation-driven and wood crib fires to be convection-driven, each governed by a different set of scaling laws. Later Emori and Iguchi *et al*. (1988) conducted flame spread experiments using two different types of fuel bed: vertically oriented allay of paraffin-coated paper strips and packed excelsior mats. They found that the above two different scaling laws also can be applied to flame spread identifying two different types of spreading mode, radiation-driven and convection-driven. Recently Finney's group in Missoula and the University of Kentucky's group are collaborating to develop scaling laws for flame spread through actual full scale forest fuelbeds (Adam, et al. 2013), which are significantly complex in nature consisting of live and dead fuels of different fuel types and geometry. This work is still in progress. The following provides summary of the above scaling studies (Emori and Saito 1983; Emori, Iguchi *et al*. 1988) and one of recent findings on St-Fr correlations (Finney, Forthofer *et al*. 2013; Finney *et al*. 2014).

Radiation-driven Fire Type: There is little effect of the fluid dynamics on the overall heat balance, and radiation is the main source of the solid fuel evaporation and ignition leading to the flame to spread. For this type of fire, Equation (1) can yield the specific scaling relationships seen in Equation (2).

$$\frac{u}{u'} = \sqrt{\frac{L_w}{L'_w}} \qquad \frac{R}{R'} = \frac{E}{E'} \qquad t = t' \qquad (2)$$

(2) Convection-driven Fire Type: Contrary to the radiation-driven type, fluid dynamics influences the heart transfer mechanism as the form of heat convection, creating a coupling between the force and heat balances, and leading to the following Equation 3.

$$\boldsymbol{\frac{u}{u'} = \frac{R}{R'} = \frac{E}{E'} = \frac{t}{t'} = \sqrt{\frac{L_w}{L'_w}}} \qquad (3)$$

The St – Fr Number Correlation

Figure 3 shows St-Fr correlation over the wide range of scale of fires. Data consist of a full scale crown fire (10m; 100m-1,000m), controlled grassland fires (3 m; 10m-100m), large scale wood crib fires (2m; 3m-10m), and wind tunnel laboratory-scale fire experiments (0.5m; 2m – 5m). The first number in parenthesis indicates a typical flame height, and the second number indicates a typical fuel bed dimension, width x length. There are two important practical implications of the St-Fr correlation that have not been previously known. First, time-varying convective heating derives from buoyant instabilities, explaining the origin of the frequency scaling from laboratory to field-scale wildfires. Second, with frequency related inversely to flame size, it suggests a negative feedback on wildfire spread rate. In other words, as fires move faster (with increasing wind for example) and release more energy, flame size increases but convective frequency decreases (according to St-Fr) and slows the convective heat transfer.

The Figure 3 correlation can provide an approximate correlation: $St \sim Fr^{-0.5}$, which indicates $F_\omega/F_i \sim (F_g/F_i)^{0.5}$, i.e., $F_\omega/(F_iF_g)^{0.5} \sim$ const. Using characteristic parameters, this relationship can yield: $(L^{1.5}\omega^2)/Ug^{0.5} \sim$ const.

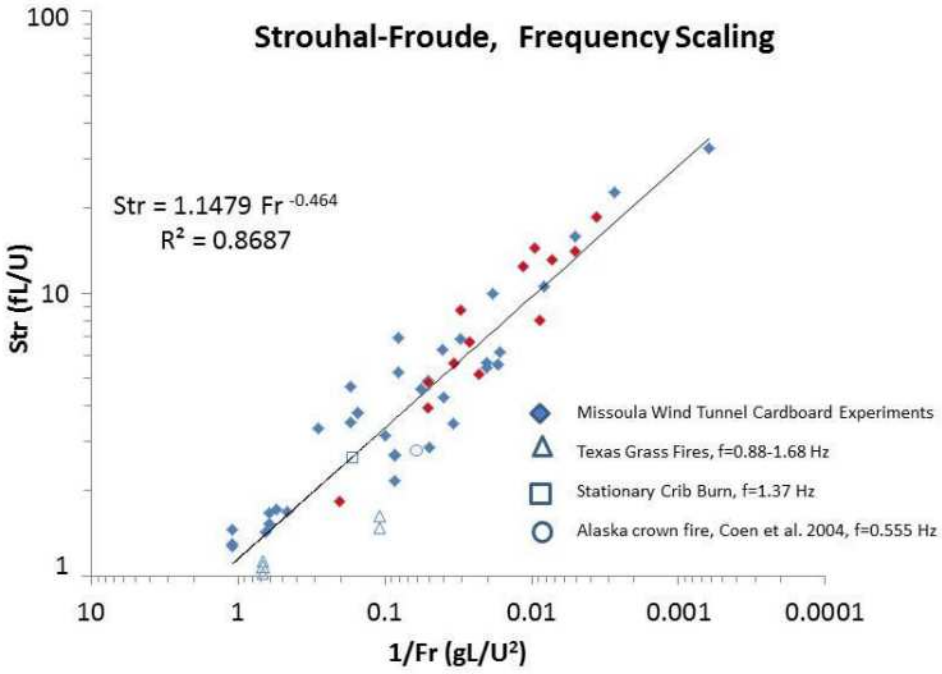

Figure 3. Strouhal (St) – Froude (Fr) number correlation for various size and type of fires including a full scale crown fire (10m; 100m-1,000m), controlled grassland fires (3 m; 10m-100m), large scale wood crib fires (2m; 3m-10m), and wind tunnel laboratory-scale fire experiments (0.5m; 2m – 5m). The first number in parenthesis indicates a typical flame height, and the second number indicates a typical fuel bed dimension (width x length) [32].

3. Summary

We provided background for the need to study spreading mechanism of actual forest fuelbeds. This study is one of our collaborative studies between USDA Forest service and University of Kentucky to achieve that goal with the scale modeling approach. We used the law approach to provide the major governing physical laws on the St-Fr correlation which have been established over a wide range of scale of fires and different types of fuels. The results indicate that previously developed scaling laws on stationary (pool and wood crib) fires and flame spreading can be extended to the current problem with possible some modifications which will be studied in the future.

The ring of fire: the relative importance of fuel packing versus intrinsic leaf flammability

Saskia Grootemaat[a], Ian J. Wright[a] and Johannes H. C. Cornelissen[b]

Abstract
Two different experimental set-ups were used to disentangle the relative importance of intrinsic leaf traits versus fuel packing for the flammability in fuel beds. Dried leaves from 25 Australian perennial species were burnt in fuel bed rings under controlled conditions. The flammability parameters were compared with the results of a previous study where individual leaves from the same species were burnt in a muffle furnace at 400°C. Fuel density (g fuel per volume) was the dominant driver for the combustibility and sustainability of the fire in the fuel bed rings; e.g., loosely packed fuel beds showed higher rates of spread. Specific leaf area (SLA, ratio of leaf area to dry mass) was not only the strongest predictor of "time-to-ignition" in the furnace set-up (higher-SLA species having shorter ignition times), but also played a major role in the build-up of the fuel bed, and thus the flammability in fuel beds.

Keywords*: combustibility, fire behaviour, fuel bed density, leaf traits, specific leaf area*

Introduction

During high intensity wildfires any organic matter will likely burn. However, at lower intensities the intrinsic properties of fuel, like fuel moisture content or leaf dimensions, can strongly influence fire behaviour (Scarff and Westoby 2006; Plucinski and Anderson 2008). In a previous study we showed that intrinsic chemical and morphological properties of leaves had strong and differential effects on the ignitibility and sustainability of fire (Grootemaat *et al*., in review). Species with higher specific leaf area (SLA) and lower moisture content showed shorter ignition times. Leaf nitrogen (N), phosphorus (P) and tannin concentrations favoured the combustion process towards charring rather than tarring, thereby shortening the flame duration and prolonging the smouldering phase (Grootemaat *et al*., in review).
In fuel beds however, fuel bed density (g fuel per volume) and packing ratio (cm^3 fuel per volume) are strong drivers of fire spread (Scarff and Westoby 2006; Engber and Varner 2012; de Magalhães and Schwilk 2012; Van Altena *et al*. 2012). Based on principles of air-flow, more densely packed fuel beds are restricted in their oxygen supply and will therefore face difficulties with their combustion (Byram 1959; Drysdale 2011).
In this study we quantified the relative importance of leaf traits and packing on the sustainability, combustibility and consumability of fire burning through fuel beds. We examined if the same drivers were important for the "flammability" of a) individual leaves and b) fuel beds. Does the ranking in species' flammability differ between the two types of experimental set-ups? We expected that the physical configuration of the leaves would dominate over the "intrinsic' effects of leaf chemistry and morphology. We also expected that leaf size and "curliness" would be the main drivers of fuel bed density, with larger and curlier leaves forming more aerated fuel beds and therefore leading to a higher combustibility (i.e. higher rate of spread, or shorter flame residence time).

Methods

Experimental burns were performed on monospecific fuel beds consisting of dried green leaves from 25 perennial Australian species, a subset of those used in the previous experiments (Table S1). These species were sampled from four vegetation types in New South Wales, eastern Australia (details in Wright *et al*. 2001). The burning experiments were run at the FLARE Lab (Fire Laboratory of Amsterdam for Research in Ecology; VU University, The Netherlands). Fuel beds were burnt following standard procedures (Van Altena *et al*. 2012). In short, air-dried leaves were placed loosely in a steel mesh ring (25 cm in diameter, 3 cm high). The leaves were equally distributed over the ring until the ring was full, resulting in an equal volume of fuel for all replicates. Six thermocouples were positioned approximately 1 cm above the fuel bed. Samples were ignited by lighting a cotton disk injected with 1ml of ethanol (96%), which was placed in the middle of the ring. Different flammability parameters were measured (Table 1) and compared to the results from our previous study. Furthermore, the role of leaf traits (Table S2) for species' flammability was analysed.

Table 1. Overview of the measured flammability variables during the experimental burns (species' means). The first six variables were measured in the fuel bed rings; the last four (shaded) variables came from our previous work on flammability of individual leaves in a muffle furnace at 400°C

Variable	Description	Flammability component	Unit	Range
Ignition frequency	Percentage of replicates that truly ignited (with flames rather than smouldering)	Ignitibility	%	33.3-100
Maximum temperature	Mean maximum temperature for 5 sensors	Combustibility	°C	480-753
Total heat released	Area under the temperature*time curve	Combustibility	°C*min	200-2620
Rate of spread	Distance from the ignition point to the edge of the ring, divided by time to edge	Combustibility	cm/s	0.05-0.64
Burning time	Fire duration; time from ignition at a sensor until the fire dies out at that sensor (mean of 5 sensors, threshold used is 50°C)	Sustainability	s	61-1407
Fuel consumption	Percentage weight lost	Consumability	%	67-98
Time to ignition	Time from the insertion of a leaf into a muffle furnace (400°C) until the first visible flame	Ignitibility	s	1.1-7.0
Flame duration	Time from the first visible flame until no more flames could be seen	Sustainability	s	0.8-10.6
Smouldering duration	Time from the end of the last visible flame until the glowing phase died out	Sustainability	s	2.4-46.0
Total burning time	Sum of flame- and smouldering duration for individual leaves in a muffle furnace	Sustainability	s	3.2-56.7

Preliminary results

3.1. Which leaf traits are important for the flammability in fuel beds?

Fuel bed density (g/cm^3) was by far the most important driver for rate of spread ($R^2 = 0.81$, $p < 0.001$; Figure 1a). Fuel beds which were more densely packed (more mass per ring-volume), showed a slower spread of the fire. This can be understood as a simple "mass-effect", i.e. higher fuel loads require more time for combustion. On the other hand, the combustion process itself could have been limited by oxygen supply. When fuel beds were more densely packed there was less physical space for airflow, leading to partly incomplete combustion. Indeed we found that the mass of unburnt material was higher when the fuel bed density was higher ($R^2 = 0.29$, $p = 0.006$). Interspecific variation in fuel bed density itself was mostly driven by specific leaf area ($R^2 = 0.72$, $p < 0.001$) and leaf curliness ($R^2 = 0.61$, $p < 0.001$), and only to a lesser extent by leaf size (expressed as one side surface area, $R^2 = 0.19$, $p = 0.036$).

Specific leaf area (SLA) and leaf curliness also showed direct effects on the rate of spread (Figure 1b and c). Species with curlier leaves, and species with higher SLA, showed a higher rate of fire spread through the fuel bed. Most likely this is a side effect of the packing: curled leaves or species with higher SLA decreased the density of the fuel beds and therefore increased the rate of fire spread.

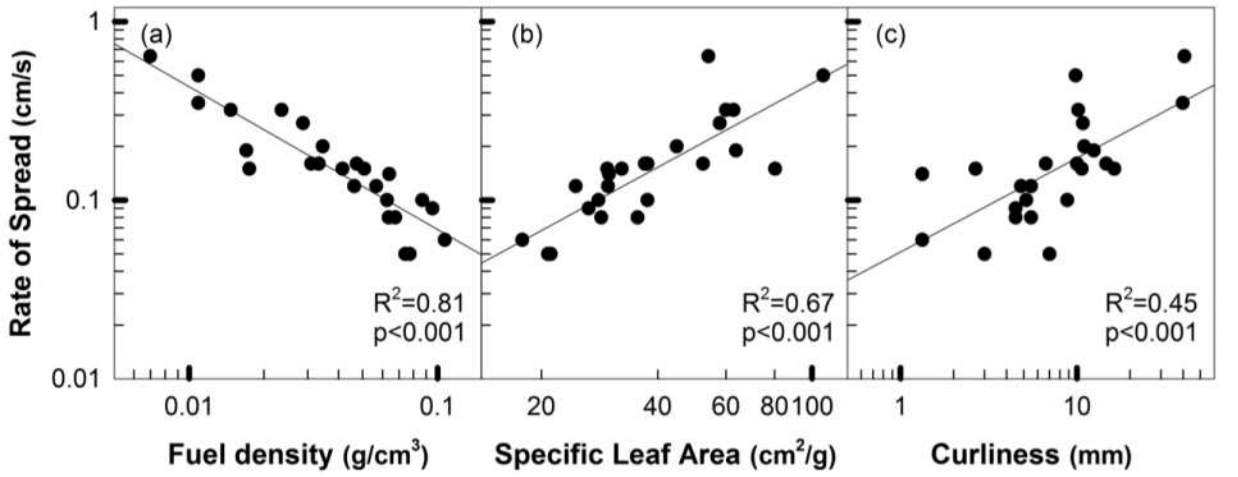

Figure 1. Bivariate relationships between "Rate of Spread" and (a) fuel bed density, (b) Specific Leaf Area and (c) leaf curliness. Each dot represents a species-mean. R^2- and p-values for the regression lines are given in the figure.

3.2. Does the ranking in species' flammability hold in two different experimental set-ups?

In contrast to our expectations we did not find a relationship between the fire-duration (total burning time) in individual leaves and the burning time in fuel beds. However, individual-leaf "time-to-ignition" showed clear relationships with four of the fuel bed fire parameters (Table 2). Most notably, the shorter the time-to-ignition of individually burnt leaves, the higher the rate of spread through the same species arranged in fuel beds ($R^2 = 0.59$, $p < 0.001$). Rate of spread can thus be seen as an accumulation of "ignition-steps".

In our previous study on individual leaves, interspecific variation in ignition times was strongly driven by specific leaf area ($R^2 = 0.70$, $p < 0.001$). Our results here suggest that SLA is the main driver of fuel density and consequently has a major influence of the combustibility in fuel beds. Leaf size and surface area per volume (SA:V) appeared to be less important than SLA.

Table 2. Intrinsic leaf flammability versus flammability in fuel beds. Only leaf intrinsic "time-to-ignition" showed significant relationships with (four out of five) fuel bed flammability parameters. The direction of the relation is expressed by "+" for positive relationships, and "-" for negative relationships; ns = not significant.

	Maximum Temperature (°C)	**Total Heat Released (°C*min)**	**Rate of Spread (cm/s)**	**Burning time (s)**	**Fuel consumption (%)**
Time To Ignition (s)	R^2 = 0.37 (+) p = 0.002	R^2 = 0.67 (+) p < 0.001	R^2 = 0.59 (-) p < 0.001	R^2 = 0.66 (+) p < 0.001	ns
Flame Duration (s)	ns	ns	ns	ns	ns
Smoulder Duration (s)	ns	ns	ns	ns	ns
Total Burning Time (s)	ns	ns	ns	ns	ns

Abstract
The paper addresses an experimental study of the flame speed and of spatial temperature distribution at various depths of the bed of pine needles of Siberian boreal forests, a study of the composition of gaseous species and distribution of their concentrations across the bed during fire spread and the study of the impact of the wind velocity on these characteristics. It has been found that, as the wind velocity rises in the range of 0.12 - 0.2 m/s, the burning regime changes dramatically, as well as the temperature and concentration profiles of gaseous species inside the bed. At low wind velocities, flame penetrates the bed, while at high ones it does not. At wind velocities 0.15 m/s and higher, as the wind velocity grows, together with the dramatic growth of the flame velocity the maximum temperature in the flame front in the middle of the bed decreases from 1200 °C to 600 °C , the width of the combustion zone increases, in accordance with the temperature and O_2 и CO_2 concentration measurements. The flame front in the middle of the bed is biased relative to the flame front on the bed surface The data obtained in the study may be used in developing a ground fire spread model.

Keywords*: pine needles;; fire spread across fuel bed; flame structure; forest fire*

Introduction

Propagation of a ground fire across a fuel forest (FF) bed is a frequently used model of a forest fire. Consideration of this model is also of practical importance, as it describes the general features of the mechanism of ground forest and steppe fires. There are many papers devoted to computer simulation of forest fire spread across a FF bed (Balbi 2007, Grishin 1997, Konev 1977, Lyons 1993, Morandini 2005, Morvan 2001, Porterie 2007, Simeoni 2003, Weber 1990). At the same time, there are unfairly few experimental studies of the process, measuring such parameters as the spread velocity, temperature and FF temperature profiles in a FF bed and outside it (Marcelli 2004, Morandini 2005, Santoni 2002, Simeoni 2003, Sukhinin 1975). The compositions of the pyrolysis and combustion products, their concentration and their profiles both in a FF bed and outside it have never been measured elsewhere. All these data, though, are required for verification of the assumptions made in certain models, by comparing the experimental data and the modeling data. Especially noteworthy are the studies of fire spread across a pine needles bed. In (Morandini 2005) temperature distribution was measured both in the gas phase and inside the bed of pine needles in still air and exposed to wind, the minimum velocity of which was 1 m/s. In (Sukhinin 1975) the same measurements were made in still air, while in (Marcelli 2004) temperature distribution was measured only over a bed of pine needles in still air. In (Morandini 2005) it was found that the minimum temperature approximately in the middle of the bed 2.3. cm thick reaches the value of 1,000 – 1,100 ° C. It is interesting that the maximum temperature

measured with a thermocouple placed over the FF bed surface at the distance of 4 cm from it was about the same. We can suppose diffusion combustion of each needle in the bed to take place. Similar results under similar conditions were obtained in (Sukhinin 1975). In this study, the temperature profile was measured for a pine needle located on the bed surface with a thermocouple embedded inside a needle. The maximum temperature of a needle reached 800 °C. The flame spread velocity across the needles bed was approximately equal to 3 mm/s. It is to be noted that in the above studies temperature profiles of the needles at different distances from the bed surface inside it were mot measured. We did not find the papers in literature which would be devoted to the composition of gaseous products and their concentration distribution in the FF bed. Therefore one of the objectives of the study was to measure under laboratory conditions the temperature profiles inside of the bed of needles of the Siberian boreal forests (SBF), to study the composition of the gaseous products and distribution of their concentrations inside the bed during flame spread across the bed and to investigate the impact of the wind velocity on these characteristics.

Methods

Materials

The materials were the pine needles from SBF. The pine needles litter was sampled from under trees in a pine forest, then leaves and twigs were removed from it, with only litter needles left. The needles thus obtained were dried at the temperature of 60 °C during 24 hours in a drying cabinet. Weight loss after drying was 7.8-9.4 %. The average length of a pine needle was 5 mm, it was 1 mm wide and 0.6 mm thick. Specific surface area was determined using the BET method. It was 0.18 m^2/g.

Measuring the flame spread velocity across the pine needles bed depending on the wind velocity

The experiments were conducted in a chamber (Fig.1.) with the dimension of 70 cm/15 cm/30 cm. A photo of setup is presented in Fig.2. Placed inside the chamber a tray with a bed of pine needles 8 cm wide and 34 cm long. A photo of a tray with a bed of pine needles is presented in Fig.3. The amount of the pine needles was 0.07 g/cm^2. The needles were placed on an asbestos board plate 10 mm thick into a space restricted by fire-clay plates, 17 mm high. The layer porosity was 0.928.

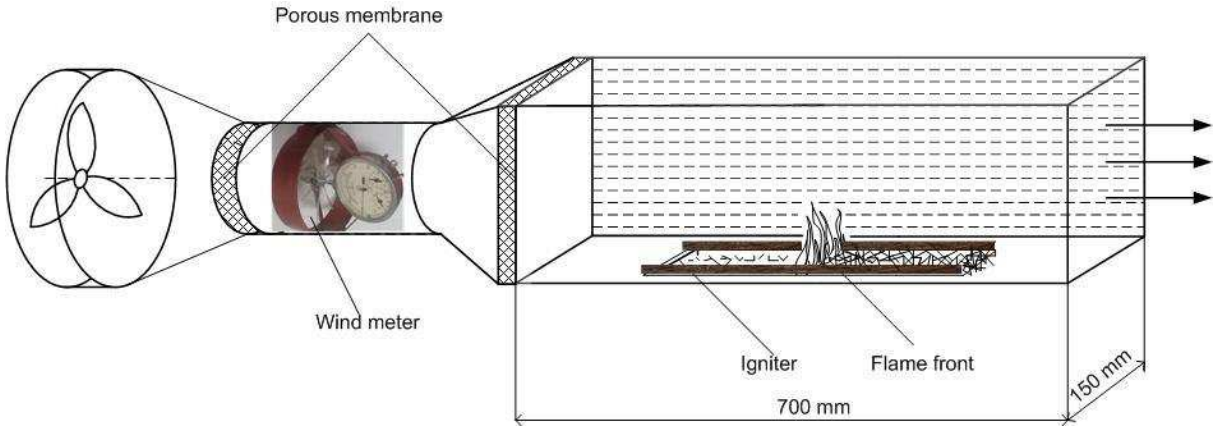

Figure 1- Experimental chamber for measuring the flame spread velocity across pine needles bed

Air was blown into the chamber from an air blower the capacity of 0.11 m^3/s. The wind velocity varied from 0 to 0.5 m/s. The air penetrated a porous filter to generate uniform flow. The air flow velocity was measured with a calibrated anemometer. The error in determining the average wind velocity was ±5%. The pine needles were ignited by a nichrome wire heated by electric current and a nearby glass

wool bundle, impregnated with 1 ml ethanol. To avoid wire sagging during heating, it was mounted with a spring. The flame spread velocity was determined by signals from three thermocouples placed along the pine needles bed near its surface and from a video recording of the burning process. Variance in measuring the velocity of flame spread across a pine needles bed is ± 15%.

Figure 2. Experimental setup for measuring the flame spread velocity across pine needles bed

Figure 3. A photo of a tray with a bed of pine needles

2.3. Measuring the temperature profiles and the composition of the gaseous products on the bed surface and inside the bed exposed to flame spread

The temperature profiles and the composition of the gaseous products on the bed surface and inside the bed were measured with two Π-shaped Pt-Pt 10% Rh thermocouples 50μm in diameter. The junction of one thermocouple (T1) was in the middle of the bed at the 13.2 cm distance from the igniter,

the junction of the other one (T2) was on the bed surface at the 12 cm distance from the igniter. The photo of the thermocouples location is shown in Figure 4.

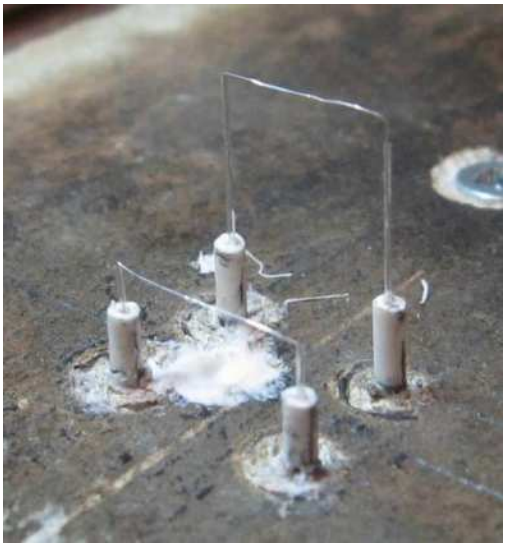

Figure 4. A photo of thermocouples location

To measure the temperature, a multichannel AD converter E14-140-M ("L-Card") was used. The measurement error of thermal EMF was ±0.5%. The temperature measurements were conducted at the frequency of 1 kHz. The thermocouples' signals were shown on the computer.
The composition of the pine needles pyrolysis products was measured by the probe mass spectrometry method. As a sampling probe, a pyrex tube was used with an internal diameter of 1.5 mm, embedded in the middle of the bed at a 18.8 cm distance from the igniter. The sample taken from the flame was cleaned from fine aerosol particles and tar and was delivered to the molecular beam system of the Hiden HPR-60 mass spectrometer. The response time of the sampling system was 2-2.5 sec, which is comparable with the time of recording one mass spectrum. Concentrations of O_2, CO_2, N_2, C_2H_5OH (ethanol), C_3H_6O (acetone), C_4H_4O (furan) in the sample studied were determined by the mass peak intensities with m/e 32, 44, 28, 31, 15 and 43, 68, accordingly. Sensitivity of the mass-spectrometer was determined by the calibration mixtures of the known composition. The ignition time and the starting time of the mass spectrometric measurements were synchronized. The dependences of mass peak intensities were measured, corresponding to the compounds chosen, as a function of time. Considering the measured average flame spread velocity across the pine needles bed, the dependences of temperature and species concentrations on time were recalculated into the respective dependences of temperature and species concentrations on the horizontal coordinate relative to the flame front.

3. Results

3.1. Dependence of the flame spread velocity across the bed of pine needles on the wind velocity

It can be seen from Figure 5, showing the results of measuring the dependence of the flame spread velocity on the wind velocity, that, as the wind velocity grows from 0 to 0.12 m/s, the flame spread velocity varies little, while with the change in the wind velocity from 0.12 m/s to 0.2 m/s, it almost triples. With the wind velocity of 0.15 - 0.2 m/s and higher, the regime of flame spread changes critically. As the wind velocity increases from 0.15 to 0.2 m/s the flame speed dramatically increases to 6 mm/s. Simultaneously, as seen from Fig.5, the temperature in the middle of the bed dramatically drops from 1200 до 600ºC. With the wind velocity higher than 0.2 m/s, probably comparable with the velocity of the pyrolysis products rise, the angle of flame slope to the horizon dramatically decreases

(with the wind velocity of 0.1 m/s, it would be close to 90 degrees), the flame seems to lie down on the pine needles layer (Figure 6).

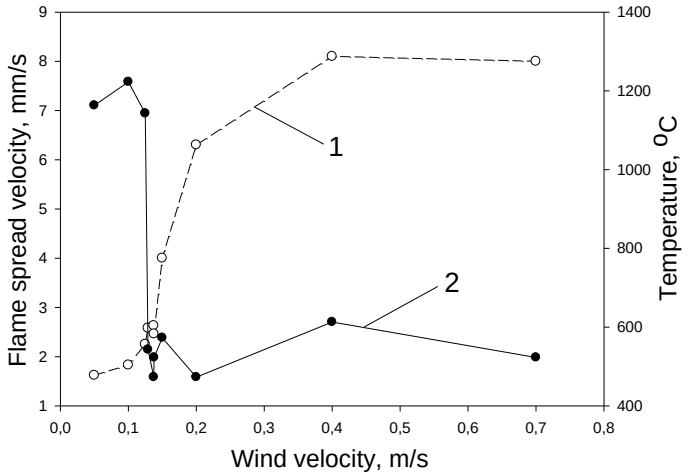

Figure 5. Dependences of the velocity of flame spread across the pine needles bed (1) and temperature in the middle of the bed (2) on the wind velocity

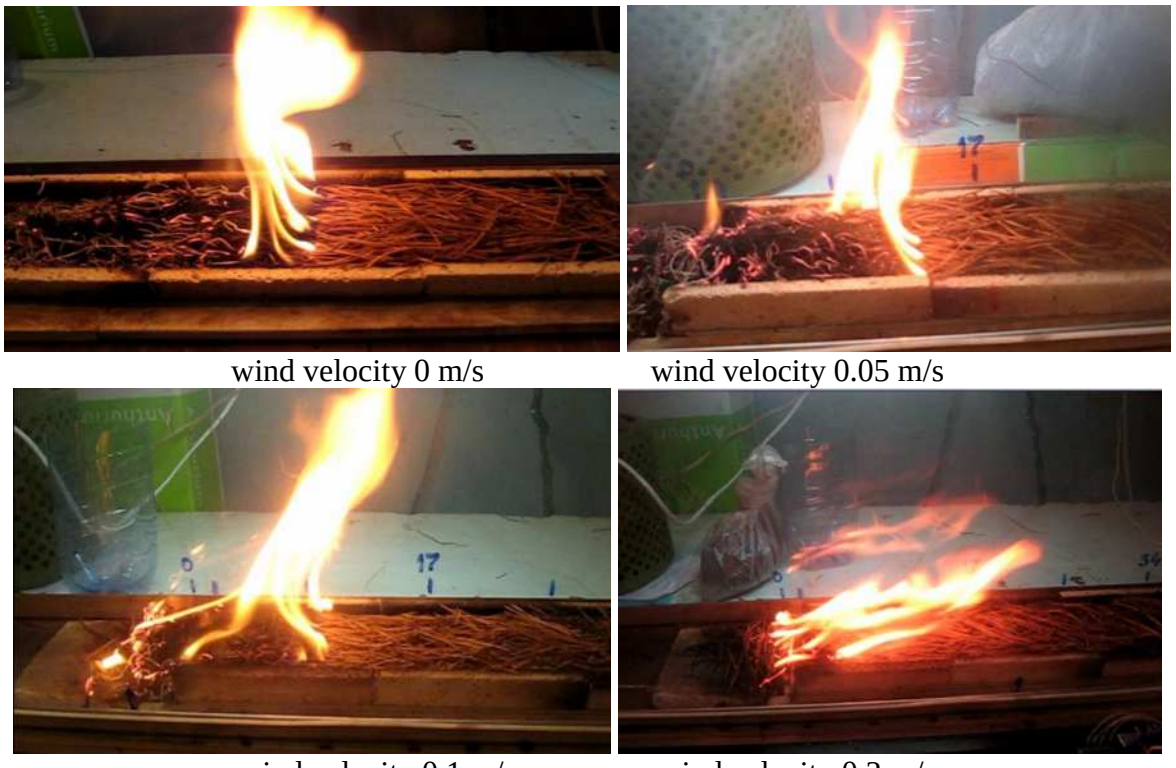

Figure 6. The photos of flame spread across a bed of pine needles depending on the wind velocity in the range from 0 to 0.2 m/s.

3.2. Temperature profiles and concentration profiles of O_2, CO_2 and volatile pyrolysis products in flame spread across a pine needles bed

Shown in the Figure 7 are the temperature profiles in the middle of the bed (T1) and on the surface (T2), considering the fact that the distance between the thermocouples was 11.8 mm, and the concentration profiles of CO_2, O_2 and ethanol inside the bed with the wind velocity of 0.1 m/s. The flame spread velocity is 2.05 mm/s. Analysis of the temperature profiles allows the following conclusions to be made:

1. Flame penetrates into the pine needles bed. The maximum temperature in the middle of the bed is 1300 °C. These data are in good agreement with the data of (Morandini 2005, Sukhinin 1975), obtained for conditions close to those of this study.
2. The flame front in the middle of the bed is 1.2 cm shifted relative to the flame front on the bed surface.
3. The width of the flame zone determined by the T2 profile is 7 cm. The width of the glowing (high temperature) zone is 1.2 cm on the bed surface (which agrees with the video recording data) and 0.9 cm in the middle of the bed.
4. Although combustion behind the flame front on the bed surface finishes at the 7 cm distance from the flame front, the temperature in this place in the middle of the bed is higher than on the bed surface, indicating continuing reactions inside the bed.

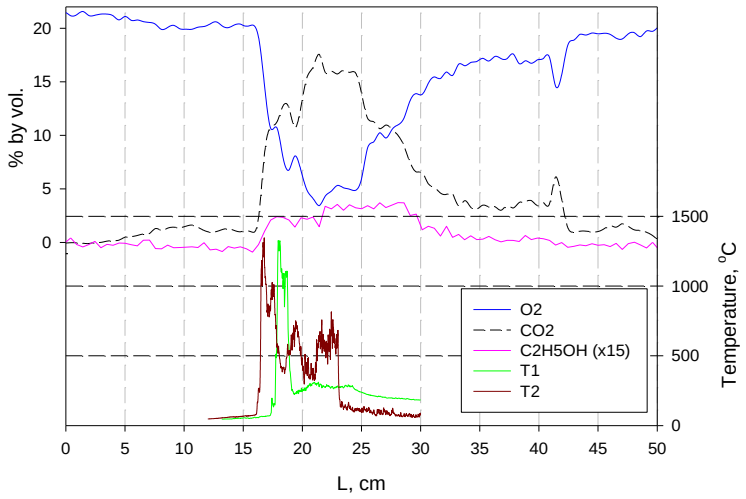

Figure 7. Temperature profiles in the middle of the pine needles bed (T1) and on the surface (T2), as well as CO_2, O2 and ethanol concentrations inside the bed, with the wind velocity of 0.1 m/s.

Thus, it follows from the results of mass spectrometric studies that:

1. As the flame front advances, O_2 concentration in the middle of the pine needles bed decreases to 4-5 %, while the maximum CO_2 concentration is reached at the distances from 6 to 9 cm from the flame front and is equal to 15-17 %. The width of the flame front determined from the O_2 и CO_2 concentration profiles is equal to 6 cm, which is close to the value of 7 cm, obtained from the data of the temperature profiles (T2). Thus, O_2 concentration in the middle of the bed does not decrease to zero. Oxygen may penetrate the bed due to diffusion and gas transfer along the bed. At the distances from the flame front greater than 9 cm, CO_2 concentration gradually decreases, while O_2 concentration goes up.
2. Maximum concentrations of two major volatile products of pine needles pyrolysis ethanol and acetone in the middle of the bed are 0.2 and 0.4-0.9 %, respectively. The width of the yield zone of the main volatile pyrolysis products is 12-13 cm. When the distances from the flame front are greater than this value, char smolders in the middle of the bed.

Similar facts are observed for the wind velocity of 0.05 m/s and in the absence of wind. However, with the wind velocity of 0.2 m/s and higher, the regime of flame spread changes critically. With the wind velocity higher than 0.2 m/s, probably comparable with the velocity of the pyrolysis products rise, the angle of flame slope to the horizon dramatically decreases. Due to this, the width of the heated zone

before the flame front expands and the front zone expands, too, which is confirmed by the temperature profiles and species concentrations in the pine needles bed at the wind velocity of 0.2 m/s shown in Figure 8.

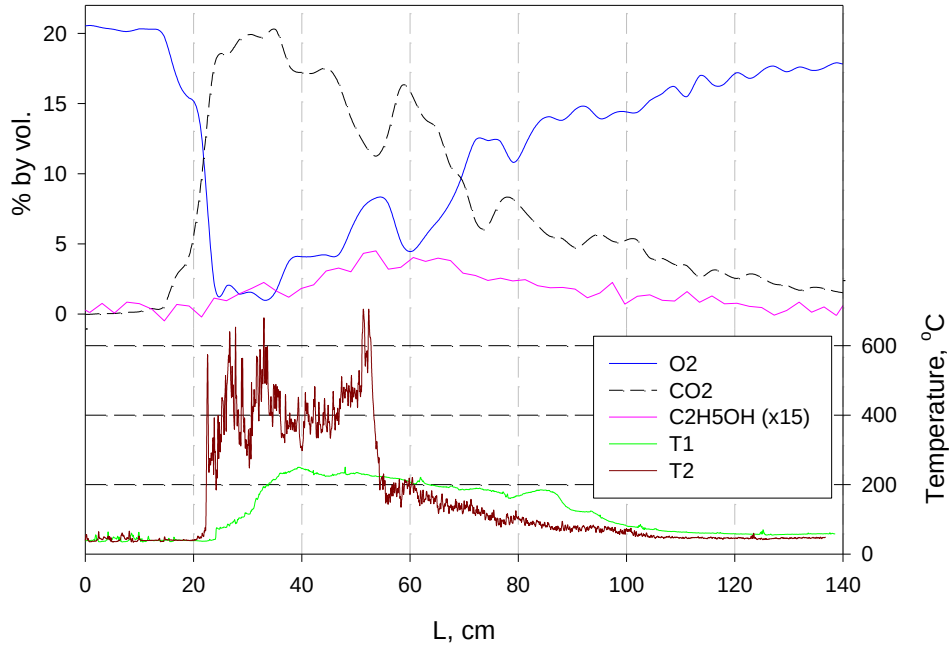

Figure 8. Temperature profiles in the middle of the pine needles bed (T1) and on the surface (T2), as well as CO_2, O_2 and ethanol concentrations inside the bed, with the wind velocity of 0.2 m/s.

It can be seen that the maximum temperature near the bed surface drops to 700 °C, evidently among other factors due to dilution of the combustion and pyrolysis products with air, while in the middle of the bed it drops to 230°C. The flame front width near the bed surface with the temperature 600-700°C increases several times due to the drop of temperature and therefore of the pyrolysis rates to become about 30 cm.

Conclusion

1. First changing the regime of flame spread across a bed of pine needles was found for changing wind velocity. It has been observed that in flame spread across a bed of pine needles there emerges a complex spatial distribution of temperatures and species concentrations, which depends on the wind velocity. The character of combustion essentially changes as the wind velocity changes from one range (0-0.12 m/s) to the other one (0.12 - 0.2 m/s). In the first range of wind velocities, the flame spread velocity is only slightly dependent on the wind velocity, while in the second range the dependence significantly increases. At low wind velocities flame penetrates the bed of pine needles, while at high wind velocities this does not occur. At wind velocities 0.12 m/s and higher, at the wind velocity grows, together with the growth of the flame velocity the maximum temperature in the flame front decreases from 1200 °C and 700 °C , the width of the flame zone, in accordance with the temperature and O_2 и CO_2 concentration measurements. The flame front in the middle of the bed is shifted relative to the flame front on the bed surface.
2. The experimental data on the dependence of the flame spread velocity across the bed of pine needles on the wind velocity obtained in the study and on the flame front structure (distribution of temperature and concentrations of gaseous species inside the bed) may be used in developing a model of ground fire spread.

Abstract
Fire-atmosphere interactions can occur at spatial scales on the order of tens of meters at the fire front and to kilometers in plumes during large fires. However, few studies have focused on the observed turbulence structure in the immediate environment of propagating fires to further understand the relative importance of ambient and fire-induced turbulence on fire front propagation. In this study, turbulence structures during the passage of fire fronts were investigated using the data obtained from two field experiments. One fire was conducted over grass fuel under strong ambient mean winds and the other conducted in a forest sub-canopy environment under light ambient winds. The main objective of this research is to investigate scale-averaged variances over different fuels before, during, and after the fire front passage in relation to different fire intensities and atmospheric conditions. Time series data from in-situ sonic anemometer arrays are analyzed using wavelet signal processing to treat non-stationary process of the fire front passage. Only a small increase in u variance over the 2-4 s band was found during the fire front passage in the grass fire environment under the strong mean winds. The variance associated with low intensity sub-canopy fire was found to increase over 2-4 s and 8-16 s bands, due to intermittent convective smoke plume pulses of the low intensity sub-canopy fire.

Keywords*: Fire-induced wind, Fire-atmosphere interaction, Grass fire, Sub-canopy fire*

Introduction

Turbulent kinetic energy (TKE) is produced in the energy containing range and transported from large to small scales without the energy production or dissipation in the inertial subrange, and it is eventually converted to internal energy in the dissipation range. Turbulent eddy motion in these three regions is well recognized in the atmospheric boundary layer. However, because dynamical coupling of the wildfire and atmosphere (Clark *et al*. 1996) may occur over a very wide range of length and time scales depending upon fire intensity and the atmospheric conditions, it is questionable whether the traditional turbulence theory holds in wildfire environments where the atmosphere becomes highly unstable given extremely high flame temperatures and large sensible heat flux, particularly near the surface.
Sun *et al*. (2009) showed that a strong downdraft caused by an interaction between the fire-induced plume circulation and a strong eddy circulation in the ABL can bring down higher momentum from aloft to the surface and increase the rate of fire spread, especially for a large fire. Downdrafts have been observed during fast spreading grassfires (Clements *et al*. 2007). Seto *et al*. (2014) showed that despite lower plume temperatures low-intensity sub-canopy fires may potentially be able to generate nearly as strong fire-induced winds as wind-driven grass fires under favorable fuel conditions due to strong coupling between fire and atmosphere.
Initial analyses of turbulence spectra during fire front passage revealed that fire can influence the energy of the flow and turbulence over a wide frequency range (Seto *et al*. 2013). Although four datasets that were representative of various fuels and terrain were analyzed in the study, more experimental datasets are now available with better horizontal and vertical coverage of turbulence

measurements. Additionally, the study only addressed qualitative aspect of the spectral energy in the spectral regions, and further investigation of TKE generation and dissipation processes during fire events are essential to corroborate the previous findings.
This paper examines the turbulence structures in fire environments during grass fire and sub-canopy fire experiments.

Experimental designs

FireFlux II, a comprehensive grassfire experiment, was conducted on 30 January 2013 at the University of Houston Coastal Center in Texas, USA and was designed with a head fire being allowed to burn directly underneath a 42-m and three 10-m micrometeorological towers (Figure 2). The fuels consist of a mixture of native grasses, including big bluestem (Andropogon gerardi), little bluestem (Schizachyrium scoparium), and long spike tridens (Tridens strictus). Each tower was equipped with multiple 3D sonic anemometers (20 m, 10 m, and 6 m AGL. The experiment was carried out with a head fire ignition under red flag warning conditions (Clements *et al*. this issue).
Three low-intensity prescribed burns were conducted during the late winter and early spring (February and March) of 2010 and 2011 at The Nature Conservancy's (TNC) Calloway Forest/Sandhills Preserve in North Carolina, USA (Figure 1). A majority of the surface fuels were in the 1-hr (defined as ¼ of an inch or less in diameter) size classification and consisted of long leaf pine litter, both cured and live wiregrass (*Aristida stricta*), American turkey oak (*Quercus laevis*), and regeneration long leaf pine. The mean tree height (h_c) was 20 m. The soil was sandy with little to no organic matter beyond the surface duff layer. In this study, turbulence data collected at a 20-m in-situ tower in 2011 was used for the analysis. The tower was equipped with multiple 3D sonic anemometers at 20 m, 10 m, and 3 m AGL. Backing and strip fire ignitions were employed during the experiment although blackline and strip head fire were also ignited around the tower. Fire propagation was limited to ground fuels. Hereafter, the two experiments discussed above are mentioned as FF2 and NC.

3. Data Processing

Streamwise and vertical velocity wavelet power spectra were computed using a continuous wavelet transform (complex Morlet) following Torrence and Compo (1998). Wavelet transforms are mathematical techniques based on group theory and square integrable representation and they use an analysing function called wavelets, which are localized in space, to decompose signals into space and scale (see Farge, 1992 for details). To examine fluctuations in local power over a range of scales, time series of scale-averaged wavelet power is presented in this study. Three wavelet scales were selected: 2-4 s, 8-16 s, and 32-64 s periods. The velocity data were averaged over 1 s before calculating the wavelet power.

Data Analysis and Discussion

4.1. Time series of averaged variances observed during FF2

Observed streamwise velocities *u* at three measurement heights in Figure 1a showed similar magnitudes to those observed before the fire front passage under a strong ambient wind of 9 m s^{-1} observed prior to the ignition (14:30-15:00 CST). Measured 1 Hz peak vertical velocities of 6 m s^{-1} at 6 m AGL and 9 m s^{-1} at 20 m AGL accompanied with a maximum plume temperature of 200°C observed at 6 m AGL compare well with the observations made at the same site under lighter ambient winds (Clements *et al*. 2007). However, a period of downdraft that was observed in Clements *et al*. did not occur during the FF2 due to the strong horizontal winds that are unfavourable for fire-induced circulations (Jenkins *et al*. 2001).

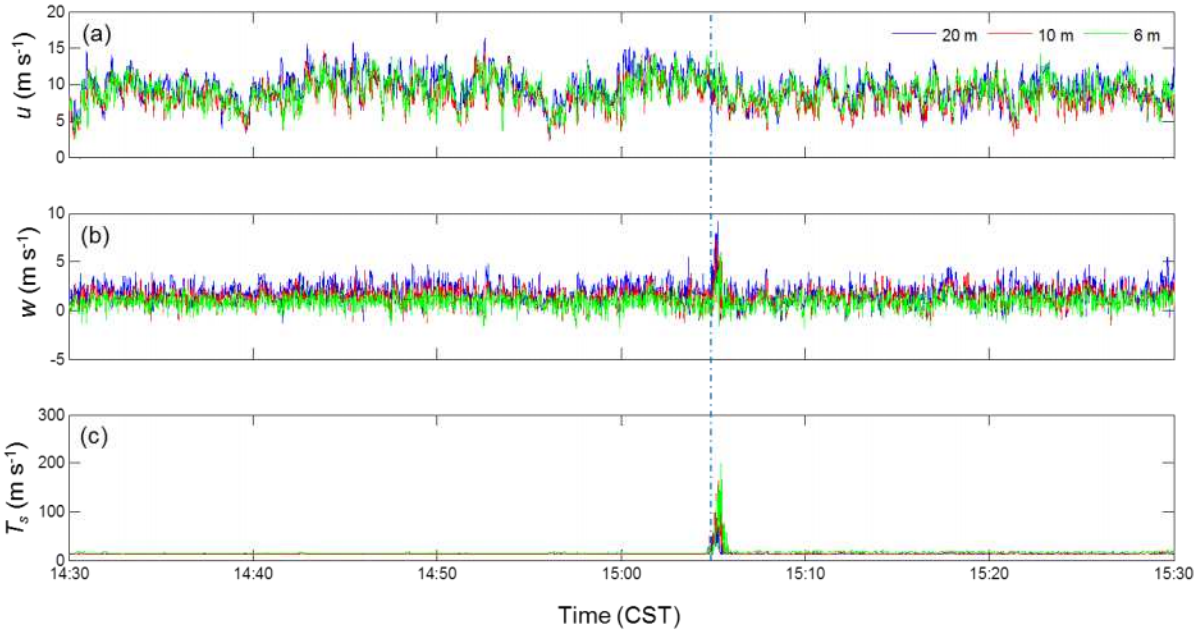

Figure 1. (a) streamwise velocity u, (b) vertical velocity w, and (c) sonic temperature T_s observed at the tower during FF2 experiment. Ignition was made at 15:04:08 CST, and fire front reached the tower around 15:05 CST as indicated by the sonic temperature spikes. Blue dashed line indicates the timing of the fire front arrival at the tower.

Figure 2 shows the *u* wavelet power averaged over three different scales/frequency bands, which give a measure of the scale-averaged variance in a certain band. Increased wavelet power over 2-4 s at 20 m, 10 m, and 6 m AGL at the time of the fire front passage suggests fire generated small-scale turbulence (2-4 s band) within the plume, where the strong updrafts were present. For larger scales than the 2-4 s band, the wavelet power remained below the ambient level over the fire, which suggest no major influence of the fire on the turbulence field for the scales (frequency) larger than 8 s (below 0.1 Hz). The strong mean winds were responsible for the large turbulent energy generation over the 8-16 s and 32-64 s scales on the background turbulence. The results indicate that fire-induced turbulence at larger scales may be supressed in the mean wind direction when the ambient winds are stronger than the fire's convection, and only smaller eddies, perhaps related to the entraining motions of the smoke plume, were enhanced by the fire.

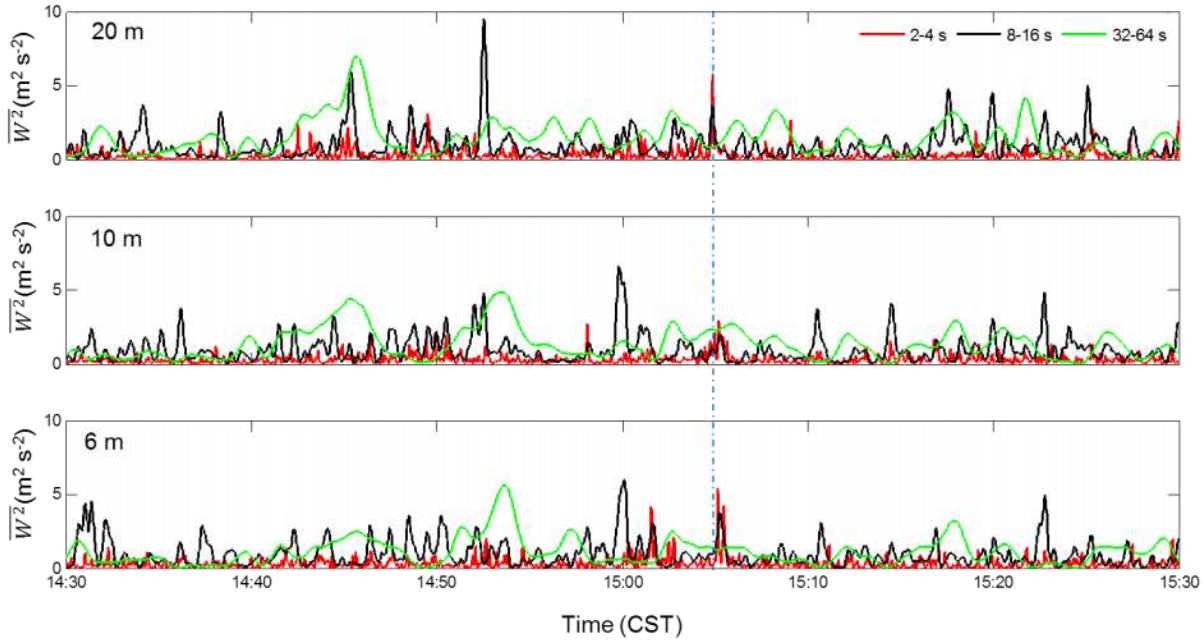

Figure 2. Scale-averaged wavelet power W^2 over the 2-4 s (red line), 8-16 s (black), and 32-64 s (green) bands for the u velocities measured at the main tower during the FF2. Blue dashed line indicates the timing of the fire front arrival at the tower.

The vertical velocity wavelet power shown in Figure 3 is well characterized by the large increases in 2-4 s scale variances at all three measurement heights. The magnitudes of their power were much larger than the variances at larger scales. The fire's strong buoyancy generates turbulence in the vertical direction that is much smaller in scale than the atmospheric turbulence generated within the boundary layer.

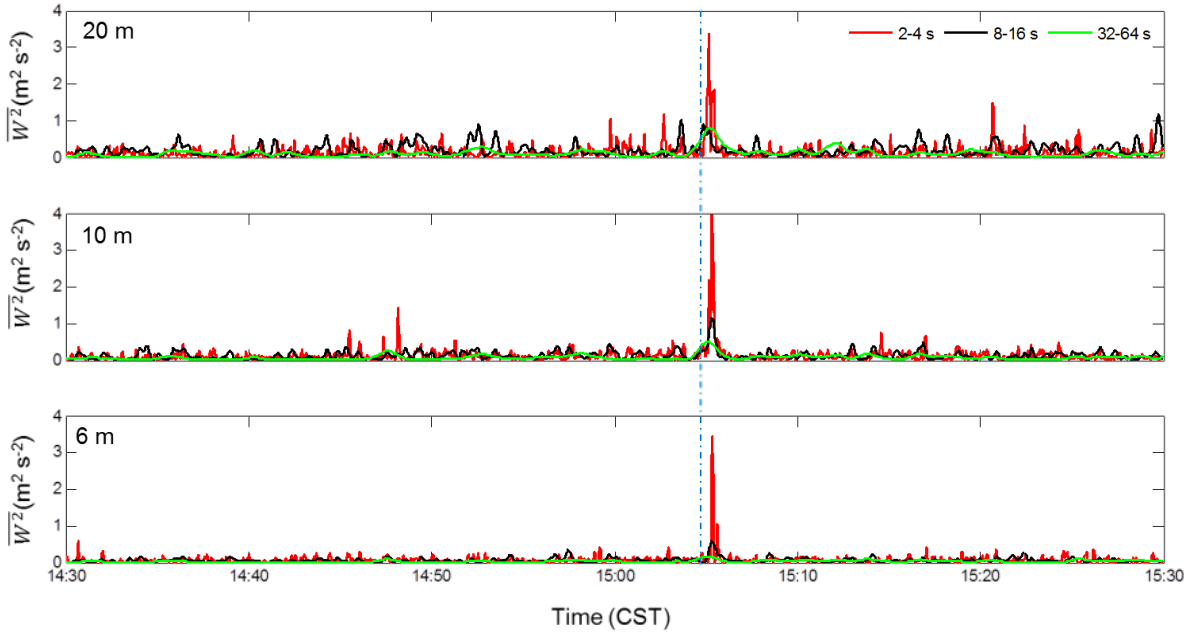

Figure 3. Scale-averaged wavelet power W^2 over the 2-4 s (red line), 8-16 s (black), and 32-64 s (green) bands for the w velocities measured at the main tower during the FF2. Blue dashed line indicates the timing of the fire front arrival at the tower.

4.2. Time series of averaged variances observed during NC

The steamwise velocity *u* at the canopy top (20 m AGL) shows larger fluctuations than those within the canopy (10 m and 3 m AGL) before and after the fire front passage, as indicated by high sonic temperatures near 100°C (Figure 4), due to the momentum absorption by the canopy layer. A head fire at 16:16 EST resulted in increased *u* velocities within the canopy and increased vertical motions at all three heights.

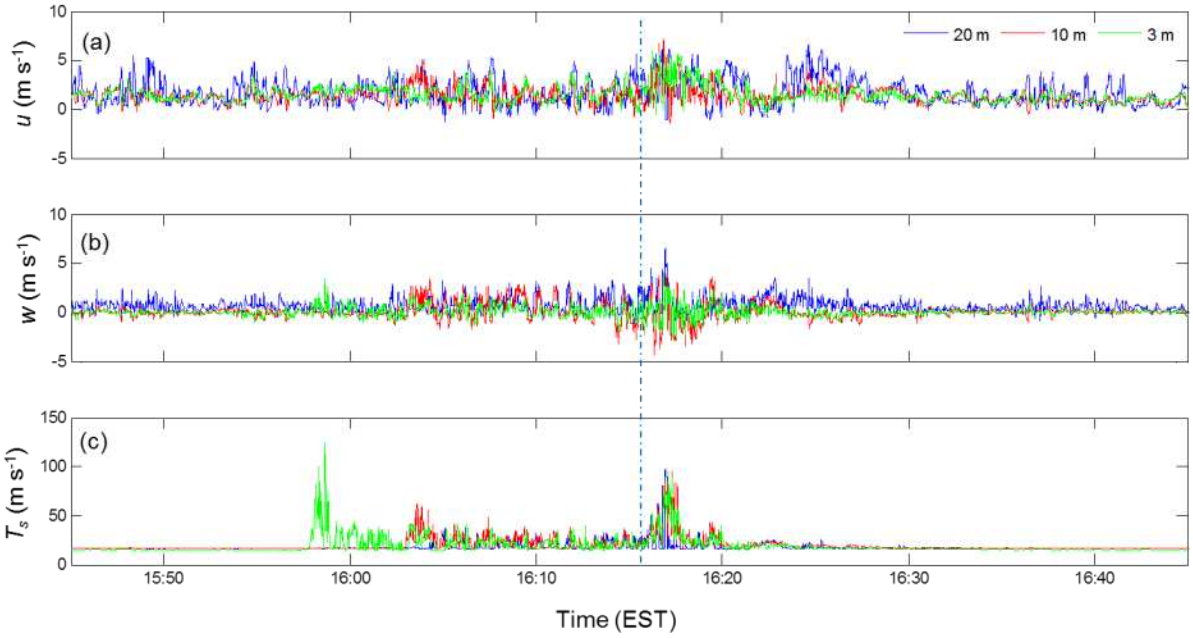

Figure 4. (a) streamwise velocity u, (b) vertical velocity w, and (c) sonic temperature T_s observed during NC experiment. Ignition was made at 11:04:08 EST. Blue dashed line indicates the timing of the fire front arrival at the tower.

The head fire at 16:16 EST was associated with increased *u* variances over the 2-4 s and 8-16 s bands both within and at the top of the canopy as compared to those observed prior to the head fire. It indicates that the turbulence structure within the plume was similar with height up to 20 m AGL. A coherent structure in the 32-64 s band variance may suggest turbulent mixing during the fire although the magnitudes of the variances observed within the canopy were still smaller than the ambient variance above the canopy. The increased wavelet variances within the canopy due to the fire were still smaller than the turbulence observed above the canopy, which indicates relatively weak turbulence generation from the low-intensity fire in the *u* direction.

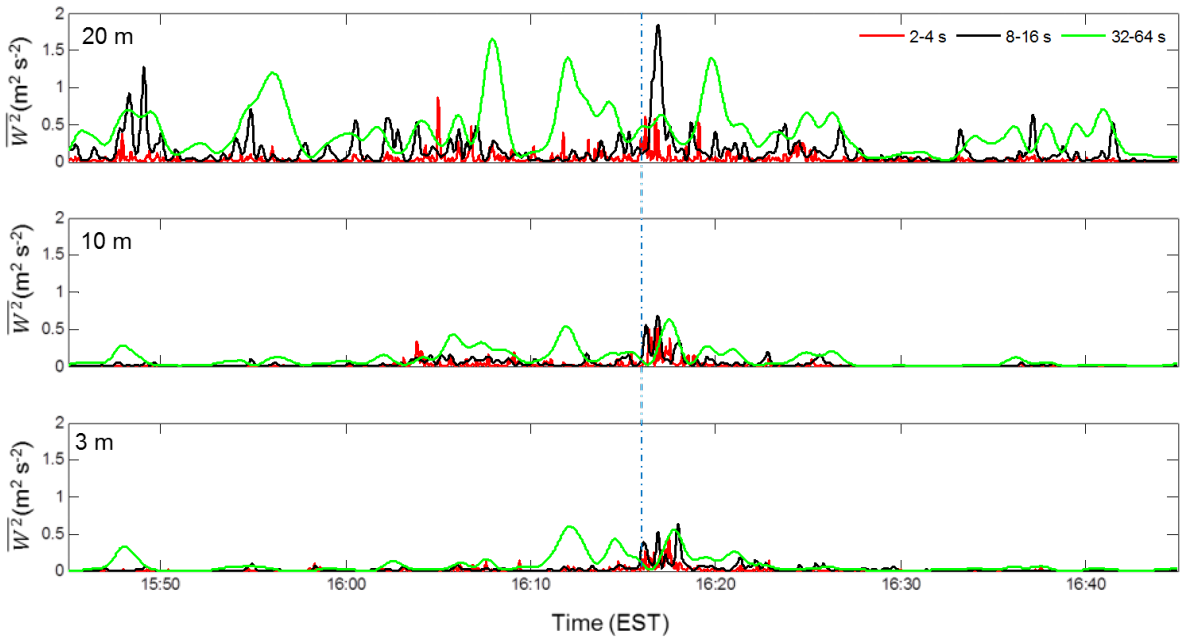

Figure 5. Scale-averaged wavelet power W^2 over the 2-4 s (red line), 8-16 s (black), and 32-64 s (green) bands for the u velocities measured at the main tower during the NC. Blue dashed line indicates the timing of the fire front arrival at the tower.

The vertical velocity variance at the canopy top was dominated by the 8-16 s band with a decreasing trend towards the ground. The *w* wavelet power over the 8-16 s band also shows a large spike similar to the *u* velocity component.

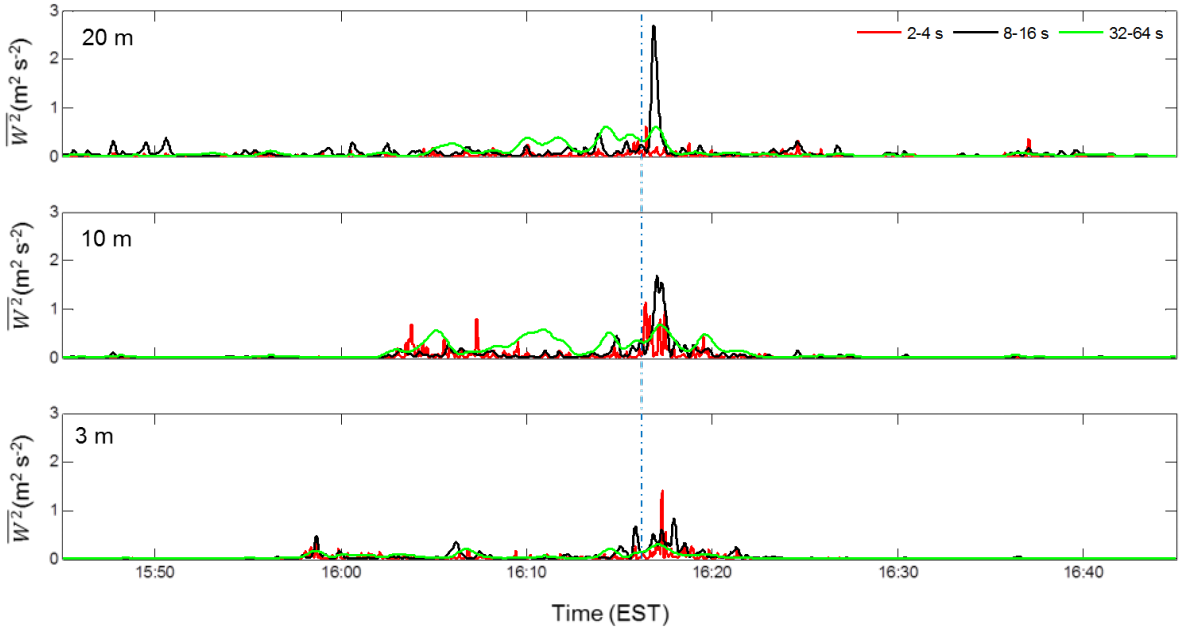

Figure 6. Scale-averaged wavelet power W^2 over the 2-4 s (red line), 8-16 s (black), and 32-64 s (green) bands for the w velocities measured at the main tower during the NC. Blue dashed line indicates the timing of the fire front arrival at the tower.

4.3. Comparisons between the two fires

The turbulence generated by the grass fire showed an increase limited primarily to the smaller (2-4 s) scale turbulence, whereas the sub-canopy fire contained slightly larger scale (8-16 s) turbulence structures. This may be associated intermittent convective smoke plume pulses of the low intensity sub-canopy fire. The magnitudes of the 2-4 s variances induced by the grass fire were 3 to 5 times larger in magnitude than those generated by the low intensity sub-canopy fire. The turbulence structure before and after the fire front passage did not show changes in the velocity spectral behaviour for the two fires under the observed conditions.

Conclusions

Turbulence structures in two experimental fires were examined using a continuous wavelet signal processing for a grass fire under strong ambient winds and a forest sub-canopy fire under light ambient winds. Only a small increase in u variance over the 2-4 s band was found during the fire front passage in the grass fire environment under the strong mean winds. The variance associated with low intensity sub-canopy fire was found to increase over 2-4 s and 8-16 s bands, due to the lower frequency smoke plume pulses. The turbulence structure before and after the fire front passage did not show changes in the velocity spectral behaviour for the two fires for the given conditions. Further analyses will include temperature variances and its relationship with the observed velocity variance signals.

Abstract
This paper highlights the results obtained from a comprehensive survey recently published by the authors on the error statistics associated with studies that have used independent data derived from field observations of wildfires, prescribed fires and experimental fires to evaluate the performance of 13 models used operationally to predict head fire rate of spread. Answers to the following kinds of questions were sought:

- How accurately can one expect to predict the spread rate of wildland fires with currently available models?
- Can models based on experimental fire data be used to predict wildfire behaviour?
- Are wildfires inherently more difficult to predict the spread rates of than prescribed fires or crown fires compared to surface fires?
- How realistic is it to expect an exact prediction of rate of fire spread?
- What is an acceptable error for rate of fire spread models?

A total of 49 studies, comprising 1278 paired observations vs. model predictions of fire spread rates for four forest fuel types (hardwood, mixedwood, conifer, eucalypt) and three non-canopied fuel types (grassland, shrubland, logging slash) from four continents (North America, Australia, Europe, Africa) were assembled. The answers to the five questions asked above are as follows:

- Mean absolute percent error varied between 20 and 310% and was homogeneous across fuel type groups. Slightly more than half of the evaluation datasets had mean absolute percent errors between 51 and 75 percent. Under-prediction bias was prevalent in 75 percent of the case 49 datasets analysed.
- Empirical-based fire spread rate models founded on solid field observations and well accepted functional forms, can adequately predict rates of fire spread well outside of the bounds of the data used in their development.
- There was no evidence to be found that predicting the rates of spread of wildfires was any more difficult than that of prescribed fires. Spread rates of crown fires were no more difficult to predict that surface fires.
- Only three percent (i.e. 35 out of 1278) of model predictions were considered to be exact (i.e. ±2.5 percent of the observed rate of fire spread).
- A ±35 percent error interval constitutes a reasonable standard for model adequacy.

Keywords*: fire spread models; fire behaviour; error; surface fires; crown fires; wildfires; prescribed fires.*

Introduction

There are a variety of aspects associated with the subject of wildland fire behaviour (Scott *et al.* 2014) and reasons to increase our knowledge on the subject through continuing research and improvements in operational practice (Cruz *et al.* 2014a,b). However, if one could boil down the whole science of wildland fire behaviour to its most practical essence, it might very well be to provide fire operations personnel with a decent estimate of just how fast a free-burning fire (Figure 1), either of planned or of unplanned origin, would likely spread based on the prevailing fire environment conditions (Van Wagner 1985).

This paper highlights the study undertaken by Cruz and Alexander (2013) that addressed the following kinds of questions:

- How accurately can one expect to predict the spread rate of wildland fires with currently available models?
- Can models based on experimental fire data be used to predict wildfire behaviour?
- Are wildfires inherently more difficult to predict than prescribed fires or crown fires compared to surface fires?
- How realistic is it to expect an exact prediction of rate of fire spread?
- What is an acceptable error for fire spread models?

It is fully recognized that the degree of accuracy in model predictions of rate of spread in wildland fires is dependent on the model's applicability to a given situation, the validity of the model's relationships, and the reliability of the model input data (Alexander and Cruz 2013b).

Figure 1. Photo of the Millers Reach #2 Fire near Anchorage, Alaska, during its major run on June 3, 1996 that involved extensive crowning in black spruce forests. Photo by: Anne Raup, Anchorage Daily News. For further information on this wildfire, see Hufford et al. (1998).

Methods

2.1. Compilation of datasets

In order to address the questions poised in the Introduction, a comprehensive effort was made to locate as many evaluation studies of rate of fire spread rate model performance in the literature as possible. The sources included:

- Scientific peer-reviewed journal articles
- Conference and workshop papers
- Technical reports from government agencies
- Post-graduate university theses

The principal requirements for inclusion in the analyses were that the evaluation data be (i) collected on outdoor experimental fires, operational prescribed fires and (or) wildfires, involving a "line fire" pattern similar to that observed on the head of a free-burning wildfire (Figure 1), as opposed to strip-head fires or point-source fire(s) (e.g. Sapsis and Kauffman 1991; Jupen *et al.* 2013) and (ii) that the dataset could not have been used in the model development (i.e. completely independent observational data) as Albini and Stocks (1986) did in their analysis. For example, Cruz *et al.* (2005) used the datasets of Alexander *et al.* 1991, Stocks *et al.* (2004) and Alexander *et al.* (2006) to test their crown fire rate of spread model.

Experimental fires carried out in fuelbeds or with head-fire widths judged too narrow to yield realistic pseudo-steady state rates of spread were excluded (e.g. Neuenschwander 1980; Schimmel and Granström 1997). This also included laboratory studies (e.g. Weise and Biging 1997; Menage *et al.* 2012). To ensure that each study included in the analysis had sufficient data to discern model adequacy for the particular fuel type and burning conditions, we restricted the analysis to studies that had at least five paired observations. Thus, studies like Brown (1982), Pickford *et al.* (1992) and Fogarty *et al.* (1997), for example, were excluded from the analysis. Finally, studies where model outputs were not fully independent, as a result of investigators fine tuning model predictions in relation to the observed rates of fire spread (e.g. Woodall 1998; Beavers 2001), were also not selected for analysis.

It was readily acknowledged that the data quality between studies would vary, especially between data obtained from experimental burning programs versus wildfire monitoring. Experimental fire studies are characterized by detailed sampling of fuel structure, weather and fire behaviour (e.g. Everson *et al.* 1985; Alexander *et al.* 1991; Stocks *et al.* 2004) whereas observations associated with wildfires tend to rely on broad assumptions regarding fuels and representativeness of weather data (e.g. Fogarty *et al.* 1997; Alexander *et al.* 2013).

Calculation of statistics

Error statistics on the rate of fire spread observations versus predictions were calculated for each of the model performance studies that qualified for inclusion. These included the root mean square error (RMSE), the mean absolute error (MAE), the mean absolute percent error (MAPE), and the mean bias error (MBE) as described by Willmott (1982). In most cases, these error statistics were not reported in the studies that we examined so it became necessary to compute them from the data contained in the associated publication or by contacting the study investigators directly for the data pairs.

The percentages of exact, under- and over-predictions were also calculated. To our knowledge, a definition for what constitutes an exact model prediction does not exist. Thus, for the purposes of this study, we elected to consider an exact model prediction as one where the error was less then ±2.5 percent of the observed rate of fire spread.

Results

Assembled database

Our extensive search for evaluation studies of rate of fire spread model performance resulted in the compilation of 49 suitable cases. At least two studies were overlooked, one consisting of eight low-intensity experimental fires (with spread rates less than 1.5 m/min) in an Australian eucalypt forest (Davis 1976) and a second one involving 28 observations (with spread rates of 1.0 to 89 m/min) garnered from a single wildfire in southern California chaparral (Weise and Fujioka 1998). The number (n) of studies by geographic distribution were as follows:

- Africa (n = 3)
- Australia (n = 14)
- Europe (n = 3)
- North America (i.e. Canada and US; n = 29)

The combined database ended up amounting to a total of 1278 individual observed rate of fire spread observation – model prediction pairs. This included three types of data (Figure 2):

- Experimental fires (*n* = 891)
- Operational prescribed fires (*n* = 182)
- Wildfires (*n* = 204)

The data encompassed a wide range in fire behaviour and fire propagation regime types, including low- to high-intensity surface fires in both canopied and non-canopied fuel complexes as well as passive and active crown fires (Van Wagner 1977) in several forest and other vegetation types that are prone to crowning (Table 1 and Figure 3). Seven broad fuel type groups could be identified in the 49 studies (Figures 4 and 5):

- Grasslands (*n* = 6)
- Shrublands (*n* = 9)
- Logging slash (*n* = 3)
- Conifer forest (*n* = 17)
- Hardwood forest (*n* = 3)
- Mixedwood forest (*n* = 2)
- Eucalypt forest (*n* = 9)

All of the studies involved either empirical (*n* = 11) or semi-empirical rate of fire spread models (*n* = 2). The lack of any physics-based models involvement simply reflects the fact that any performance evaluation studies carried out to date with these type of models has involved four or less paired cases of observation and model prediction (Alexander and Cruz 2013a).

Table 1. Sample size, range in rate of fire spread (ROS), and summary of error statistics by type of fire involved in the 1278 pairs garnered from the 49 comparison studies as compiled by Cruz and Alexander (2013)

Type of fire	No. of fires	ROS range (m/min)	Exact predictions	Under-predictions			Over-predictions		
				No. of fires	Mean MAPE (%)	Standard deviation	No. of fires	Mean MAPE (%)	Standard deviation
Surface fires	994	0.1 – 150.9	32	631	48%	25%	346	99%	137%
Crown fires	266	3.4 – 175	3	180	51%	22%	86	61%	63%

Mean absolute percent errors

The mean absolute percent error (MAPE) is a very popular measure of the accuracy of a predictive model or system. It represents the summed differences between the individual predicted versus observed values divided by the observed value; multiplying it by 100 makes it a percentage error. MAPE values were found to vary between 20 and 310 percent and were homogeneous across the seven fuel type groups. The distribution of model comparisons by MAPE classes were as follows:

- 30 percent or less (*n* = 7)
- 31 to 50 percent (*n* = 9)
- 51 to 75 percent (*n* = 26)
- 76 percent and greater (*n* = 7)

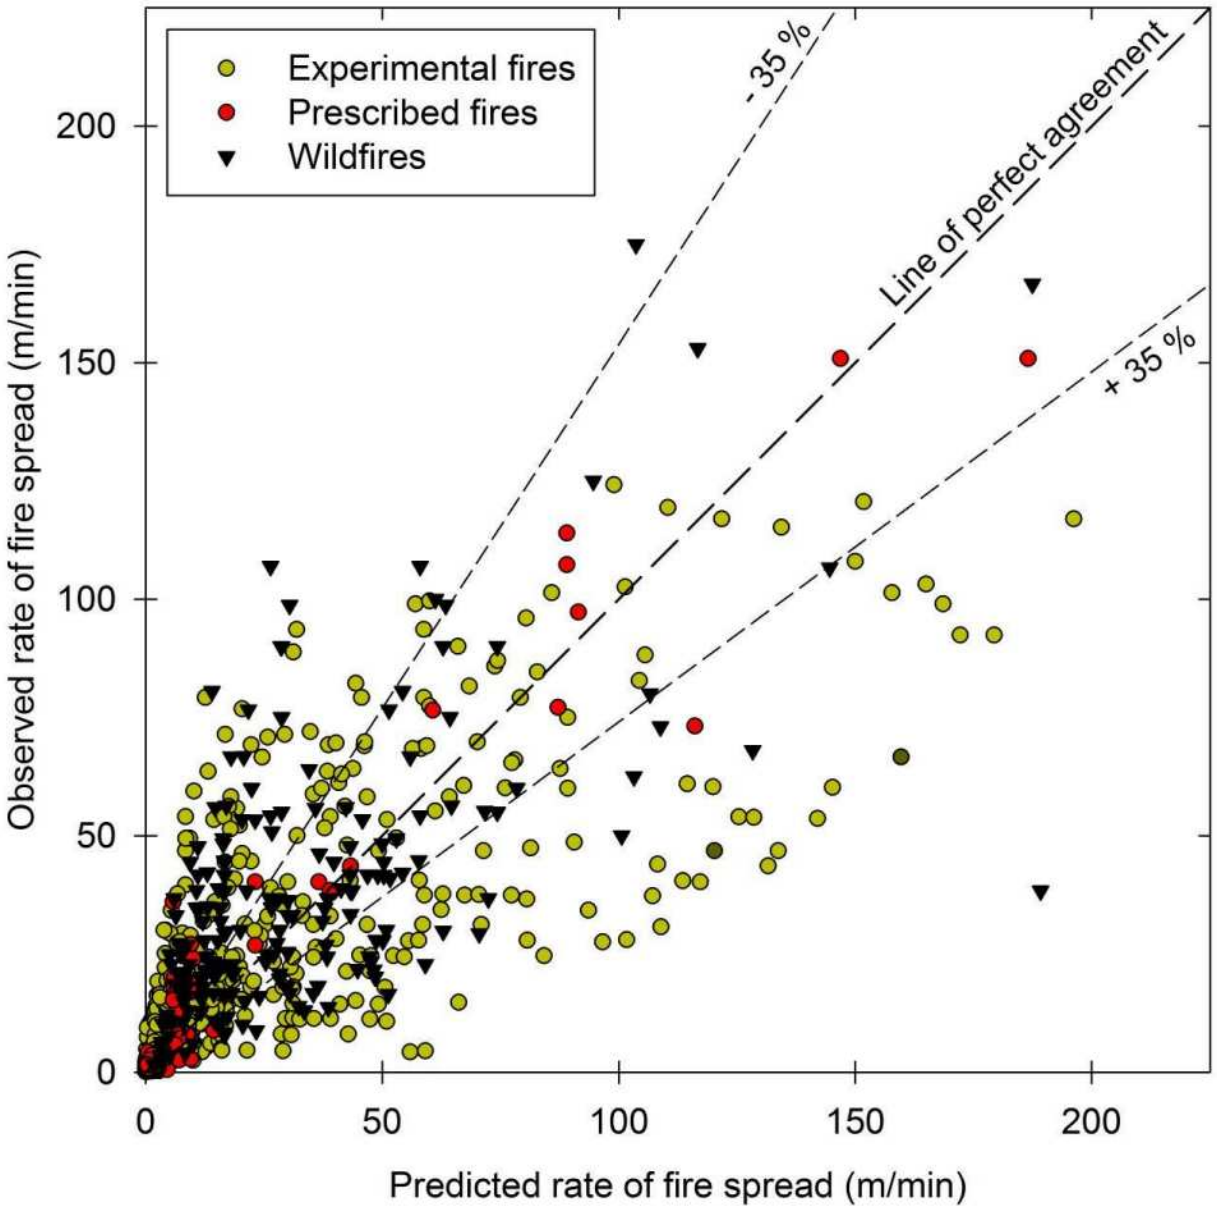

***Figure 2.** Observed rates of fire spread versus model predictions by type of data involved in the 1278 pairs garnered from the 49 comparison studies as compiled by Cruz and Alexander (2013). The two dashed lines around the line of perfect agreement indicate the ±35 percent error interval.*

The lowest errors (i.e., from 20 to 30 percent) were associated with seven studies involving experimental fires and prescribed fires where fuel and weather inputs would have been measured onsite. For comparisons dealing exclusively with wildfires, errors varied from 33 to 59 percent.

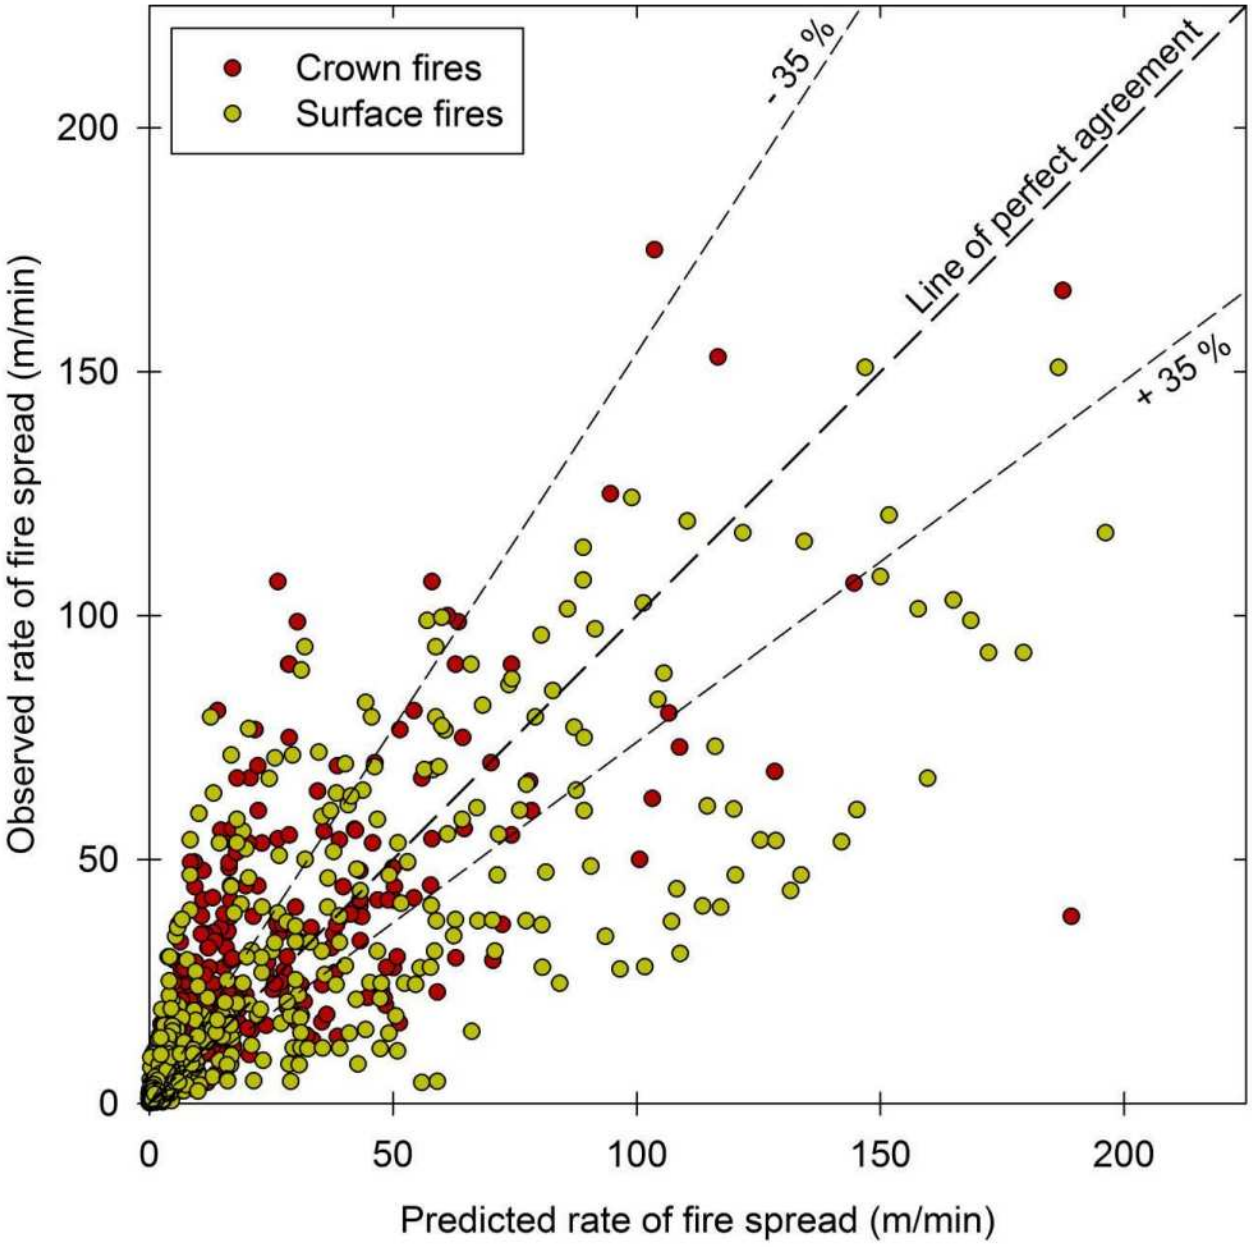

Figure 3. Observed rates of fire spread versus model predictions by type of fire involved in the 1278 pairs garnered from the 49 comparison studies as compiled by Cruz and Alexander (2013). The two dashed lines around the line of perfect agreement indicate the ±35 percent error interval.

Discussion

4.1. How accurately can one expect to predict the spread rate of wildland fires with currently available models?

No significant differences were found for under- and over-prediction errors by the type of data source (Figure 2). However, it was found that the rate of fire spread models examined under-prediction occurred in 818 of the 1278 model comparisons (i.e. 64 percent).

Although the range in rate of fire spread in the independent wildfire datasets was much higher than in the datasets used in model development, the model structure allowed for consistent predictions over the full range of observed fire behaviour. In most cases, under-prediction bias was small. There were,

however, combinations of model and fuel type that resulted in a predominant, if not total, under-prediction bias. This included, for example, Rothermel's (1972) surface fire rate of spread model in conifer forests and in logging slash, and both the Rothermel (1991) and Schaaf *et al.* (2007) crown fire rate of spread models.

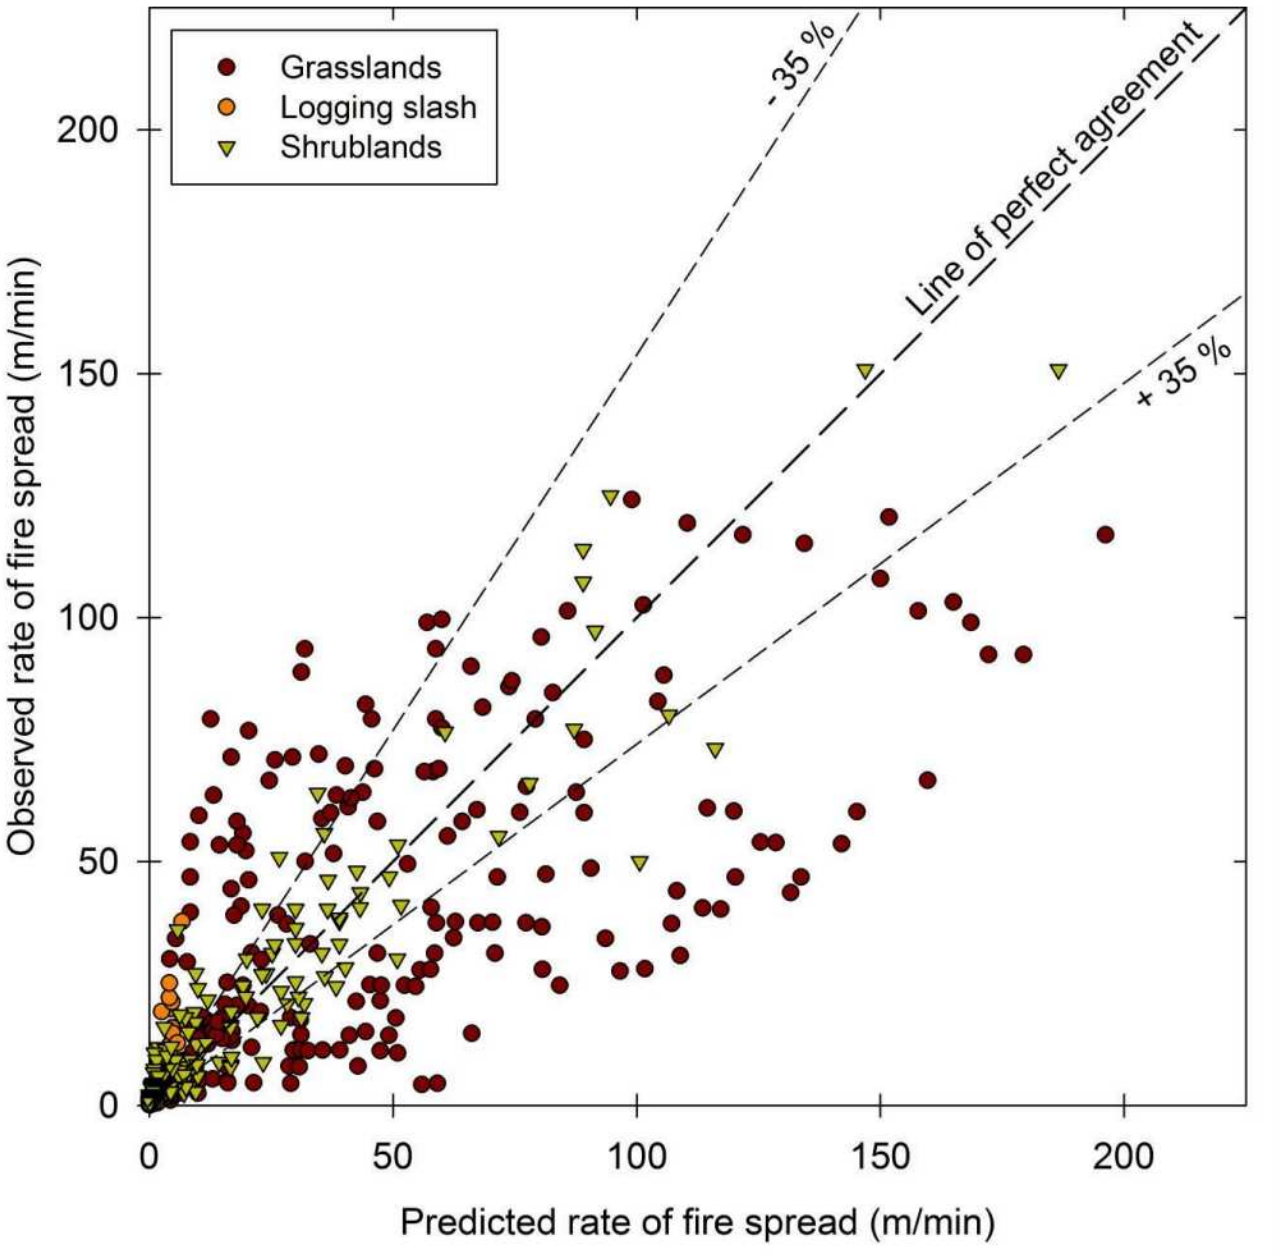

Figure 4. Observed rates of fire spread versus model predictions for non-canopied fuel types (grassland, shrubland and logging slash) involved in the 441 pairs garnered from the 17 comparison studies as compiled by Cruz and Alexander (2013). The two dashed lines around the line of perfect agreement indicate the ±35 percent error interval.

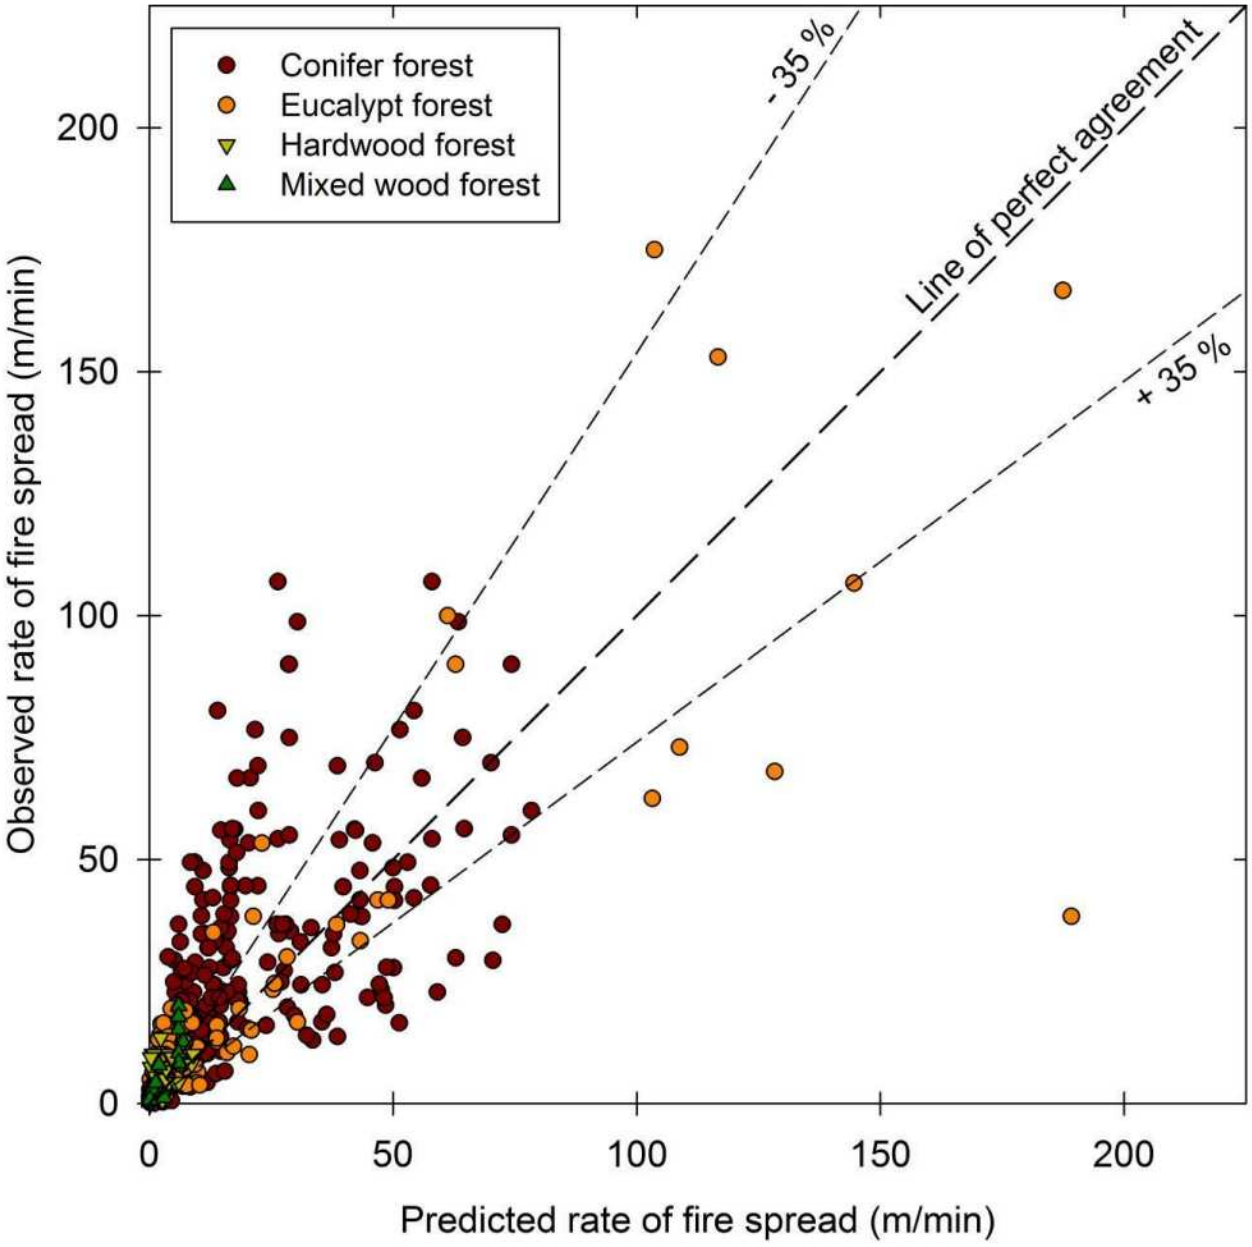

Figure 5. Observed rates of fire spread versus model predictions for forest canopied fuel types (hardwood forest, mixedwood forest, conifer forest and eucalypt forest) involved in the 837 pairs garnered from the 32 comparison studies as compiled by Cruz and Alexander (2013). The two dashed lines around the line of perfect agreement indicate the ±35 percent error interval.

4.2. Can models based on experimental fire data be used to predict wildfire behaviour?

Only two of the 13 rate of fire spread models considered in the study were separately evaluated against both experimental fire and wildfire datasets. This included the models developed by Cruz *et al.* (2005) and Cheney *et al.* (2012) where the MAPE values for the experimental fires where 26 and 35 percent, respectively. In turn, the Cruz *et al.* (2005) model yielded MAPE values of 46 and 52 percent for two separate wildfire datasets, while for the Cheney *et al.* (2012) model, the MAPE was 54 percent.

The increase in MAPE is expected given the uncertain nature of the exact environmental conditions associated with the wildfires. In these evaluations against wildfire data, both the Cruz *et al.* (2005) model, which is the basis for the *Crown Fire Initiation and Spread* (*CFIS*) system (Alexander *et al.*

2006), and the Cheney *et al.* (2012) model were extended well beyond the bounds of dead fuel moisture content, wind speed, and rate of fire spread used in their development. This implies that the underlying functional relationships in these models are valid for far drier and windier wildfire conditions than those involved in the model development, a conclusion that Fernandes (2014) has also recently shown to be valid.

4.3. Are wildfires inherently more difficult to predict the spread rates of than prescribed fires or crown fires compared to surface fires?

Examination of error statistics revealed no discernible difference in the ability to predict wildfire rates of spread from those associated with prescribed fires.

Some fire researchers have contended on the basis of the dynamic nature of crown fires that their behaviour is more unpredictable than that of surface fires (e.g. Cohen *et al.* 2006). However, according to the error statistics computed for surface and crown fires, there appears to be no differences, at least with respect to predicting rate of fire spread (Table 1). In fact, the highest MAPE values were obtained for surface fires rather than for crown fires.

4.4. How realistic is it to expect an exact prediction of rate of fire spread?

On the basis of the 49 studies and 1278 paired observations versus model predictions complied and analyzed, we found that the concept of an exact prediction of rate of fire spread to be an elusive one. Only three percent of the predictions (i.e. 35 out of 1278) were considered to be exact. It thus appears that the only certainty about rate of fire spread predictions is that it is extremely unlikely that a prediction will exactly match the observed fire spread rate.

4.5. What is an acceptable error for fire spread models?

McArthur (1977) considered that the fire danger meters he had developed for Australian grasslands and eucalypt forests could predict rate of fire spread and other fire behaviour characteristics to within ±20 percent of the actual observed value. Kilinc *et al.* (2013) have recently shown this assertion to have been quite optimistic.

From a statistical standpoint one might think that a ±1.0 standard deviation as a reasonable measure for an acceptable error. Assuming a normal distribution, such a quantity corresponds to a 34.1 percent departure from the mean. Richard C. Rothermel (USDA Forest Service retired, personal communication, 2012) was to remark to the authors that "I do like your suggestion of one standard deviation being used as a criteria for evaluating what can be expected in model prediction". This error threshold is also consistent with the average errors associated with several experimental field studies of fire behaviour.

According to the present study only two out of the 49 model performance studies (i.e. 4 percent) had a MAPE of 20 percent and no study had any less of a value. Eight of the 49 model comparisons (i.e. 17 percent) had a MAPE equal to or less than 35 percent suggesting that this could constitute a realistic benchmark by which to judge good model performance when accurate input data is available. On the basis of this outcome and the aforementioned considerations, it would appear that a ±35 percent error would constitute a reasonable and conservative standard for fire spread rate model performance.

Of course a ±35 percent error benchmark is only deemed applicable to research studies. In operational practice, given the uncertainty in the estimation of the input data, often times involving large spatial (e.g. >1000 ha) and temporal (i.e. from one to several hours) scales, would understandably, result in wider error intervals.

Conclusions

A comprehensive survey of the error statistics associated with evaluation studies of rate of fire spread models was undertaken by Cruz and Alexander (2013) in order to gauge the general predictive ability

of such models. This has led to new insights into some of the uncertainties associated with model predictions of free-burning wildland fire behaviour. This survey has also accordingly highlighted the importance of model evaluation (Cruz *et al.* 2003) based on independent datasets and encouraged others to do so (e.g. Anderson *et al.* 2014 in review).

It is worth noting that our evaluation study focused on models of forward or head fire rate of spread (i.e. in one dimension). More recent studies evaluating spatially explicit fire propagation models have relied on a distinct number of metrics to quantify the error associated with wildland fire growth simulations (e.g. Filippi *et al*. 2014a,b). These were not considered in our analysis as the spatial outputs are only partially dependent on the fire spread rate.

Unsteady phenomena affecting the propagation of surface fires

Abstract
The unsteadiness coming from thermo-convective and shear instabilities or from the time variations of the external conditions affecting the fire (wind gusts for example), affecting the propagation of a surface fire, has been studied numerically using a multiphase approach. Two regimes of propagation (plume dominated and plume driven) have been identified, governed by two forces: the buoyancy resulting from the density gradient inside and outside the plume and the inertia of the wind. The degree of non-linearity associated with these two physical mechanisms, can explain the magnitude of unsteadiness of the fire behaviour. It participates also of the impact (sometimes linear and sometimes strongly non-linear) of the impact of wind conditions upon the fire spread. For weak wind conditions (exhibiting potentially a more non linear behaviour), a sinusoidal time variation of the wind speed has been tested with five frequencies (0.25, 0.5, 1, 2 and 3 Hz) nearly equal to the frequency (1.4 Hz) characterizing the thermo-convective instability (in assimilating the fire front as a pool fire) and to the shear instability (0.26 Hz).

Keywords*: surface fire, multiphase model, wind/fire interaction*

Introduction

With ambient temperature and relative air humidity, the wind is certainly one of the most important weather parameter affecting the conditions of ignition and propagation of wildland fires. Various experimental studies carried out at small scale in a wind tunnel and at large scale on the field, have highlighted a power law relationship ($ROS \sim U_W^B$) between the rate of spread (ROS) of a surface fire and the wind velocity (U_W) [1, 2, 3, 4, 5]. The fact that the wind's exponent B varies from 0.4 [3] to 2 [5], shows that this relationship is not fully understood. Direct observations of fires in grassland [6], have highlighted that the curve representing the relation ROS versus U_W can be decomposed in three zones: a linear zone (wind's exponent B nearly equal to one), bounded by two non-linear zones for weak (B>1) and strong (B<1) wind conditions. Because experimental fires must be conducted in safe conditions, the range of variations of wind conditions cannot be extended sufficiently, to observe in all cases, these changes of fire behaviour. Numerical simulations performed in shrubland, which are not submitted to the same constraints, have been able to reproduce this kind of behaviour [7]. Analysis of experimental results obtained in a fire wind-tunnel [8], seem indicating that sudden changes of slope in the curve ROS vs U_W can be attributed to a change in the main mode of heat transfer (by convection and radiation) between the flame and the solid fuel layer. It is well known that the relative importance between these two mechanisms of heat transfer, is strongly affected by the view angle between the flame and the unburned fuel and consequently by the trajectory of the flame (more or less vertical). This trajectory is affected by two forces along two directions: vertically the buoyancy and horizontally the inertial force of the wind. The relative importance of these two forces can be evaluated from a non dimensional parameter, the Byram's convective number [9]:

$$N_C = \frac{2gI_B}{\rho C_P T_0 \left(U_W - ROS\right)^3} \quad \text{(Eq.1)}$$

where g is the acceleration of gravitation, I_B is the fireline intensity, ρ , C_P , and T_0 are the density, the specific heat and the temperature of the ambient air.
From the value taken by this similitude parameter, two great regimes of fire propagation have been identified:

- For $N_C >> 1$, the plume dominated fires, characterized by a flame trajectory more or less vertical, a general trend of the air flow (near the fire) to be symmetrically aspirated by the fire front,
- For $N_C << 1$, the wind driven fires, characterized by a flame horizontally sheared by the wind flow, pushing hot gases toward the vegetation layer located ahead of the fire front,

The propagation of surface fires can be affected by unsteady phenomena coming from the fire itself (internal fluctuations of the fire intensity) and from variations of external parameters such as time variations of the wind velocity (gusts). Depending of the fire propagation regime (plume dominated or wind driven) the consequences for the forecasting of fire behaviour are more or less significant. Previous experimental observations have shown that the relationship between the fire rate of spread and the wind velocity was not as straightforward (as a monotonous curve) in all wind conditions [10, 11].
It is in this general context, that the present study has been conducted, in focussing our attention on the effects of these two sources of unsteadiness upon the behaviour of a surface fire in propagation through a homogeneous fuel layer representative of grassland.

The study was based on numerical simulations, in using a multiphase formulation, details of the physical and numerical models can be found in previously published articles [7, 9, 12, 13].

In the first part of the paper, unsteady signals of fireline intensity have been analyzed for various quasi steady wind conditions (U_W) ranged between 1 and 25 m/s (10m open wind velocity). With these values, the simulations covered a large range of conditions of propagation from plume dominated to wind driven fires (N_C ranged nearly between 0.1 and 1000). Then the effects of a sinusoidal time variation of the wind flow (representing wind gusts) have been explored for relatively moderated wind conditions (U_W=2 m/s , ΔU_W= +/- 1 m/s). In this case, four frequencies were tested 0.25, 0.5, 1, 2 and 3 Hz.

Physical multiphase model

The numerical simulation of the behaviour of wildland fires is very challenging and can be qualified as a complex multi-scale and multi-physics problem. The main difficulty results from the wide spectral band of length scales, associated to physical mechanisms governing the fire behaviour (atmospheric turbulence, combustion, pyrolysis, radiation heat transfer …) which are for most of them non-linear. Even if we limit the description of the problem to the immediate neighbourhood of the fire front, a large range of spatial scales are concerned: the turbulent integral length scale of the boundary layer flow above the canopy (more or less equal to the height of the canopy, 0.7 m here), the corresponding Kolmogorov micro-scale (< 1 mm), the length of extinction characterizing the vegetation layer (0.5 m here), the flame thickness (~ 500 □m for a hydrocarbon flame) [9]. Of course, it is impossible to explicitly take into account all these length scales, the effects of the smallest ones (Kolmogorov micro-scale and flame thickness) must be reproduced using physical models [15]. In the same order of idea, it is impossible to reproduce with all details, the structure of the vegetation layer. In place of representing in details all the elements constituting the vegetation (foliage, twigs, trunk), an averaging procedure has been introduced which consists in representing the vegetation as an equivalent sparse porous media. This approach can be assimilated as a sort of homogenization step, is often referenced in the literature as a multiphase formulation of forest fire modelling [7, 12, 14]. The main advantage of this formulation is the possibility of taking into account all the terms of interaction between the gas

phase and the vegetation, without the necessity of representing in detail the very complex interface (fractal) between these two phases. The numerical simulations (2D) have been carried out in a computational domain, 170 m long and 35 m high, inside which a 150 m long and 0.7 m high homogeneous vegetation layer has been positioned (see Figure 1). The inlet wind flow has been reproduced with a logarithmic velocity profile (Eq. 2) at the left end side of the domain (the constant A was adjusted to ensure a known value of the wind velocity 10 m above the ground level), z0 = 0.01 m corresponding to a nude soil. A 20 m long nude zone (without any vegetation) has been built near the entrance, to ensure the establishment of the boundary layer flow (see Figure 1).

$$U_X(z) = A \times U_{10} \times Ln\left(\frac{z + z_0}{z_0}\right) \qquad \text{(Eq.2)}$$

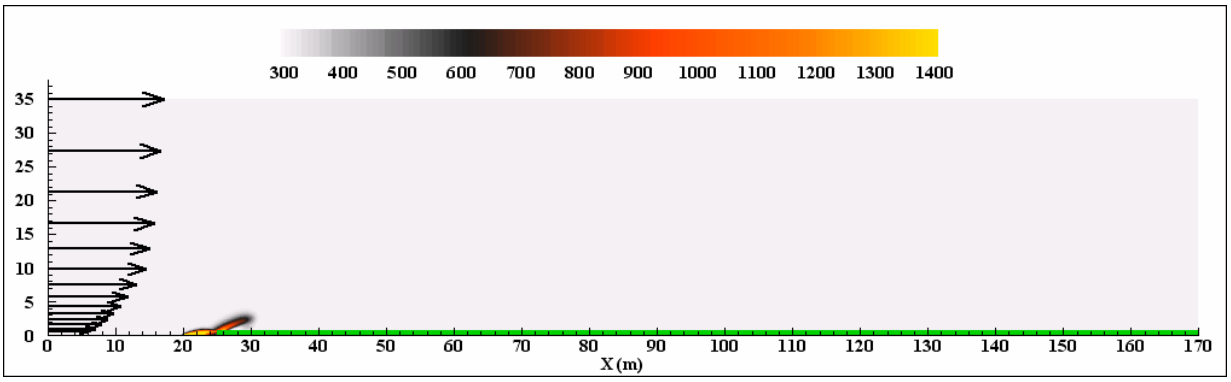

Figure 1. Computational domain and boundary conditions.

The vegetation layer (here a homogeneous grass) has been represented using the set of physical properties from data collected on the field [16]. To guarantee an optimal accuracy, the simulations have been performed using a dynamic adaptive mesh attached to the fire front (positioned from the first pick of temperature inside the vegetation). The size of the grid mesh in the vicinity of the fire front, has been adjusted to guarantee that the radiation heat transfer and the turbulent flow inside the vegetation were correctly reproduced [9, 17].

Table 1. Solid fuel physical properties and external conditions imposed in the present numerical simulations (Anderson 1982).

Solid fuel density (kg/m^3)	500
Volume fraction x 10^3	2
Fuel moisture content (FMC) (%)	10
Fuel depth (m)	0.7
Fuel load (t/ha)	7
Surface area to volume ratio (m^{-1})	4000
Length of extinction (m)	0.5
Leaf Area Index (LAI)	2.8
10m open wind velocity (m/s)	1-25

Plume dominated fires are supposed to be mainly governed by the buoyancy force resulting from the difference of density between the external atmosphere and the hot gases inside the thermal plume. For this reason, the behaviour of this kind of fire must present some similarities with pool fire. It is well known that the dynamic of pool fires is governed by thermal-convective instabilities, marked by vertical oscillations of the flame height and of the heat release rate, with a frequency f_B related to the acceleration of gravity (g) and the diameter (D_{Fire}) of the pool fire as following:

$$f_B = (0.5 \pm 0.04)\left(\frac{g}{D_{Fire}}\right)^{1/2} \qquad \text{(Eq.3)}$$

Wind driven fires are more affected by the inertia force of the wind, a consequence of that is that the dynamics of the fire can potentially be affected by the shear layer instability (Kelvin-Helmholtz) resulting from the rapid deceleration of the external flow due to the presence of the vegetation. For this reason, we have also introduced in our analysis the characteristics frequency f_{KH} associated with this instability along the steamwise direction:

$$f_{KH} = \frac{0.15 \times U_H}{H} \qquad \text{(Eq.4)}$$

where U_H is the wind velocity at the top (Z = H) of the canopy.
Because the behaviour of surface fires can be affected by these two forces (the buoyancy and the inertia of the wind), we have compared the frequencies extracted from the fast Fourier transform (FFT) analysis of the fire intensity signals with these two characteristics frequencies.

Results and discussion

A first set of numerical simulations has been performed for a large range of wind velocity (from 1 to 25 m/s) in order to cover both, plume dominated and wind driven fires. The results shown in Figure 2 is a good illustration of the difference of interaction between the fire front and the surrounding atmosphere, for weak (UW = 1 m/s) and strong (UW = 20 m/s) wind conditions. For weak wind conditions, the trajectory of the flame was nearly vertical, promoting the development of a vertical thermal plume forming an obstacle for the incoming wind which was not able to cross the fire front (the same tendency has also been observed in 3D for the same wind conditions [21]). The burning zone was fed in fresh air symmetrically on both side of the fire front (see Figure 2 on top).

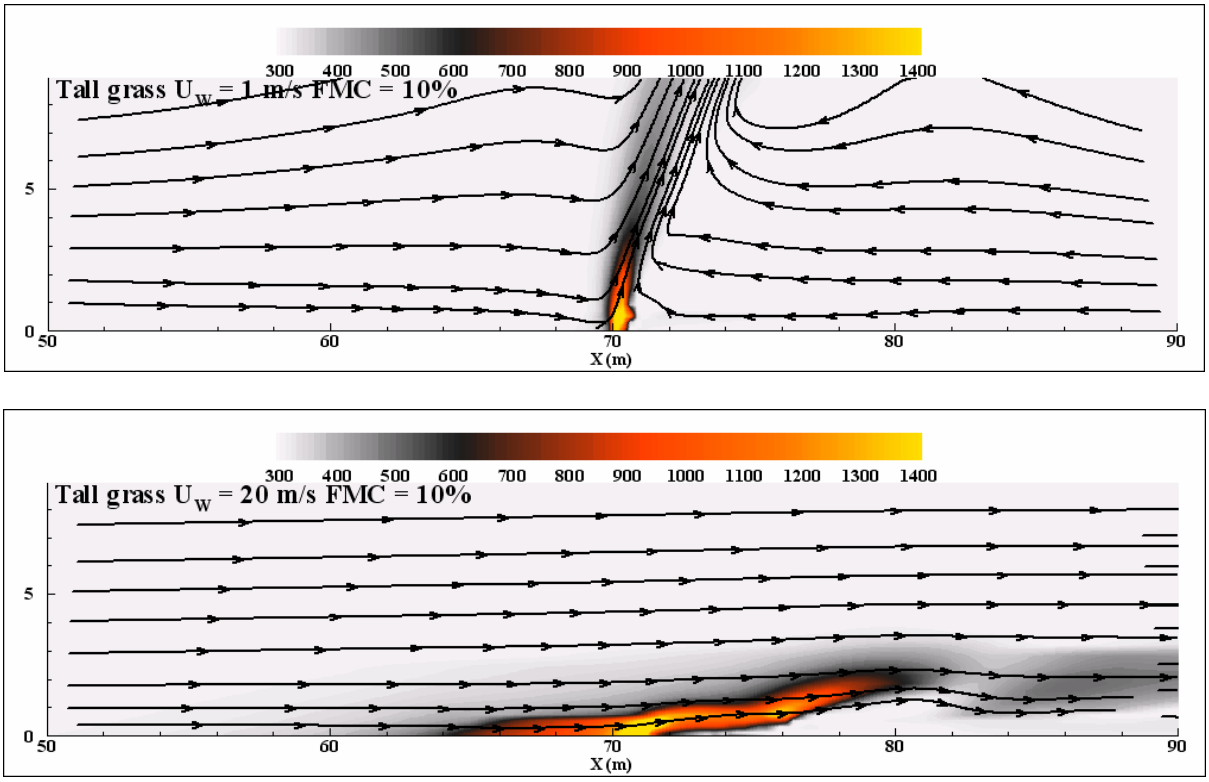

Figure 2. Snapshot of the temperature field and gas flow (streamlines) calculated for two values of the wind velocity: UW = 1 and 20 m/s.

We must underline that 2D simulations contribute to enforce this behaviour (in 3D the formation of peaks and troughs along the fire front [8], allowed to reduce the role of barrier played by the fire front). For strong wind conditions, the trajectory of the flame was significantly deviated by the wind flow (see Figure 2 on bottom) and the incoming wind flow was able to cross the fire front, contributing to transport hot gases from the burning zone toward the vegetation layer. As shown in Table 2, the action of the wind flow upon the fire behaviour (in terms of rate of spread and fire intensity) cannot be reduced to a monotonic curve, confirming the existence of multiple regimes of propagation. This kind of non linear interaction between wind and fire has already be observed experimentally and reported in the literature [10, 11, 12]. The signals of fire intensity obtained for the same wind conditions (UW = 1 m/s and 20 m/s) are shown in Figure 3 (see also Table 2).
Between 1 and 20 m/s, the rate of spread and the fire intensity, has increased by a factor 2.8 and 2.6 respectively. An other interesting information extracted from these fire intensity signals, is the ratio between the standard deviation and the average value, which decreased from 0.28 to 0.18 (as the wind speed increases from 1 to 20 m/s). This trend was confirmed for the whole range of variation of the wind speed (see Figure 4), indicating that the relative level of unsteadiness of the fire behaviour was more pronounced for plume dominated fires than for wind driven fires. The same kind non-linear effect has already been observed experimentally [6] and numerically [7] for the relationship linked the rate of spread and the wind velocity. It is already known that the behaviour of plume dominated fires is more difficult to predict compared to fires piloted by a strong wind.

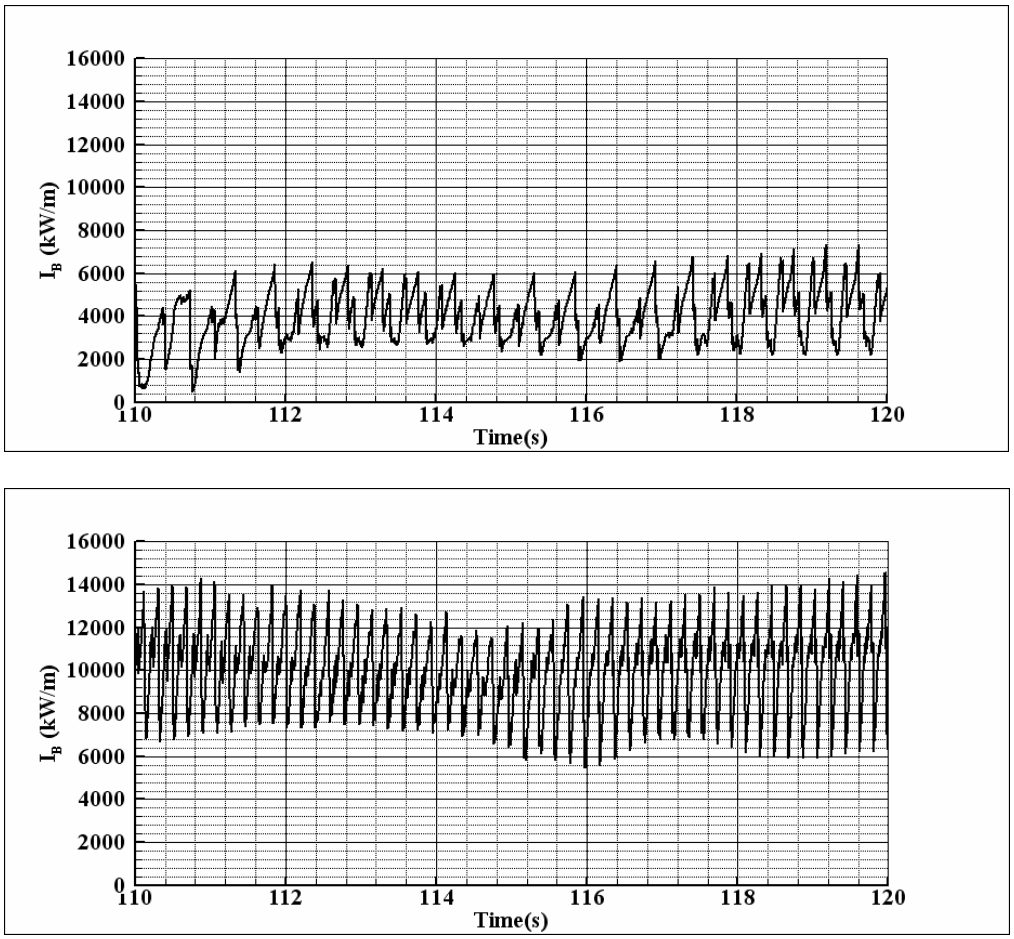

Figure 3. Time history of fireline intensity for two values of wind velocity: UW = 1 (top) and 20 m/s (bottom).

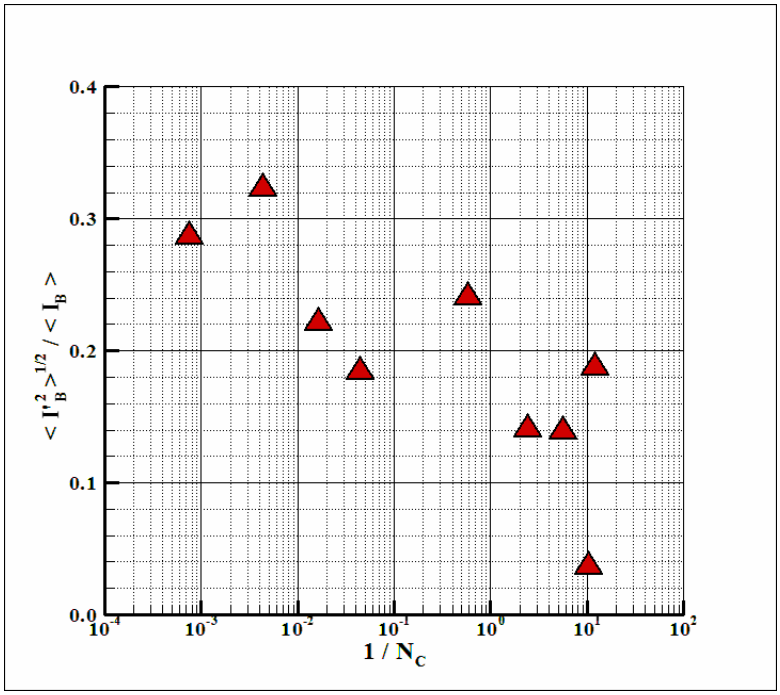

Figure 4. Ratio standard deviation / mean value of the fireline intensity as a function of the convective Byram number.

This difference of behaviour versus the wind velocity, results mainly from the dominant mechanism of heat transfer between the flame and the vegetation. If the radiation heat transfer plays a major role in the propagation of the fire, because this physical mechanism is intrinsically more non-linear compared to convection heat transfer (because of the σT4 of the Stefan-Boltzmann law), it is not surprising that this kind of surface fire can exhibited less predictable sudden changes [12].

Fast Fourier transform (FFT) of the fire intensity signal (see an example in Figure 5) has allowed identifying the energy distribution on a frequency domain. As shown in Figure 5, for UW = 1 m/s, the major contribution (maximum level of energy) was associated to a σto the frequency characterizing the buoyancy instability (1.6 Hz) compared to the Kelvin-Helmholtz instability (0.1 Hz).

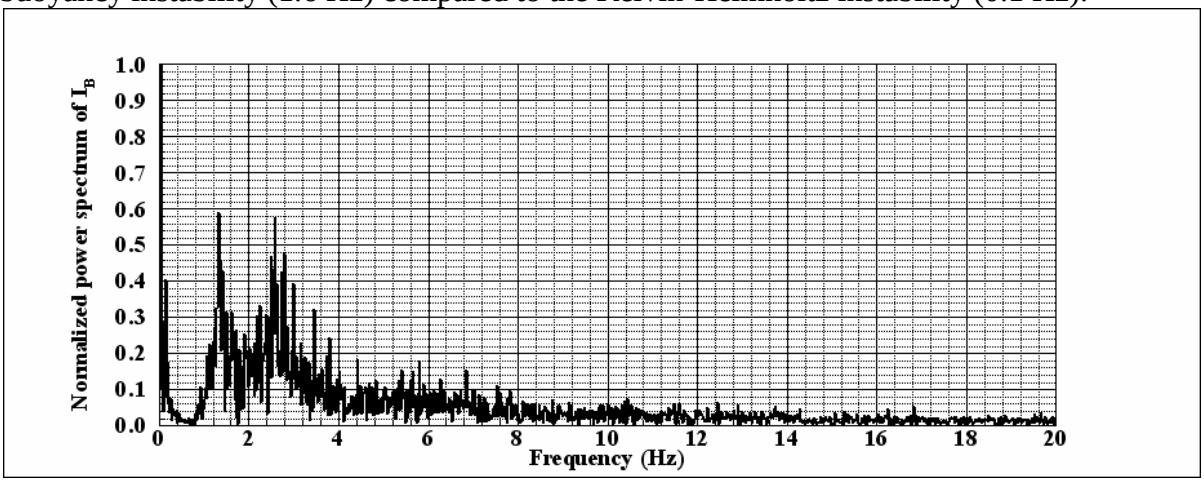

Figure 5. FFT analysis of fireline intensity signal obtained for U_W = 1 m/s.

In analysing the data in Table 2 and considering that the wind velocity promoted an increase of the depth of the fire front (see Figure 2), consequently its effect upon the two frequencies associated to the two forces (buoyancy and inertia) were symmetrically opposed: it decreased for the first one, and it increased for the second one. Considering that the situation observed during the propagation of a

surface fire differed from the two simplified models used for the analysis in frequencies (steady pool fire and boundary layer canopy interaction), we can still conclude that, as the behaviour of the fire moved from plume dominated fire to wind driven fire, the instability governing the fire intensity signal, changed from a thermal-convective type instability to a shear type instability.
In order to study the response of a surface fire in propagation, we have performed a second set of simulations, in adding a sinusoidal variation, in order to reproduce schematically wind gusts.

$$U_X(z) = A \times U_W \times Ln\left(\frac{z + z_0}{z_0}\right) + \Delta U_W \sin(2\pi \times F \times t)$$

where ΔU_W and F are respectively the amplitude and the frequency of wind variations. The present study has been limited to one wind conditions U_W = 2 m/s and ΔU_W = 1 m/s (the wind speed varied between 1 and 3 m/s), the frequency F varied between 0.25 and 3 Hz. This wind condition (U_W = 2 m/s) has been chosen because it represented a situation for which we have found (in quasi steady wind conditions) a relatively high value of the variation of the rate of spread (*ROS*) versus U_W (see Table 2).

Table 2. Wind speed, Rate of spread, Fire intensity (average value, standard deviation, frequency), Thermal-convective and Kelvin-Helmholtz frequencies.

UW (m/s)	1	2	3	4	8	12	15	20	25
ROS (m/s)	0.46	0.84	1.06	1.18	1.24	1.23	1.10	1.28	2.51
IB (kW/m)	3798	6468	8179	9155	9604	9331	8602	9913	20098
<I'B2>1/2 (kW/m)	1088	2090	1806	1683	2313	1311	1191	1856	738
f (Hz)	2.3	3.4	4.2	4.8	5.0	5.0	5.5	5.5	5.5
fB (Hz)	1.6	1.4	1.2	1.1	0.9	0.8	0.7	0.6	0.5
fKH (Hz)	0.1	0.2	0.4	0.5	3.2	1.1	1.6	2.0	2.6

The curve shown in Figure 6 is the time evolution of the fire intensity obtained with a sinusoidal variation at a frequency of 0.25 Hz, in comparison we have also added the result obtained in quasi-steady wind conditions.

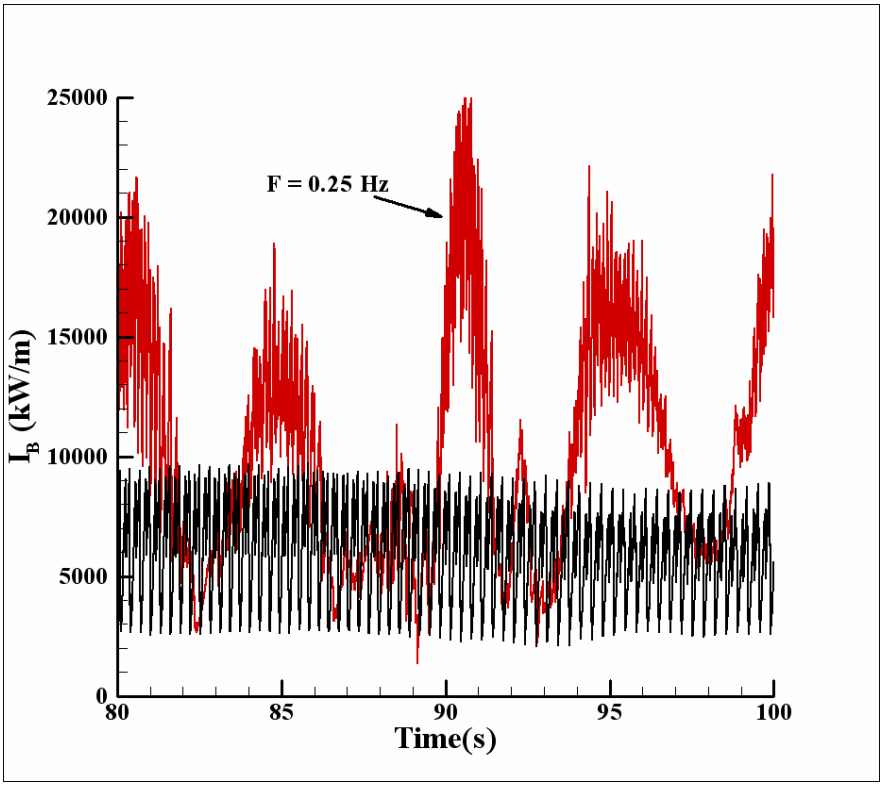

Figure 6 –Time evolution of the fireline intensity obtained for U_W = 2 m/s with and without a sinusoidal variation (F = 0.25 Hz).

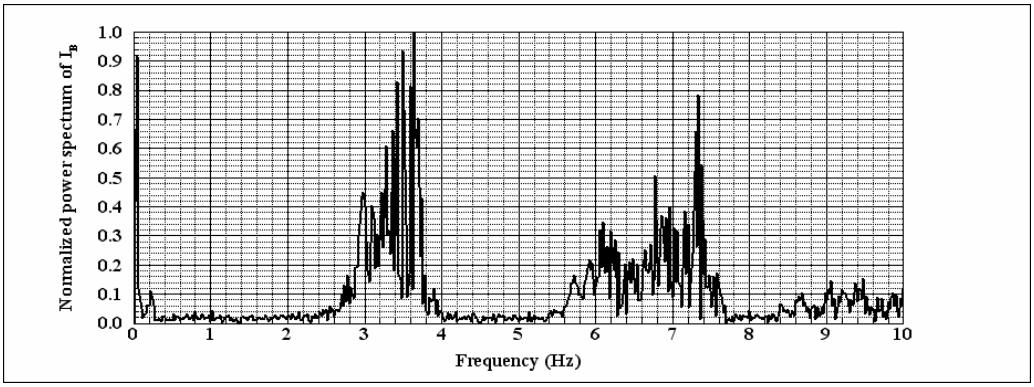
This is for this frequency (0.25 Hz), nearly equal to the frequency characterizing the Kelvin-Helmholtz instability (see Table 2) that we have obtained the maximum effect. We can notice that this relatively small change in wind conditions, has promoted a huge modification of the behaviour of the fire. While the maximum value observed in quasi-steady state varied from 7000 to 12000 kW/m, for a wind velocity ranging between 1 and 3 m/s, the same value has increased up to 20000-25000 kW/m (the fire intensity signal was modulated with a sinusoid at frequency of 0.21 Hz) in simply adding an unsteady variation. We have also noticed that this sort of resonance mechanism decreased rapidly as the excitation frequency exceeded this critical value, the maximum fire intensity observed with a frequency F = 0.5 Hz reached 18000 kW/m and decreased to 10000 kW/m for F = 1 Hz (quasi identical than the value observed in quasi steady wind conditions for U_W = 2 m/s).
The normalized spectra of the fire intensity signals shown in Figure 7, has confirmed this coupling mechanism between the frequency at which the wind velocity was excited and the characteristic frequency of the Kelvin-Helmhotz instability. The evolution of the fire intensity (average value and standard deviation) as a function of the wind gusts frequency F is represented in Figure 8.



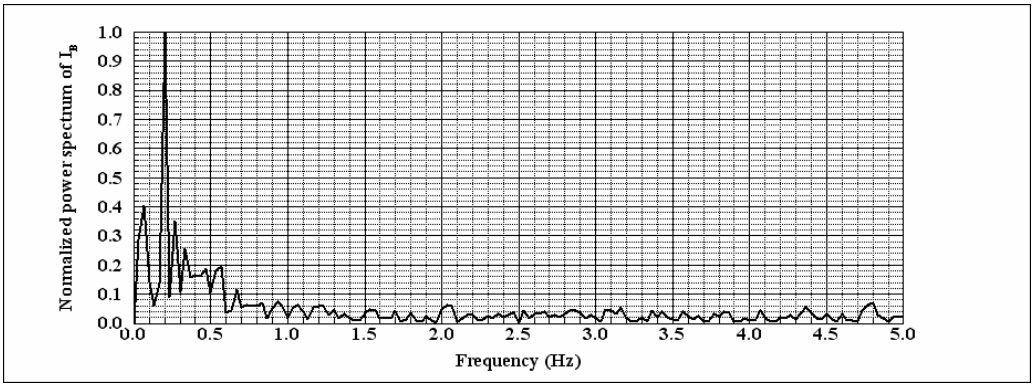


Figure 7. FFT analysis of fireline intensity signal obtained for U_W = 2 m/s without (top) and with (bottom) a sinusoidal time variation (amplitude 2 m/s, frequency 0.25 Hz).

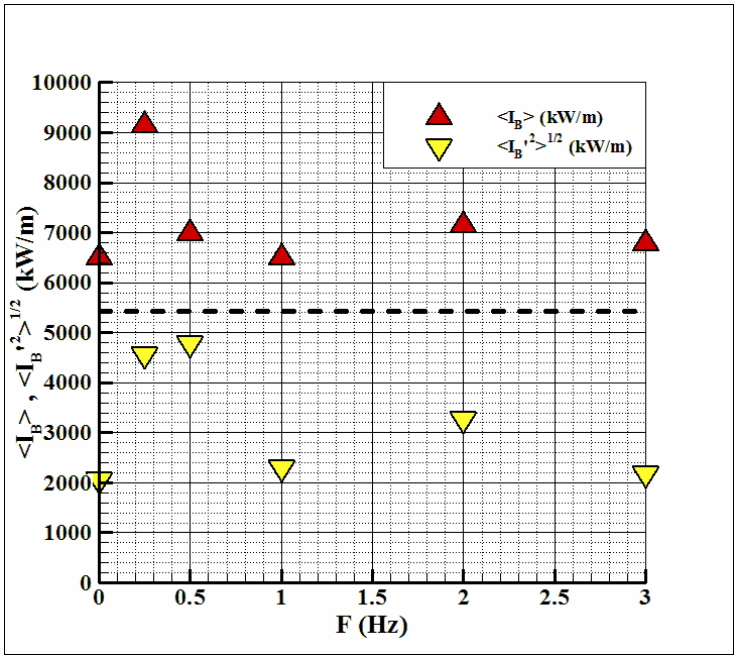

Figure 8. Fireline intensity and standard deviation obtained for UW = 2 m/s and a sinusoidal time variation (frequency ranged between 0.25 Hz and 3 Hz).

These numerical data show that two frequencies seemed increasing the unsteady effects, a first one (with the larger effect) for F = 0.25 Hz (near the Kelvin-Helmoltz frequency for these conditions of wind and vegetation) and a second one for F = 2 Hz (not far from the plume instability).

Conclusion

Numerical simulations of surface fires propagating through homogeneous vegetation layer on a flat terrain have been carried out for a large range of wind conditions, covering the two regimes of propagation (plume dominated and wind driven) referenced in the literature. The FFT analysis of the time variation of the fireline intensity signals, has allowed identifying that the unsteady motions of the flame front were governed by two instabilities (by shear and by density gradient). Then a second set of numerical simulations, reproducing the wind gusts, has allowed to highlight a coupling mechanism between forced and internal instability modes, which was able to modify significantly the fire behaviour.

Abstract
This paper presents a testing of surface wildfire rate of spread (ROS) field observations ($ROS_{observed(surface)}$) versus rate of spread predictions ($ROS_{predicted(surface)}$) from BehavePlus (Andrews *et al*., 2005) for tall and short Mediterranean shrublands, Sarcopoterium spinosum (small xeric shrub, up to 0.5 m height) and grass. In order to evaluate the degree of their agreement and analyse the results of their correlations, surface or passive crown fire behaviour data as well as meteorological, topography and forest fuels data had to be prepared according to specific criteria in order to ensure their quality and compatibility.
Ninety five fire behaviour data records were created from field observations and measurements made during the evolution of specific wildfires in Greece, in the last seven fire seasons (2007-2013). The data were classified depending on the fuel model that describes the fuel types they had spread in and, thus, four data subsets were generated that correspond to the following four fuel models for Greece which had been developed in 2001 (Dimitrakopoulos *et al* 2001, Dimitrakopoulos 2002): a) "Evergreen-schlerophyllous shrublands (1.5 - 3 m)" for tall maquis (38 cases), b) "Evergreen schlerophyllous shrublands (up to 1.5 m)" for short maquis (13 cases), c) "Phrygana II (Sarcopoterium spinosum)" for phryganic areas where the dominant species was Sarcopoterium spinosum (26 cases) and d) "Mediterranean grasslands" for grass (18 cases). After creating the database, the BehavePlus system was used to produce rate of spread predictions for each of the ninety five cases and flame length (FL) predictions ($FL_{predicted}$ values) for the twenty six cases of *Sarcopoterium spinosum* dominated phrygana fields.
The main finding is that for the four Greek fuel models tested, BehavePlus can be a useful tool for predictions of fire behaviour. However, there is a relatively consistent over-prediction of ROS for the models "Evergreen-schlerophyllous shrublands (1.5 - 3 m)" for tall maquis, "Evergreen schlerophyllous shrublands (up to 1.5 m)" for short maquis (13 cases), and "Phrygana II (Sarcopoterium spinosum)", while there a significant under-prediction for the "Mediterranean grasslands" fuel model.
Four linear regression equations describing mathematically the relation of the predicted to the observed ROS were developed. They are statistically significant and can be used for adjusting BehavePlus predictions to match "real world" fire behaviour.
A further finding was that flame length is seriously under-predicted when using BehavePlus with the Phrygana II fuel model to predict fire behaviour in *Sarcopoterium spinosum* dominated phrygana fields. This is an important result that can be very useful for the safety of firefighters.

Keywords*: Mediterranean shrubs, maquis, phrygana, fuel model, wildfire behaviour prediction, BehavePlus, wildfire field observations, Greece*

Introduction

Modern wildfire management requires use of reliable fire behaviour prediction and fire spread simulation systems. However, broad operational adoption of such systems can be achieved and benefits can be maximized only if their strengths and generalizations, weaknesses or limitations are well known. Continuous and extensive testing of fire behaviour prediction systems in the laboratory, in experimental field burns as well as in actual wildfires, is necessary since it detects their "limits",

documents their proper use and increases, eventually, their contribution to fire fighting safety and efficiency. Globally, fire managers and scientists often utilise data sets that come from documented wildfires and test the predictions of fire behaviour modelling systems, such as the popular system BehavePlus (Andrews *et al*., 2005), versus field observations, aiming to evaluate the degree of their agreement. Measurements of weather conditions and topography as well as information about the forest fuels (fuel models), are necessary as inputs for using the BehavePlus system. Until now, many studies have shown minor or significant disagreements between fire behaviour observations and predictions which have often been attributed to the inadequacy of stylized fuel models to represent the existing forest fuel conditions.

In Greece, some testing of BehavePlus took place after the fires of 2007 which had mostly spread under extreme weather conditions and had caused huge damages (Athanasiou and Xanthopoulos, 2010). That testing had shown a very good agreement between fire behaviour observations and predictions for tall Mediterranean shrublands that were described by the "Evergreen-schlerophyllous shrublands (1.5 - 3 m)" fuel model for tall maquis, which had been developed and published earlier (Dimitrakopoulos *et al* 2001, Dimitrakopoulos 2002). The collection of fire behaviour data continued in the field during the following fire seasons, enriching the database and allowing a "stress test" of the initial and preliminary conclusions for the above model, in a wider range of conditions.

Moreover, additional fire behaviour data were recorded presenting an opportunity for testing BehavePlus surface fire behaviour predictions for three more fuel types: a) short maquis, b) small xeric shrubs, up to 0.5 m height (called phrygana in Greece) and c) grass. These types can be described by three previously developed fuel models for Greece by the same authors: a) "Evergreen schlerophyllous shrublands (up to 1.5 m)", b) "Phrygana II (*Sarcopoterium spinosum*)" and c) "Mediterranean grasslands".

The current paper is part of the Ph.D. thesis of the first author. A data subset of documented wildfires of the last seven fire seasons (2007 – 2013) in Greece were utilised, aiming to evaluate the degree of agreement of BehavePlus predictions with observed fire behaviour for four out of the seven fuel models that have been developed for Greece, to introduce adjustments if needed, and ultimately to contribute towards wider adoption of prediction systems into fire management.

2. Methods

A database including meteorological, topography, forest fuels and fire behaviour data was initially created in 2007 and is continuously enlarged with field measured observations made during specific fires. It now consists of detailed data collected during 32 low, medium or high intensity wildfires which took place under a variety of meteorological conditions, topography and fuels. More than one data records (fire behaviour cases) resulted from each of these fires as most of them run their course for many hours. The database now includes 185 records. Its fields contain detailed information about the observed fire rate of spread and flame length and reliable data about the fire type, crowning initiation and propagation, crown fire type, spreading in canyon, spotting (Athanasiou and Xanthopoulos, 2013), wind direction versus slope, wind adjustment factor and midflame wind speed (Rothermel, 1983), downslope or upslope fire spread, fire spread direction in relation to wind (head fire, backward, or sideward moving) and, where relevant, such observations as strong wind turbulence occurrence, convection column generation, etc.

Fieldwork and data processing

The fire behaviour observations were matched with the related meteorological, topography and forest fuels information following specific procedures (Athanasiou and Xanthopoulos, 2010). The forest fuel types, in which the fires spread, were identified through visual assessment and were described by the suitable fuel models for Greece when such a description was possible. Slope, aspect and altitude were

measured using a Garmin etrex Summit GPS device in the field, and later using the ArcGIS 9.3 Geographic Information System (GIS) software by ESRI Corporation in the office. Air temperature in degrees Celsius (^{o}C), relative humidity in (%) and wind speed and gusts in kilometers per hour (km/h), were measured using an electronic weather instrument (type: Thermometer – Anemometer - Hygrometer Model N^{o} AM4205). Additionally, wind direction azimuth was determined using a compass.

Fire rate of spread ($ROS_{observed}$), in (km/h), was calculated by knowing the exact time for every fire head, finger, tail or flank location (Alexander and Thomas, 2003) and applying simple geometry (Clements *et al*., 1983) or using the GIS software, through the following steps:

a) recording the geographic coordinates of observer's positions with the GPS device and measuring the observations' horizontal azimuth with a compass,
b) taking plenty of sequential digital photographs (in JPG format and known time) using a Canon Powershot S3is digital camera [which has a lens with a focal length ranging from 36 mm (wide Angle) to 432 mm (telephoto)],
c) pinpointing the sequential locations of the fire on the photograph (figures 1, 2, 3 and 4) or on the map.

Flame length ($FL_{observed}$) in (m), was calculated also by applying simple geometry (Clements *et al*., 1983) for the cases that this was possible.

Defining the fire behavior data samples

The first step of the analysis was the preparation of the data according to specific criteria in order to ensure data quality and compatibility. Active crown fires and cases of surface fire behaviour affected by spotting, a strong convection column or other factors that resulted in extreme fire behaviour (e.g. box canyon or turbulence) were excluded. The excluded cases fall in two main categories of: a) fires that were dominated by factors that cannot be explained by the ordinary fire spread physical laws, therefore these cases are not comparable with BehavePlus predictions or b) fires which spread in fuel situations and complexes that consist of several mixed fuel types that cannot yet be described by the existing seven fuel models, for Greece. The remaining 95 cases of surface or passive crown fire behaviour ($ROS_{observed(surface)}$) were then classified depending on the fuel model that describes the fuel types they had spread in. Four data subsets were generated that correspond to the following four fuel models for Greece:

a) "Evergreen-schlerophyllous shrublands (1.5 - 3 m)" for tall maquis (38 cases),
b) "Evergreen schlerophyllous shrublands (up to 1.5 m)" for short maquis (13 cases),
c) "Phrygana II (*Sarcopoterium spinosum*)" for phryganic areas where the dominant species was *Sarcopoterium spinosum* (26 cases) and
d) "Mediterranean grasslands" for grass (18 cases).

Analysis

On-site meteorological measurements, measured slope values and the four fuel models for tall maquis, short maquis, *Sarcopoterium spinosum* dominated phryganic areas and grass, were used as inputs for predicting surface fire rate of spread values ($ROS_{predicted\ (surface)}$) with BehavePlus. The values of the four fuel models parameters are summarized and reported in table 1 and typical photos are shown in Figure 5 in an effort to facilitate further testing by researchers and use by fire managers in Mediterranean countries with fuel situations that can be described by these fuel models.
The NEWMDL module of the original BEHAVE system (Burgan and Rotrhermel 1984) was used to calculate the overall fuel load in the dead fine fuels (1hr) category of the fuel models, adding the load of litter to that of the rest of 1 hr fuels and then to calculate a weighted fuel bed depth. Furthermore, NEWMDL produced an estimate for the "dead fuel moisture of extinction" for each model. Such values had not been reported previously.
Fine (1-h) dead Fuel Moisture Content (FMC %) value was calculated using Rothermel's methodology (1983) using: a) air temperature and relative humidity measurements, b) month and time of day of the observation, c) elevation difference between the location where the meteorological measurements were made and the fire spread location, d) slope and aspect of the fire spread location and e) surface fuels shading percentage.

Table 1. The values of the parameters of the four fuel models that were used as inputs for predicting surface fire rate of spread ($ROS_{predicted(surface)}$) with BehavePlus.

FUEL MODEL / **PARAMETER**	**Evergreen schlerophyllous shrublands (1.5 – 3.0 m)**	**Evergreen schlerophyllous shrublands (up to 1.5 m)**	**Phrygana II (*Sarcopoterium spinosum*)**	**Mediterranean grasslands**
1 HR (MTON/HA)	17.88	9.91	3.50	4.82
10 HR (MTON/HA)	13.30	6.80	1.02	0.49
100 HR (MTON/HA)	8.5	3.60	0.28	0
LIVE HERB (MTON/HA)	0	0	0	0
LIVE WOODY (MTON/HA)	10.60	7.70	0.85	0
1 HR S/V (1/CM)	55	55	65	78

LIVE HERB S/V (1/CM)	-	-	-	-
LIVE WOODY S/V (1/CM)	55	55	65	-
FUEL BED DEPTH (CM)	203.58	102.19	40.00	27.53
EXT MOISTURE (%)	34	34	20	14
HEAT CONTENT (J/G)	20000	20000	19054	18600

The 10-h dead FMC value was assumed equal to the 1-h dead FMC also (Andrews *et al*., 2005) (which is a commonly applied and acceptable approach) while the necessary 100-h dead FMC% and live woody FMC% values were assigned according to values of unpublished measurements in Attica for that time period and year.

Figure 5(a). Tall maquis fuel model

Figure 5(b). Short maquis fuel model

Figure 5(c). Phrygana II fuel model

Figure 5(d). Grass fuel model

The 26 surface fire behaviour observations in phryganic areas included 26 $FL_{observed}$ values that consist a complete subset which could be compared with predictions ($FL_{predicted}$ values) that were obtained using the fuel model "Phrygana II (*Sarcopoterium spinosum*)".

Results

The maximum, minimum, mean and standard deviation of $ROS_{observed(surface)}$ values for the subsets of 38, 13, 26 and 18 observations, referring to surface fire behaviour during pure surface fires or passive crown fires, are reported in table 2.

Table 2. Descriptive statistics summary of surface $ROS_{observed(surface)}$ values for the four fuel types (N:number of observations / cases)

ROS values (km/h)	**Tall maquis N = 38**	**Short maquis N = 13**	**Phrygana II (dominant species: *Sarcopoterium spinosum*) N = 26**	**Grass N = 18**
max	3.31	1.65	2.71	11.03
min	0.09	0.05	0.02	0.04
mean	0.90	0.45	0.54	1.95
std. deviation	0.80	0.45	0.59	3.28

The pairs of rate of spread observed values ($ROS_{observed(surface)}$) and BehavePlus predicted values ($ROS_{predicted(surface)}$), were correlated via linear regression, for every fuel model subset, resulting in the four following equations. The plots of these equations are shown in figure 6.

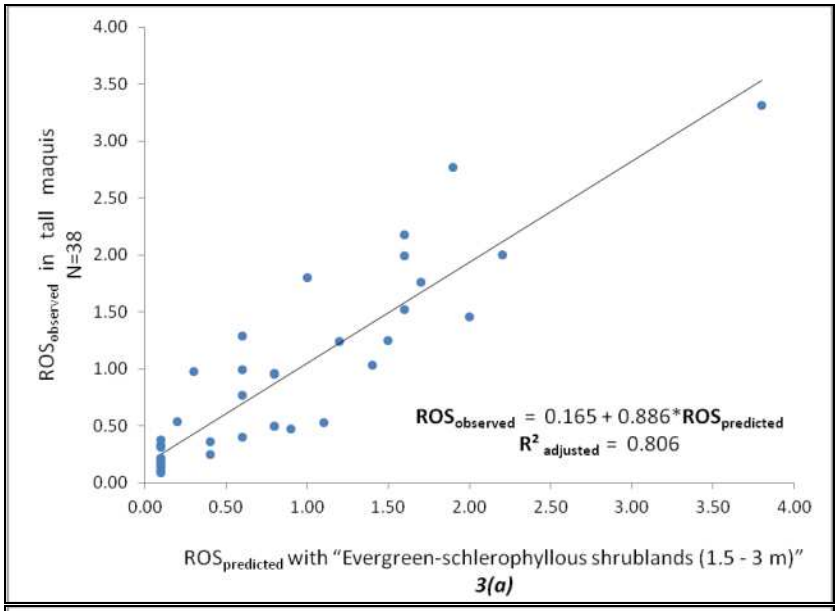
$$\mathbf{ROS_{observed} = 0.165 + 0.886 * ROS_{predicted}},\ \text{adjusted } \mathbf{R^2 = 0.806}, \text{ (tall maquis)} \quad (1)$$

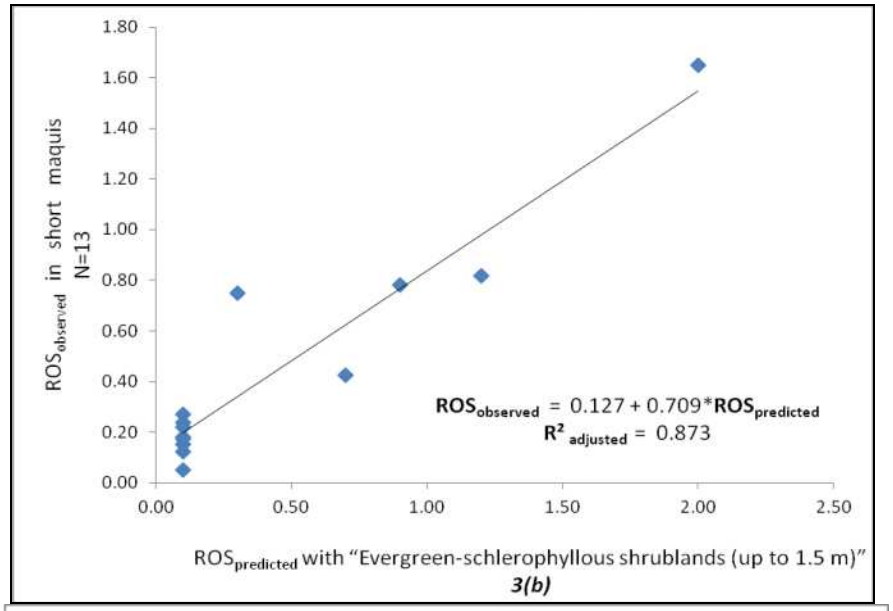
$$\mathbf{ROS_{observed} = 0.127 + 0.709 * ROS_{predicted}},\ \text{adjusted } \mathbf{R^2 = 0.873}, \text{ (short maquis)} \quad (2)$$

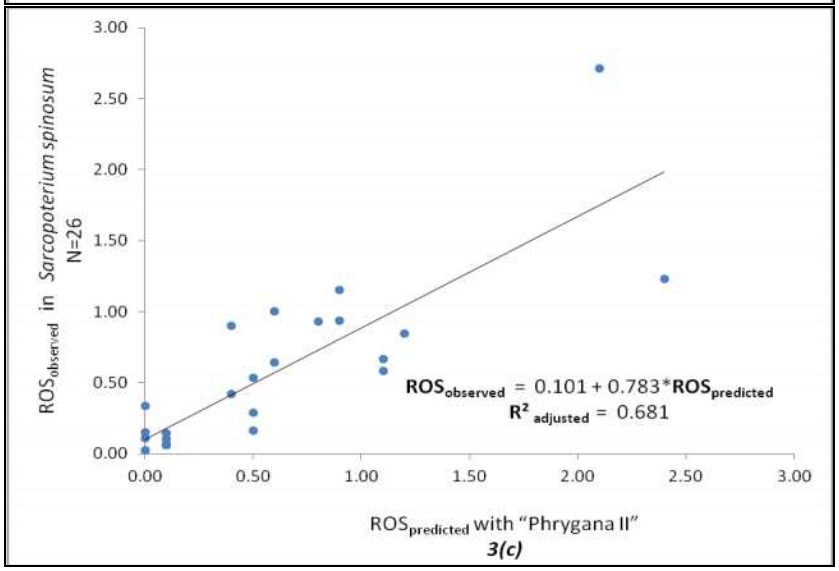
$$\mathbf{ROS_{observed} = 0.101 + 0.783 * ROS_{predicted}},\ \text{adjusted } \mathbf{R^2 = 0.681}, \text{ (*Sarcopoterium spinosum*)} \quad (3)$$

$$\mathbf{ROS_{observed} = -0.023 + 1.562 * ROS_{predicted}},\ \text{adjusted } \mathbf{R^2 = 0.847}, \text{ (grass)} \quad (4)$$

The four equations are statistically significant ($p<0.001$) and the p-values of their slope coefficients are statistically significant ($p<0.001$). The p-values of the constants of equations (1), (3) and (4) are not statistically significant ($p\text{-value}_1=0.052$, $p\text{-value}_3=0.266$ and $p\text{-value}_4=0.950$, respectively) while the p-value of the constant of equation (2) is statistically significant ($p\text{-value}_2=0.046$).
The adjusted R^2 values of the regression equations (1), (2) and (4) indicate that their unexplained errors are low while the adjusted R^2 value of equation (3) shows that the unexplained error is relatively higher. This is probably the result of using this fuel model to describe fuel situations and complexes of significant heterogeneity (figure 6c).
The ROS data subsets analysis was followed by a preliminary investigation that concerned the FL of surface fires in phryganic areas (figure 7). Plotting the observed and predicted FL values for the 26 cases in this subset it became clear that in only two cases $FL_{observed}$ was lower than $FL_{predicted}$. The ratio between $FL_{observed}$ and $FL_{predicted}$ varied between 0.3 and 5.0 with an average value of 2.3 and a standard deviation of 1.2. In general, $FL_{observed}$ values were more than twice the values of $FL_{predicted}$ for the fuel model Phrygana II.







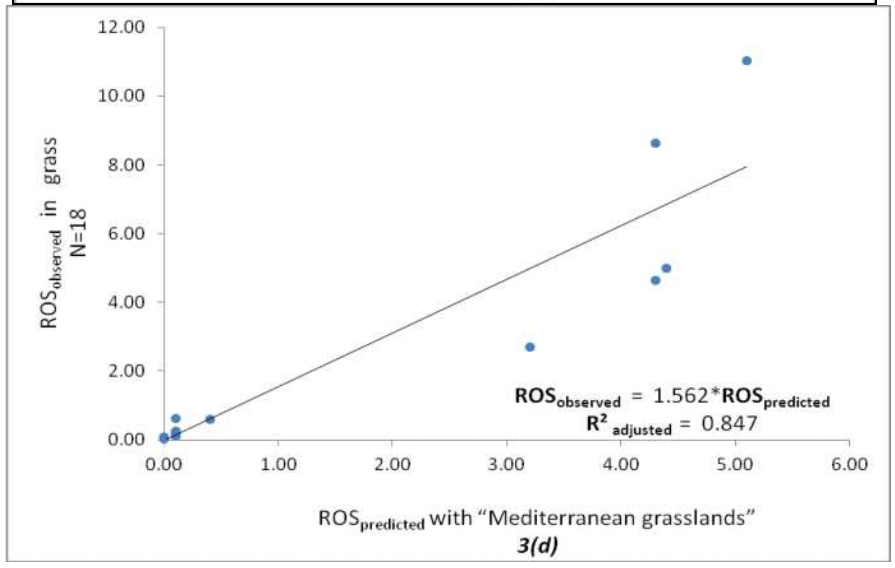


Figure 6 (a), (b), (c) & (d): – Correlations of surface $ROS_{observed}$ and $ROS_{predicted}$ values (in km/h) for the four data subsets

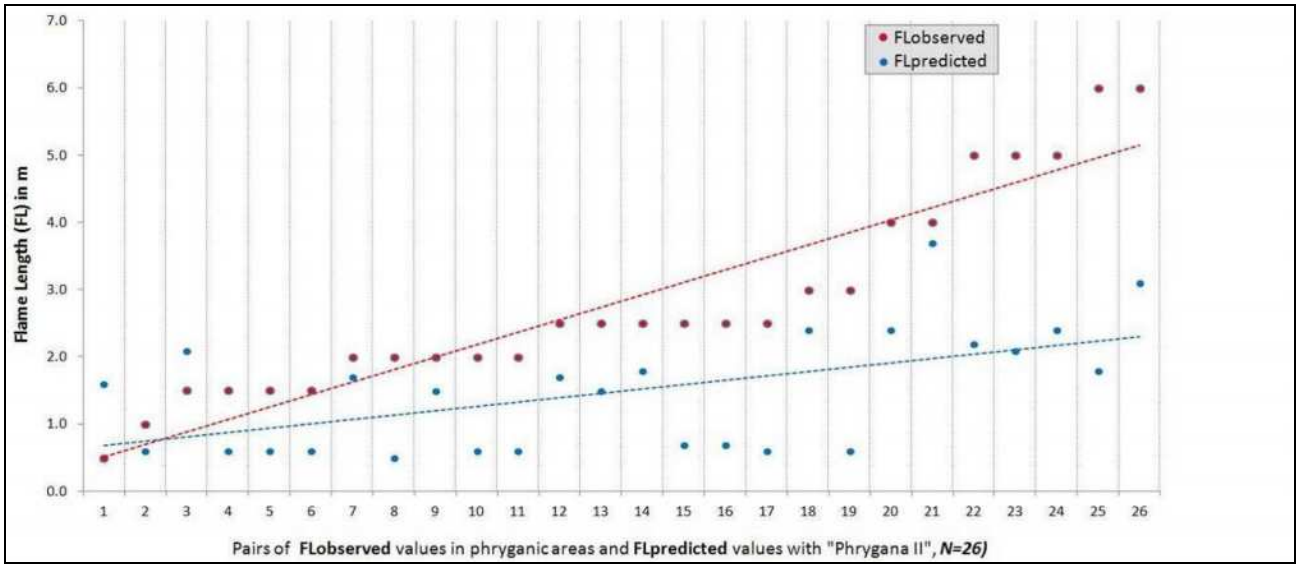

Figure 7. Plot of observed and predicted flame length for Sarcopoterium spinosum dominated phrygana fields. The pairs of values are sorted in ascending order of $FL_{observed}$.

Discussion

The pairs of $ROS_{observed(surface)}$ values and BehavePlus $ROS_{predicted(surface)}$ values, were correlated via linear regression for each of the data subsets, resulting in four statistically significant ($p<0.001$) equations with good adjusted R^2 values. The p-values of their slope coefficients were also statistically significant ($p<0.001$). This was not true for the constants of the equations for tall maquis, *Sarcopoterium spinosum* and grass, whereas the constant of the equation for short maquis was statistically significant. The non-significance of the constants of the three equations means that this term is not significantly different from 0.

The unexplained error of the equations was low for the short and tall maquis as well as for grass but was higher for the quite flammable xeric shrub *Sarcopoterium spinosum*. This higher unexplained error may be attributed to the fact that the fuel model "Phrygana II (*Sarcopoterium spinosum*)" was used to describe relatively heterogeneous fuel situations, including for example a variable percentage of other phryganic species such as *Cistus creticus*, *Cistus salvifolius*, etc.

Table 3 shows the calculated $ROS_{observed(surface)}$ values from solving the four equations for a range of plausible $ROS_{predicted(surface)}$ values, providing an insight on the degree of agreement of predictions vs observations for the level of accuracy that is required in operational applications. From this table it becomes clear that the agreement for the fuel model "Evergreen-schlerophyllous shrublands (1.5 - 3 m)" is very good, confirming the conclusions of Athanasiou and Xanthopoulos (2010). Due to this good agreement it seems unnecessary to adjust BehavePlus ROS predictions to the somewhat lower "real world" values that would result from corrections based on equation (1).

The agreement for the "Evergreen schlerophyllous shrublands (up to 1.5 m)" and for the "Phrygana II" models is also relatively good although it is clear that BehavePlus predictions are quite higher than the ROS observations. Because of this over-prediction it is advisable, when obtaining ROS estimates for fires in these two fuel models, to adjust these estimates using equations (2) and (3) respectively. It should be mentioned here that equation (2), in spite of its good adjusted R^2 value and the fact that its constant and slope coefficient are statistically significant, should be considered as preliminary. The number of observations that were analysed was small (N=13) so the result does not inspire confidence for broad operational use. Further work is needed for this fuel type.

Table 3. Solution of equations (1)-(4) for a range of values of $ROS_{predicted(surface)}$ (km/h).

	ROSobserved(surface)			
ROSpredicted(surface)	Tall maquis	Short maquis	Phygana II	Grass
0	0.165	0.127	0.101	-0.023
1	1.051	0.836	0.884	1.539
2	1.937	1.545	1.667	3.101
3	2.823	2.254	2.450	4.663
4	3.709	2.963	3.233	6.225
5	4.595	3.672	4.016	7.787
6	5.481	4.381	4.799	9.349
7	6.367	5.09	5.582	10.911
8	7.253	5.799	6.365	12.473
9	8.139	6.508	7.148	14.035
10	9.025	7.217	7.931	15.597

In the case of grasslands, table 3 shows that BehavePlus strongly underpredicts ROS. As equation (4) is statistically significant and its adjusted R^2 value is high ($R^2_{adjusted}$ = 0.847), this under-prediction should be taken into consideration when using BehavePlus for ROS prediction in grasslands with the Greek grass fuel model. Equation (4) should be used for obtaining adjusted $ROS_{observed(surface}$ i.e. "real world" ROS estimates.

The analysis of flame length in phryganic areas showed that on average $FL_{observed}$ was 2.3 times greater than the $FL_{predicted}$ values obtained through BehavePlus using the Phrygana II fuel model. The FL predictions tended to underestimate notably the actual FL that was measured in the field. There were only two exceptions, out of the twenty six cases, in which $FL_{predicted}$ was greater than the $FL_{observed}$ value (figure 7).

Underestimating the expected FL in phrygana is a serious problem for another reason as well: as shown in figure 7 the underestimation takes place in a narrow band of FL values that includes the FL threshold value of 1.2 m which is considered as the limit for direct attack on the flames with hand tools (Deeming *et al*., 1977, Hirsch and Martell, 1996). For ten out of the twenty six cases the prediction value was lower than the hand tools threshold value while the actually observed flame length was greater than that.

Phrygana have been the cause of many firefighting accidents in Greece as they are flashy fuels and respond very quickly to changes of the environmental conditions (wind, topography, relative humidity) (Xanthopoulos, 2007). The reliability of FL predictions for a wide range of meteorological conditions, topography and fuel situations is crucial and mandatory since flame length affects the personnel extinguishment capacity and FL predictions inaccuracy could jeopardize the safety of the firefighters in these fine, quite flammable and flashy fuels.

Conclusions

The main finding of the work presented here is that for the four Greek fuel models tested, BehavePlus can be a useful tool for predictions of fire behaviour. However, there is a relatively consistent over-prediction of ROS for the models "Evergreen-schlerophyllous shrublands (1.5 - 3 m)" for tall maquis, "Evergreen schlerophyllous shrublands (up to 1.5 m)" for short maquis (13 cases), and "Phrygana II (*Sarcopoterium spinosum*)", while there is a significant under-prediction for the "Mediterranean grasslands" fuel model.

The four linear regression equations that were developed are statistically significant and can be used for adjusting BehavePlus predictions to match "real world" fire behaviour, at least as documented in

the present study. Such an adjustment could also be incorporated in fire spread simulation systems used in Greece.
The finding that flame length is seriously under-predicted when using BehavePlus with the Phrygana II fuel model to predict fire behaviour in Sarcopoterium spinosum dominated phrygana fields is an important result that can be very useful for the safety of firefighters. It should be seriously taken into consideration in operational firefighting in the country.
Future work, as data continue being collected and the data base is expanded, are expected to shed additional light in the issues discussed in this paper, ultimately improving fire behaviour prediction and firefighter safety in Greece.

7. Aknowledgements

The research reported here is part of the Ph.D. thesis of the first author and was sponsored, in part, by the International Association of Wildland Fire (IAWF) through the Doctoral Student Scholarship Award for 2014. Participation of the second author was supported by a research project of the Institute of Mediterranean Forest Ecosystems and Forest Products Technology (IMFE&FPT) titled "Forest fuels standardization and management methodology in Attica"; The project was co-funded by the European Regional Development Fund (ERDF) through the Greek General Secretariat for Research and Technology (Project code: ATT-63), and also by a research project of IMFE&FPT titled "Investigation of the relation between the water potential of forest plants and forest fires".

Abstract

The relationship between fire behaviour and ambient wind flow is often presumed, but seldom measured. General understanding of observed fire behaviour suggests an increase in fire intensity associated with increased wind speed (Van Wagner 1987, Rothermel 1991, Finny *et al*. 2006, Forthofer 2007). Fire behaviour characteristics (such as temperature, radiant and total heat flux, 2- and 3-dimensional velocities, and air flow) are extremely difficult to measure in-situ (Jimenez *et al*. 2007). Studies base on these phenomena often correlate empirical data either from observed wildland fire or laboratory experiments, but few data sets exist that capture ambient wind flow simultaneously with corresponding in-situ fire behaviour measurements.

This paper reports on the corresponding fire behaviour and wind field relationship on six field study plots that were instrumented with several fire behaviour packages (Butler el al. 2004), and a network of wind anemometer towers deployed around the perimeter of each plot. The study plots were part of the Prescribed Fire Combustion and Atmospheric Dynamics Research Experiment (RxCADRE) 2012 field campaign, with the objectives aimed at developing synergies between fuels, fuel consumption, fire behaviour, smoke management, and fire effects measurements for fire model development and evaluation.

Keywords*: Fire behaviour, prescribed fire, surface wind flow, anemometer, thermograghy*

Introduction

Fire-atmosphere interactions (FAI) are defined as the interactions between presently burning fuels and the atmosphere, in addition to interactions between fuels that will eventually burn in a given fire and the atmosphere (Potter 2012). Currently, much of the meteorological sampling for fire behaviour applications and science is performed at a very coarse resolution (i.e., hundreds of meters to kilometers), such as the standard Remote Automated Weather Stations (RAWS) networks in existence throughout the United States (Horel and Dong 2010). Additionally, these data are often captured or averaged at a coarse time resolution (i.e., hourly to daily), although surface flows are constantly fluctuating.

Wildland fire researchers have recognized the benefit of in-situ measurements of fire intensity and behaviour as a critical component in the effort to develop improved fire management decision support models. Past measurements consisted primarily of observations of rate of spread, gas temperatures, and fuel consumption, and have been both field based (Barrows 1951; Cheney *et al*. 1993; Fons 1946) and laboratory based (Catchpole *et al*. 1998; Fons 1946; Rothermel 1972). New mathematical models include additional physics which has led to the need for additional measurements, particularly of the basic heat and chemical processes occurring in fire in addition to the local surface wind flow.

Recent studies have focused on understanding the role of both radiative and convective energy transport to wildland fire ignition and spread (Morandini and Silvani 2010).

When considering relationships between energy transport in wildland flames and particle ignition it is unclear how small particles respond to temporal fluctuations in the heating source. Thus the temporal characteristics of the heating regime are relevant to increased understanding of wildland fire behaviour (Frankman *et al*. 2012)

There is an increasing need to measure fire-atmosphere interactions at finer scales in order to better understand the role of near-surface wind and thermodynamic structures of fire behaviour (Clements *et al*. 2007). While useful at a landscape scale and possibly for the largest fires, both spatial and temporal scales of near-surface wind and thermodynamic structures presently are highly generalized. Interpolation between these sparsely dispersed points does not consider the spatial heterogeneity or micro-scale influences that impact the smaller fires on the landscape, nor do they capture the fluctuations at a fine temporal scale.

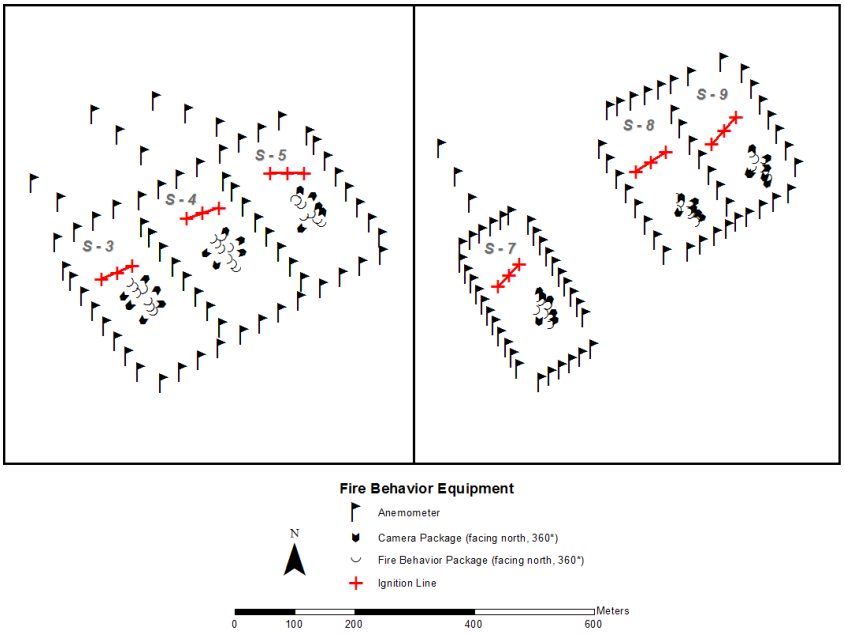

Figure 1. Equipment layout for the six 100mx200m plots.

For this study, six plots (S3, S4, S5, S7, S8, S9) measuring roughly 100m x 200m, and oriented in a northwest/southeast (long-axis) alignment, were highly instrumented in order to capture time-resolved surface wind flow and corresponding in-situ fire behaviour (Figure 1). The plots were chosen and aligned based on generally homogenous fuels and predicted general wind direction. Plots S3, 4, and 5 were in a predominantly grass fuel type, while plots S7, 8, and 9 were in a predominantly grass/shrub fuel type. Multiple cup-and-vane anemometers were set up with 20m spacing around each plot, with adjacent plot edges sharing anemometers. Additionally, five to seven in-situ fire behaviour packages (FBPs) recording heat flux, air temperature, and 2-D mass flow at 10Hz were deployed within each of the plots in order to characterize the fire behaviour throughout plot ignition. Finally, visible and infrared 1Hz-averaged imagery were collected from an elevated 26m platform located at the upwind edge of each plot. All instruments were synchronized to Greenwich Mean Time (GMT).

Methods – Surface Wind Field Measurements

The six replicate burn blocks were burned during two separate burning periods. Three of the replicates (S3, S4, S5) were individually burned on November 1, 2012; the other three replicates (S7, S8, S9) were individually burned on November 7, 2012. In order to provide a continuous flaming front, two

lighters with drip torches uniformly and rapidly ignited the burn blocks, starting at the middle point of the ignition line and simultaneously working in opposite directions toward both ends; these points are marked in Figure 1. Detailed fuels, fuel consumption, fire behaviour, heat flux, and fire effects data were collected on the plots before and during the burns. Table 1 provides instrumentation and ignition specifics for each replicate burn block.

Surface wind and surface fire behaviour measurements were collected on all burn units. Multiple cup-and-vane anemometers (S-WCA-M003, Onset Computer Corporation) were set up with approximately 20m spacing around each small plot, with adjacent plot edges sharing anemometers (Figure 1; Table 1). These instruments measure wind speed and direction at 3.3m above ground level (AGL); the data are used to characterize surface flow patterns before and during the burns. Cup revolutions and unit vector components are accumulated every three seconds for the duration of the logging interval. Wind speed is the average speed for the entire logging interval (0-44 m/s ± 0-4%). Gust speed is the highest three-second wind recorded during the logging interval. Average direction is calculated from the average of the vector components (0-358 º ± 5º).

Methods – In-Situ Energy Measurements

In-situ fire behaviour was measured using portable fire behaviour packages (FBPs) developed at the US Forest Service, RMRS Fire Science Lab. The FBPs measure air temperature during fire passage, radiant and convective heat flux emitted from the flames and horizontal and vertical air flow. The sensor package measures 27 cm by 15 cm by 18 cm and in its current configuration weighs approximately 5.3 kg. Various enclosure materials consist of 0.37mm thick aluminium welded at the seams. A 12 volt 4.5 Ah sealed lithium polymer battery provides power to the sensor array and data logger. The data loggers used are Campbell Scientific® model CR1000 and are capable of logging over one million samples, providing 3.5 hours of continuous data logging at 10 Hz. This logger is user-programmable and accepts a wide range of analog and digital inputs and outputs. All of the FBPs incorporate a Medtherm® Dual Sensor Heat Flux sensor (Model 64-20T) that provide incident total and radiant energy flux, a type K fine wire thermocouple (nominally 0.05 mm diameter wire) for measuring gas temperature, a custom designed narrow angle radiometer (Butler 1993) to characterize flame emissive power, and two pressure based flow sensors (McCaffrey and Heskestad 1976) to characterize air flow. Table 2 provides details about individual sensors and their engineering specifications.

Table 2. In-situ Fire Behaviour Package (FBP) Specifications

Narrow Angle	
Sensor	20-40 element thermopile
Spectral Band of Sensor	0.15 – 7.0 μm with sapphire window
Field of View	~4.5º controlled by aperture in sensor housing
Transient Response	Time constant of sensor nominally 30msec
Units of Measurement	Calibrated to provide emissive power of volume in FOV in kW/m^2
Total Energy Sensor	Medtherm Corp® Model 64-20T Dual total Heat Flux Sensor/Radiometer
Sensor	Schmidt-Boelter Thermopile
Spectral Band of Sensor	All incident thermal energy
Field of View	~130º controlled by aperture in sensor housing
Transient Response	< 290msec
Units of Measurement	Total heat flux incident on sensor face in kW/m^2
Hemispherical Radiometer	Medtherm Corp® Model 64-20T Dual total Heat Flux Sensor/Radiometer
Sensor	Schmidt-Boelter Thermopile (Medtherm Inc)
Spectral Band of Sensor	0.15 – 7.0 μm with sapphire window
Field of View	~130º controlled by window aperture
Transient Response	< 290msec
Units of Measurement	Radiant energy incident on sensor face in kW/m^2
Air Temperature	
Sensor	Type K bare wire butt welded thermocouple, new, shiny, connected to 27ga lead wire
Wire Diameter	0.05mm
Bead Diameter	~0.08-0.13mm
Units of Measurement	Degrees Celsius
Air Mass Flow	
Sensor	SDXL005D4 temperature compensated differential pressure sensor
Pressure Range	0-5 in H_2O
Sensor Design	Pressure sensor is coupled to custom designed bidirectional probe with ±60º directional sensitivity.
Units of Measurement	Calibrated to convert dynamic pressure to velocity in m-s-1 assuming incompressible flow
Sensor Housing	150× 180 × 270 (mm)
Housing Weight	7.7 kg
Insulation Material	Cotronics Corp® 2.5cm thick ceramic blanket
Tripod Mount	½ inch female NCT fitting permantly mounted to base of enclosure.
Power Requirements	12V DC
Power Supply	Rechargeable Internal Battery
Data Logging	Campbell Scientific Model CR1000
Sampling Frequency	Variable but generally set at 10 Hz

The sensors were calibrated prior to deployment as described elsewhere (Butler and Jimenez 2009). Integration of the heat flux time histories can provide a measure of fire total, radiative and convective energy per unit area as a function of heating time. In all cases the FBPs were positioned to sense fire from the expected spread direction (e.g., facing the oncoming fire front) based on wind direction, terrain, and lighting procedures. All FBPs were located nominally 1.0 m above the mineral soil.
Incident radiant and total heat flux at the surface of the FBPs were evaluated to determine convective heating at the sensor face (Frankman *et al.* 2010). The fine wire thermocouple has a response time of approximately 0.01 s and was used to sense flame presence and flame residence time. Flame arrival at the FBP was indicated by a nearly vertical increase (~3000-5000°C/s) in temperature to several hundreds of degrees above ambient. This temperature increase was almost always associated with a nearly instantaneous increase in heat flux at the sensor (4 to 25 $kW/m^2/s$). The completion of the flame event was indicated by a rapid decay in air temperature. In some cases the thermocouple failed, in which case the radiometer data alone was used to gauge the arrival and completion of flaming combustion. Flame radiative and convective energy were calculated by integrating the respective signals over the period of flaming combustion.

Methods – Infrared Thermography Measurements

Visible and near infrared (IR) imagery were captured using cameras situated on a 26 m boom lift. To lessen the likelihood of unburned fuels obscuring the IR signal from the fire, the lift was located 10-25 m from the control lines demarcating the small units; it was positioned at the centre of and perpendicular to the ignition line upwind of the units in all cases except S9. Prior to ignition of each plot, an image of the plot indicating the ambient temperature range (0-300 C) was collected. The oblique IR imagery was collected using a FLIR Inc SC660. The SC660 has a focal plane array resolution of 640 x 480 pixels, a sensitivity of 0.03°C, spatial resolution of 1.3 mrad and a thermal accuracy of ± 2%. The field of view of the oblique imagery covered the majority of the area of the small burn blocks and captured the entire fire perimeter from ignition until the fire passed the central instrument cluster and/or reached the downwind control line. Emissivity was set at 0.98 and the air temperature and relative humidity were noted for post processing. The temperature range for all cameras during the fires was set to 300-1500°C for collecting active fire IR data. High definition digital visual imagery was collected before and during the fire from video cameras located adjacent to the IR cameras. Post-processing resolution of this imagery is 1m x 1m.
Twelve ground control points for each small burn block were identified using surveyed positions of hot targets, instruments, and ignition points. The pre-fire IR image was critical for identifying ground control points.
For all IR imagery, the native file format was converted to an ASCII array of temperatures in K with rows and three columns where x,y,z = pixel row, pixel column, and temperature. Temperatures were then converted into W m^{-2} using the Stefan-Boltzmann equation for a gray body emitter. Mean residence time was calculated as the average amount of time a pixel was measured to be >525°C (Draper point) and maximum residence time was the maximum number of times a single pixel was measured to be >525°C.
For the oblique platform, images were processed using Python 2.7 programming language and rectified using GDAL (Geospatial Data Abstraction Library, 1.10.1, www.gdal.org). Once rectified, each image was converted back to radiometric temperature values, by back calculating using the previous equations, and estimates of fire radiative power (FRP) by pixel were calculated using the Stefan-Boltzmann Law for a grey body emitter.
Fire pixel values were summed across units at each time step to give total fire radiative energy (FRE) for the whole fire. Total fire radiative energy density (FRED) was calculated across oblique IR images (Figure 2). The total FRED images visually illustrate the area recorded by the oblique IR camera, as well as the distortion caused by the oblique angle.

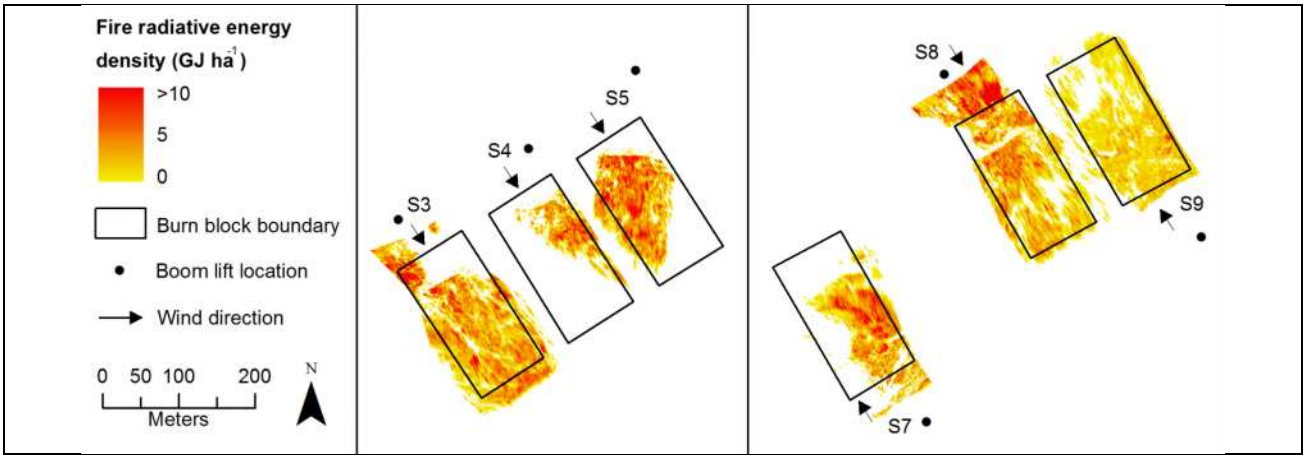

Figure 2. *Total FRED (GJ ha^{-1}) across oblique IR imagery.*

Results and Discussion

The aim of the RxCADRE campaign effort was to simultaneously acquire fine- to coarse-scale fuels, weather, and fire behaviour information during a suite of low-intensity prescribed fire experiments. This paper outlines a dense instrumentation network designed to measure the fine-scale meteorology within and around each burn block and couple that with fire behaviour and effects.

Preliminary results suggest that multiple fire behaviour and fire weather platforms can successfully capture small scale fire and terrain induced fluctuations, which may influence local fire-atmosphere interactions at the fire front. Initial analyses of the cup-and-vane anemometer data suggest that the relatively low fire intensity may not have been powerful enough to influence local weather conditions, as wind speed and direction differences related to the passage of the fire front were not detectable within the gridded surface level anemometer array. Table 3 outlines the overall average wind direction and speed, as well as the minimum and maximum wind speed, measured during each burning period for each of the six plots.

Table 3. Overall measurements for the cup-and-vane anemometer

Plot	Average Wind Direction, ø	Average Wind Speed, mph	Minimum Wind Speed, mph	Maximum Wind Speed, mph
S3	275.66	5.29	0.00	14.94
S4	275.06	7.65	0.00	18.03
S5	251.12	6.51	0.00	16.20
S7	274.69	8.08	0.00	19.15
S8	292.35	9.01	0.00	21.97
S9	270.30	9.03	0.00	21.59

For this study fire intensity was measured both in-situ by FBPs and remotely from IR cameras on an elevated oblique angle platform. The fire behaviour per unit (e.g., each of the six plots) is further interpreted using visual observations of flame properties; derived rate of spread values (based on observations of visual video footage, calculations based on infrared images, and fire time of arrival at fire behaviour packages); air temperature measurements; total and radiant energy measured incident on the in-situ FBPs; and derived values for fire radiative energy and fire convective energy.

Table 4 presents measurements derived from the FBP data for each of the six replicate burn blocks. These measurements include average radiative heat flux over the flaming period (Q_R), average convective flux over the flaming period (Q_C), average total heat flux at sensor for the flaming period

(Q_T), averaged flame emissive power from the narrow angle sensor (E_F), averaged kinetic air temperature (T_{air}) and averaged flame residence time from heat flux data (t_{flame}) for each of the burn plots. In general, the shrub/grass plots (S7,8,9) showed higher radiant, convective, and total heat flux, as well as higher emissive power than the grass plots (S3,4,5).
Table 5 outlines measurements derived from the oblique IR imagery for each of the six plots. Measurements include the active flaming duration, mean active flaming area, total area burned, total FRE, Mean FRP, Max FRP, and mean FRED. Total area burned is the mean number of $1m^2$ pixels burned at 1Hz (across IR images), and excludes unburned areas (pixels) within burn blocks.

Table 4. Averaged in-situ fire behaviour package data for each plot.

Plot	Average Radiant Heat Flux (kW/m^2)	Average Convective Heat Flux (kW/m^2)	Average Total Heat Flux (kW/m^2)	Average Flame Emissive Power (kW/m^2)	Average Kinetic Air Temperature (C)	Average Flame Residence Time (sec)
S3	7.5	5.9	12.1	23.0	821.6	103
S4	3.6	1.2	4.5	15.1	463	211
S5	3.7	5.5	8.6	14.5	682	12.3
S7	10.5	10.2	19.9	44.1	707	204
S8	12.9	12.5	23.7	42.8	922	122
S9	11.7	8.9	19.4	30.3	780.6	93

Table 5: Oblique IR imagery data for each plot.

Plot	Active flaming duration (min)	Mean (SD) active flaming area (m^2)	Total area burned (ha)	Total FRE (GJ)	Mean (SD) FRP (MW)	Max FRP (MW)	Mean (SD) FRED ($GJ\ ha^{-1}$)
S3	26	324 (286)	2.16	5.7	4.2 (3.8)	15.4	3.0 (2.5)
S4	20	88 (86)	0.50	1.3	1.2 (1.4)	5.5	3.0 (2.5)
S5	29	289 (203)	1.14	5.9	3.9 (3.0)	14.0	3.9 (2.9)
S7	29	150 (217)	1.14	3.1	2.1(3.3)	18.8	3.0 (2.6)
S8	23	353 (356)	2.31	6.3	5.1 (6.7)	41.4	3.0 (3.1)
S9	17	177 (173)	1.82	1.9	2.0 (2.0)	7.8	1.2 (1.0)

Comparisons between the in-situ fire behaviour measurements and oblique IR are not complete and therefore are not presented in this paper. However; the in-situ point source data show slightly greater heat flux measurements in plots S7-S9 which is in alignment with the grass/shrub fuel complex versus the dominant grass fuel component in plots S3-S5. A similar trend is not as apparent in the oblique IR data.
The calculations and analysis used between point source measurements (FBPs) and landscape scale measurements (IR) show promising similarities and it is our belief that the two techniques provide in depth detail pertaining to the micro scale fire environment. In these six low intensity grass fires, the interactions between fire behaviour and ambient wind flow are non-existent or difficult to detect. However, similar replicated measurements in a high intensity shrub or forest fire might elucidate some relationship between fire behaviour and micrometeorology. From this study we hope to determine that precise measurements at multiple scales in space and time are important for capturing and understanding the variability associated with both large and small scale fires in terms of wind flow and fire behaviour.

Abstract
Bibliometrics allows to analyze on behalf of literature searches the existing knowledge around a specific topic and identify tendencies in its development. Tropical forests are characterized naturally by a low regime of fires. However human activities have dramatically changed this phenomenon. Since tropical rain forests are a hot spot of world's diversity, we conducted a bibliometric study of occurrence and effects of fires in tropical rain-forests. The aim of this work is to identify the main tendencies in biological literature about this subject, diagnose knowledge areas with a poor development and to define the geographic location of the performed studies and their methodological approach. This analysis will allow to identify the main gaps in the research of fires in tropical rain forests and contribute to direction the following research projects. We retrieved more than 2000 documents of indexed journals from the following bibliographic databases: Web of Science, Scopus, Science Direct, Biosis and Zoological abstracts. We selected the papers of words related with forest fires and tropical rain forests by an advanced search using logic and boolean operators. We considered for this study the fields: the document title, authors, adscription institution, publication year, journal name,
Keywords and descriptors, country, knowledge area and abstract. With this information we designed and normalized the database. Then, we considered all the papers focused on the study of fires in tropical forests and we classified other works that not specifically worked on fires but mention it as an important element of their studies. We did this by looking for the words "fire" and "tropical forest" in the
Keywords and abstracts. Then we analysed the documents by their geographic location and by the field of knowledge. We found an increasing interest in this topic in the scientific community since early 1950 to the present. The journals with more works in the theme were Forest ecology and management and Biotropica. We consider that this bibliometric review will help to the decisions making.

Keywords*: publication temporality, authors, indexed journals, knowledge fields, study site locations, bibliometrical studies*

Introduction

The generation of new information has impacted scientific work since the appearance of computers and the development of software. This technology allows to analyze on behalf of literature searches the existing knowledge on a specific topic and to identify tendencies in its development (Michán-Aguirre and Muñóz-Velasco 2013). It known as bibliometrics, which is a set of methods to quantitatively analyze academic literature (Wilson 1999; Hull *et al*. 2008).
Forest fires are related with global warming, decrease of forested area, loss of biodiversity and an increase of erosion. There are a lot of ecological parameters that change after a forest fire like vegetation cover, density, structure, composition, diversity and productivity. Therefore, forest fires are recognized as an interesting topic among foresters. Tropical forests are characterized naturally by a low fire regime (Bowman *et al*. 2011). However, in the last decades forest fires have become increasing events in these fragile ecosystems (Cochrane 2001). This relationship has been widely explored in temperate and mediterranean forests where plants have adapted to fire.

Agricultural and ranching activities are highly associated with forest fires. It is known that swidden cultivation is still an important agricultural practice, especially in areas where intensive agriculture is not possible (Van Vliet *et al*. 2012). However, fire plays also an important role in many parts of the world where it induces land uses change to for example cattle production or the cultivation of biofuel plants.
Bibliometric studies have been used for example to understand the direction of several ecologic phenomena such as changes in diversity and impact of conservation strategies (Song and Zhao 2013), by studying the information process and its change over time (Young and Wolf 2006; Stork and Astrin 2014).

According to FAO (1993) tropical forests are located in tropical areas within different biogeographic origins. They have a high plant and animal richness and show a wide range in composition, structure, functionality and productivity. The evergreen tropical rain forests are located in regions where the total annual rainfall is greater than 2500 mm and the dry season is either short or inexistent.
Since tropical rain forests are a hot spot of world's diversity and lately have been increasingly affected by fire to induce land use change, the objective of this study is to know the state of the art of tropical rain forest fire research. In particular, we wanted to determine which countries that possess tropical rain forest have reported fires and how this subject is addressed by the scientific community. It is important to detect the causes of unusual fire regime in tropical forest and which are the expected changes. The aim of this work is to identify the main tendencies in biological literature about this subject, detect the knowledge gaps and to define the geographic location of the performed studies and their methodological approaches.

Methods

We retrieved articles of indexed journals published until April 2013 from the following bibliographic databases: Web of Science, Scopus, Science Direct, Biosis and Zoological abstracts. We selected the papers by an advanced search (filtered) using the logic and boolean operators AND, OR, NOT, ?, * and "" that included words related with forest fires and tropical rain forests (Figure 1). We considered for this study the following fields: (1) the document's title, (2) authors, (3) adscription institution, (4) publication year, (5) journal name, (6) keywords and descriptors, (7) country, (8) discipline and (9) abstract. With this information we constructed a database and normalized records eliminating all the papers that were within the scope of our objectives and completed and annotated all the nine fields. Pre-processing included duplicate deletion and pertinence selection. In addition, we selected the documents that mention in their title the word soil, as it is an important compartment that changes after a forest fire and we re-classified the soil types according to the WRB soil classification (IUSS, 2007). Then, we considered all the papers focused on the study of fires in tropical forests and we classified other works that not specifically worked on fires but mention it as an important element in their studies. We did this by looking for the words "fire" and "tropical forest" in the keywords and abstracts and all of their synonyms and homonyms which were defined utilizing the Cab Abstracts thesaurus. The results of the search were restricted to only articles from environmental disciplines. The whole process of the method is resumed in Figure 2.

TITLE-ABS-KEY ("Tropical rain forest" OR "Tropical timber*" OR "Tropics" OR "Tropical countr*" OR "Tropical climat*" OR "Tropical America" OR "tropical crop*" OR "Tropical burn weed*" OR "Tropical forest*" OR "Tropical dry forest*" OR "Tropical seasonal forest*" OR "Semi-evergreen seasonal forest*" OR "Deciduous seasonal forests" OR "Equatorial forest*" OR "Rain forest*" OR "Tropical rain forest*" OR "Tropical timber*" OR "Tropics" OR "Tropical countr*" OR "Tropical climat*" OR "Tropical America") AND TITLE-ABS-KEY ("Fire regime*" OR" Managed wild land fire*" OR "Prescribed natural fire*" OR "Prescribed fire*" OR "Natural fire*" OR "Wild fire*" OR "Wildfire*" OR "Let burn" OR "Manager-ignited fire*" OR "Wild land fire*" OR "Burn*" OR "Ignition*" OR "Shifting agriculture*" OR "Shifting cultivation*" OR "Hot spot*" OR "Indian fire*" OR "Slash-and-burn*" OR "Fire*" OR "Slash and burn*" OR "Ash*" OR "Fuel*" OR "Fire trend*" OR "Fire *adapted" OR "fire-*" OR "Fire regime*" OR "Managed wild land fire*" OR "Prescribed natural fire*" OR "Prescribed fire*" OR "Natural fire*" OR "Wild fire*" OR "Wildfire*"OR "fire history" OR "fire trend*")*

Figure 1. Terms and algorithms used in the advanced search

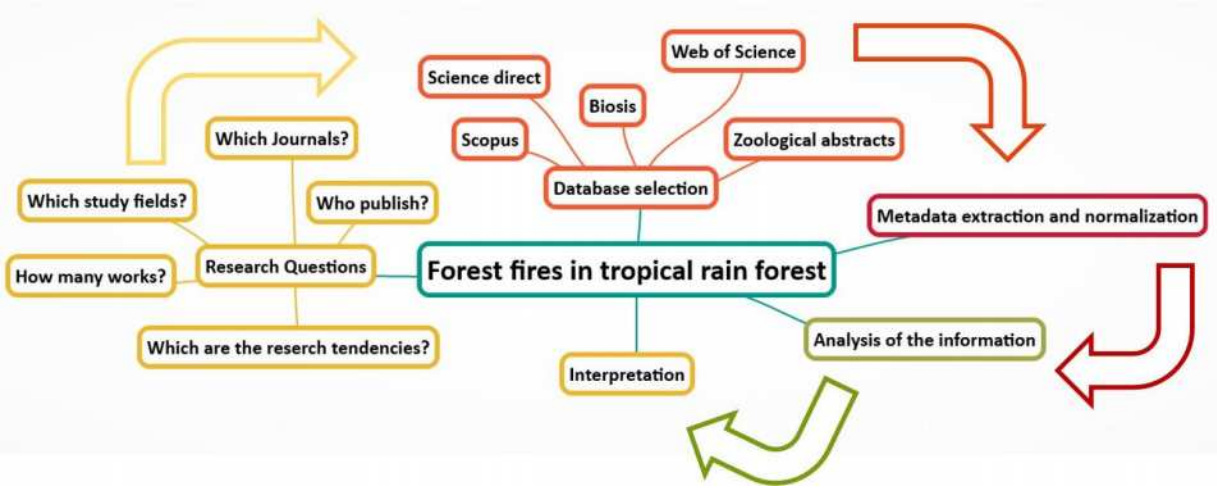

Figure 2. Stages of the documental research

Statistical analysis

Absolute and relative frequencies of the above fields were obtained. We analysed the documents by their geographic location and by field of knowledge. We also calculated the frequency of words appearing in the title and keywords of the documents to see which are the main fields addressed by the scientific community. We conducted a keyword analysis, by calculating the probability to find one word by inserting another one.

3. Results

In total we recorded 2000 publications. The following results belong to the analysis of these records. Reports on fires in tropical rain forests started in 1960. From the beginning of the 1980's articles on fire in tropical rain forests have been growing steadily. This growth pattern is shown for papers that either just report a forest fire in a tropical forest (N = 1982) or focus specifically on this phenomenon (N = 498) (Figure 3).

Research about tropical rainforest fires was conducted in 42 countries. Most of these studies have been done in the American continent (49.34 %), followed by Asia (26.54 %), Australia (15.79 %) and Africa (8.33 %). The most productive countries of each region were Brazil (141), Venezuela (18) and México (16) for America; Indonesia (55), India (25) and Malaysia (23) for Asia; Australia (63) for Australia

and Cameroon (10) and Madagascar (7) for Africa. However, the distribution in the number of these studies does not reveal which countries have more forest fires in their corresponding tropical rainforests. Tropical rain forest are decreasing their area due to deforestation and in many cases fire is a tool that facilitates the advance of agriculture. Figure 4 shows the remains of tropical forests distributed around the world. The Amazon, for example is the greatest area covered with rainforest in the world, and also one of the regions in which forest fires are most studied. Although, this is not related with the real number of forest fires in this area, but rather is related with the number of investigations conducted in these areas. These data show that rather few studies exist on fire studies in these forests, in which plants have not adapted to cope and to recover after a fire and in consequence allows exotic plants to disseminate.

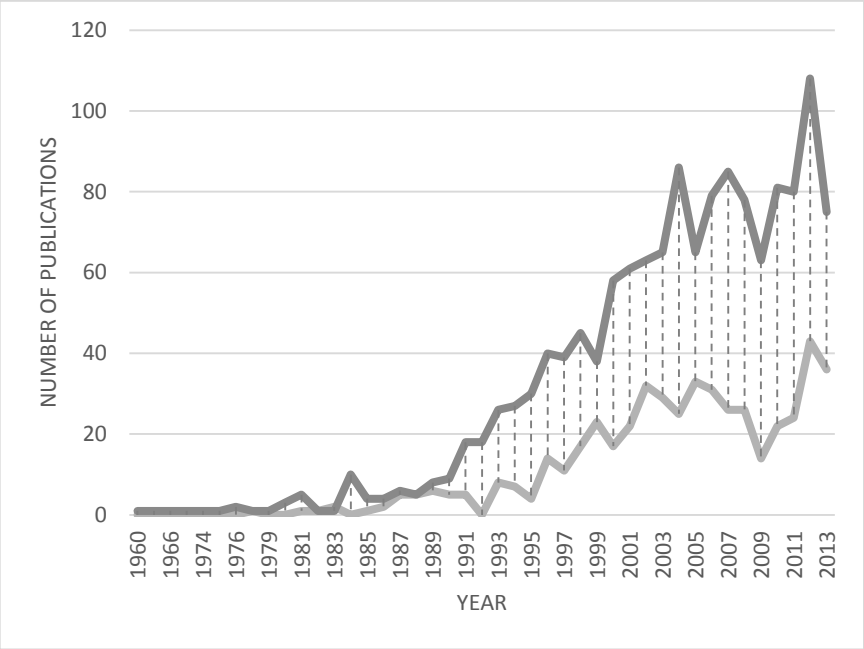

Figure 3. Temporal variation in the number of publications. Lines in dark grey denote studies in which forest fires are mentioned (N = 1982), and lines in light grey represent publications focused on tropical rainforest fires until April 2013 (N = 498).

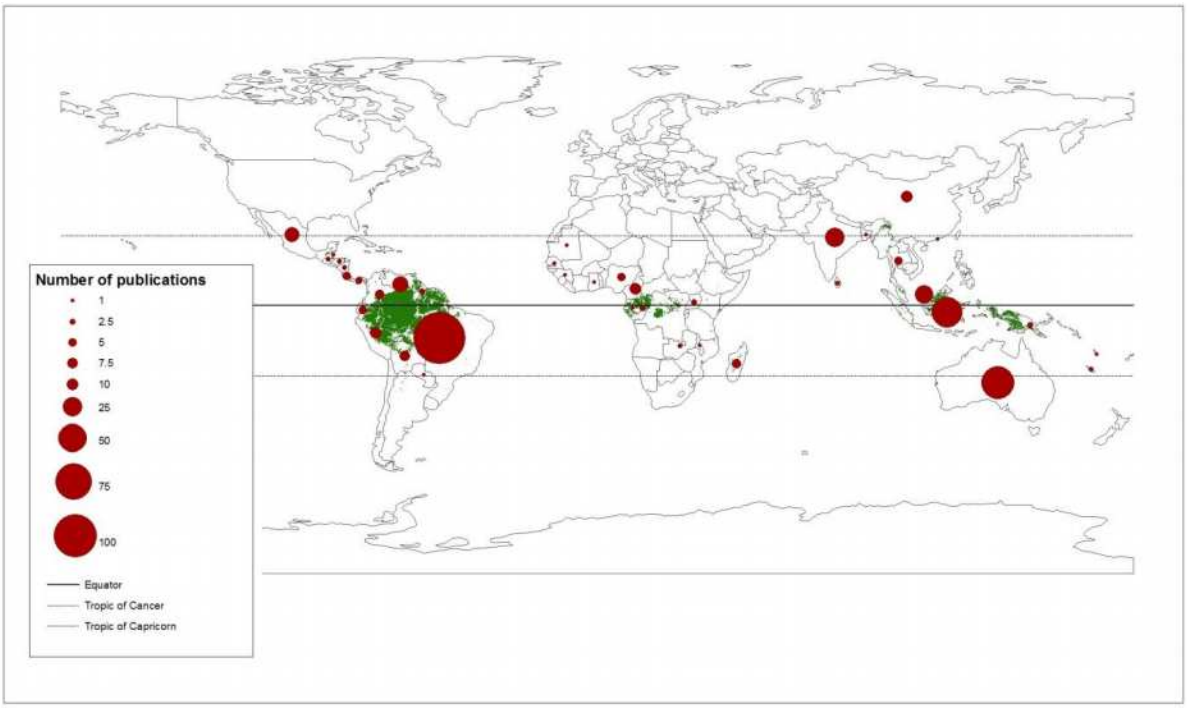

Figure 4. Spatial distribution of publications at global scale focused on fires in tropical rainforests. Green areas represent the principal remains of tropical rainforests (Wildlife Conservation Society). Red dots represent the number of publications.

The journals with most studies dealing with the topic were Forest Ecology and Management, Biotropica and the International Journal of Remote Sensing with 24, 20, 18 and 17 publications, respectively. Terms like slash and burn agriculture are frequent. The papers were published in 192 international journals. We identified ten journals that form together 31.53% of the published scientific articles related with fires in tropical forests. The contribution of each journal was: Forest Ecology and Management (4.82 %), Biotropica (4.02 %), International Journal of Remote Sensing (3.61 %), Journal of Tropical Ecology (3.61 %), Remote Sensing of Environment (3.21 %), Biodiversity and Conservation (2.81 %), Agriculture, Ecosystems and Environment (2.61 %), Ecological Applications (2.41 %), Journal of Biogeography (2.41 %) and Austral Ecology (2.21 %) (Figure 5).

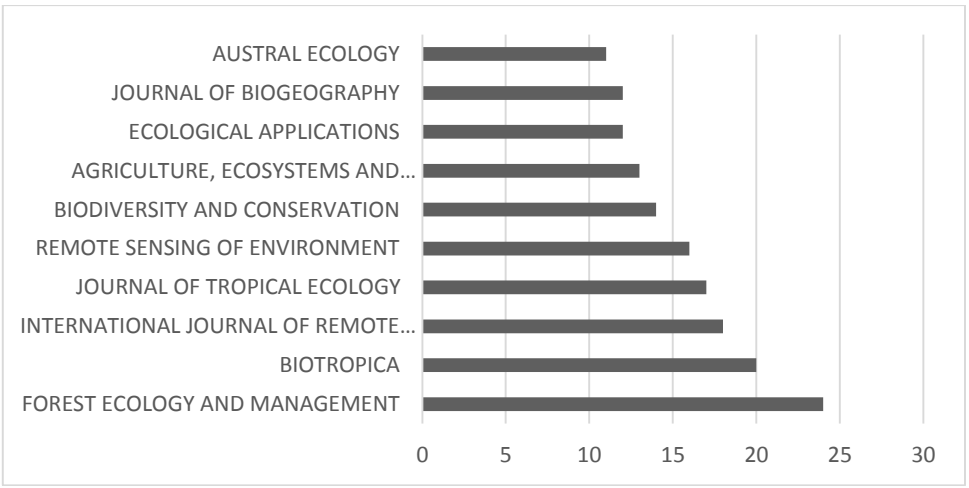

Figure 5. Main journals and the number of publications related with fires in tropical rain forests. N = 498 articles.

There were 5195 terms in our keyword analysis. These terms provide information on the main interests in the scientific community related with fires in tropical rainforests. As expected, fire, forest, tropic, burn and shifting are the words that appear most in the literacy, since these were the terms selected in the advanced search. Other terms are *cultivation*, *effect*, *use*, *Amazon* and *change*, which were the five most repeated terms among the key words in the published documents. The key words *cultivation* and *use* are related with human activities such as agricultural practices in which fire is used for several purposes. On the other hand, the term *effect* shows that the effect of fire is one of the main research topics. Apparently, rainforest are unnaturally burned with more frequency than expected in nature. It is of particular interest that *Amazon* is one of the most frequent words since it is the largest area covered with tropical forests and also the area where more scientific articles are produced. Table 1 shows the most used terms among which regions or countries can be identified, in which the causes of fire are being studied around the world. The majority of documents are associated with ecological disciplines followed by soil science, agronomy and remote sensing (Figure 7).

Table 2. Stemmed key word frequency (N = 498)

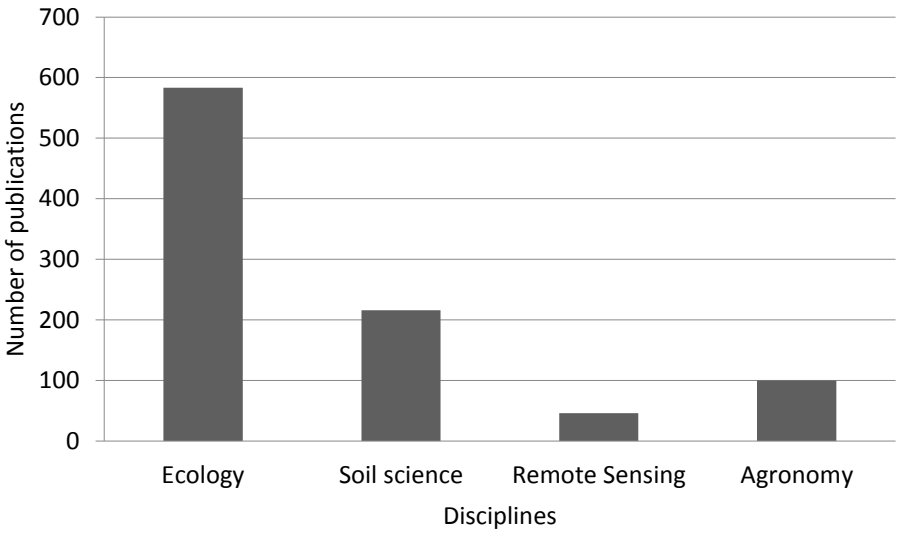

Figure 7. Disciplines that study forest fires in tropical rainforests

Only 32 of the reviewed articles were focused on the changes occurring in soil after a fire in tropical rainforests. From these studies, 15 did not report the kind of soil present in the study area. The principal topics taken into account were physicochemical changes in the soils after a fire, but also the effects of fires on macro and microbiota. In soil the most commonly reported changes are the soil pH, organic matter content and exchangeable cations like potassium and calcium, as well as changes in nitrate and phosphorus contents. These properties are important for farmers to assure a good harvest. Their loss over time leads to soil degradation.

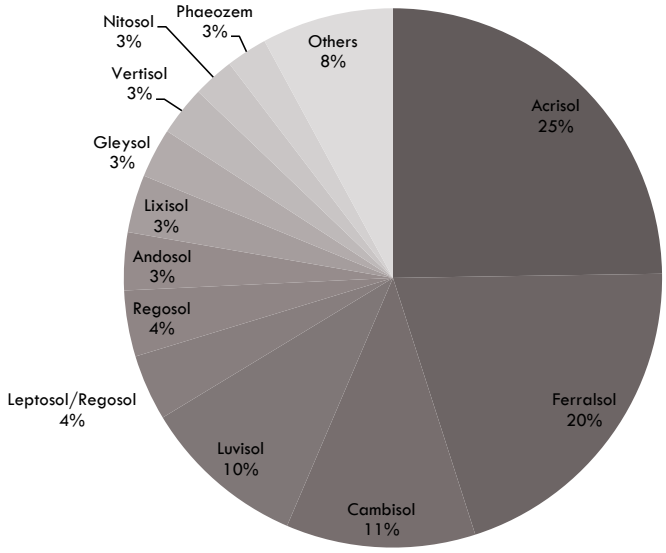

Figure 7. Main soil reference groups in which studies on fires in tropical rainforests have been done.

Discussion

Forest fires represent a threat for the relicts of tropical forests around the world. Natural fires in these ecosystems are rarely reported. Instead, publications on forest fires are increasing. Fires on tropical rainforests appear to be more frequent, intense and extended over the time (Pyne 1995; Cochrane 2002). Mouillot and Field (2005) estimate that in the 1990's alone 54 Mha yr^{-1} of tropical rainforests were affected by fire. Some consequences on the environment are gas emissions, which between 1997 and 1998 represented approximately 40% of the emissions produced by burning of fossil fuel (Cochrane 2003). It is necessary to know the real numbers of fires occurring in the tropical rain forest over the world and which is the extent of these events. These studies ought to reveal the causes, which can be a high rate of land conversion to agriculture or pasture, proximity to roads and rural roads, population density or climatological causes which include long periods of dryness related to the climatic global changes. Taking in account a mesoscale approach (mesoscales γ and β, 2-20, 20-200 km, respectively; Stull 1988), relatively few remote sensing studies were focused in detection, burned area calculation and land use change.

Spatially, forest fires are reported worldwide. According with information of the World Bank (2014) most of the countries in the tropics have a high rural population and low GDP per capita, excepting Australia. Conversely, continents like Africa show less reports of fires in their forest than more developed regions as Australia. In the case of America, there is a vast production of articles in the Amazon region, such as Brazil, Venezuela and others. Nevertheless, there is a smaller productivity of articles in Central America. In Asia the largest number of articles have been published in Indonesia, India and Malaysia.

The discipline of most research studies was ecology. Among the most studied ecological factors were: *diversity*, *structure*, *recovery* and *composition*. These variables reflect that most of the ecological studies are focused on the community level, but also some investigations deal with landscape and ecosystem scale. Biomass, for example is one of the most important elements in ecology, but also in management and prevention of fires. In the case of remote sensing the principal interests were focused in detection of forest, the calculation of the burned area and on land use change. Therefore biomass should be included in the remote sensing studies to make models with an ecosystem approach that explain a huge part of the fire dynamic and improve the fire management and prevention programs.

Agriculture activities usually are the origin of fire and soil properties change are a consequence of these activities which also are related with crop productivity. A deep bibliometric study can help us to understand how and which changes in soil properties, after fires and over time, are generalizable. We need to synthetize and make deep bibliometric studies to relate all the ecosystem properties studied until now to bigger scales. This initial bibliometric study is a first step in a research topic to understand how bibliometric studies in different fields, as in other cases have shown to understand different phenomena and how they have helped on making decisions about different topics like conservation of biodiversity (Stork and Astrin 2014) or which are the ecological consequences of land use change (Hasanagas *et al*. 2010). Bibliometric studies in different fields have allowed to understand complex phenomena and in some cases they can help to take decisions (Hasanagas *et al*. 2010). Finally, we consider that this bibliometric review will help to the decisions making helping us to understand the relevance of the different scale approaches and the gaps in fire ecology to evaluate both the effects of climatic change, the real relevance of shifting cultivation and other anthropogenic activities on fire dynamics, its consequences, management and prevention.

Changing fire regimes: The response of litter-dwelling invertebrates to altered seasonality and frequency of fire

Alan York

University of Melbourne, 4 Water Street Creswick VIC 3363 Australia, alan.york@unimelb.edu.au

Abstract
Mediterranean climate regions are experiencing changes that are projected to have significant impacts on patterns of temperature and rainfall, thereby affecting key ecosystem drivers such as fire regimes. In the sclerophyll-dominated vegetation communities of southern Australia, land managers are responding to increased wildfire probabilities through the use of more frequent low intensity (prescribed) fire. With burning occurring more often throughout the year, plant and animal communities are experiencing altered fire regimes; with changes to both frequency and season of burn. Here I report on the results of a long-term, replicated study, investigating the effects of fire frequency (high vs low) and seasonality (autumn vs spring) on a biodiverse and functionally important component of the fauna (litter-dwelling invertebrates). At the ordinal level, three broad patterns of response were detected: (i) no effect of fire treatment on abundance, (ii) a burning treatment effect, suggesting that fire in any season and at any frequency lowers abundance, and (iii) a significant negative effect of fire frequency on abundance. No season of fire effects were apparent for any group. The mechanisms underpinning these responses warrant further investigation, particularly in light of proposed increases in the amount of prescribed fire to be applied to these forest systems in coming years.

Keywords: climate change, fire regime, invertebrates, prescribed fire

Introduction

The application of prescribed fire in many regions is becoming more common amid forecasted increases in the frequency and severity of wildfire under climate change (Stephens *et al.* 2012; Cary *et al.* 2012; Flannigan *et al.* 2013). For example, in the state of Victoria in south-eastern Australia, a long term program of prescribed burning on an annual rolling target of 5% of public land (equating to a minimum of 385,000 ha per year) was introduced following severe wildfires in 2009 (Attiwill and Adams 2013). Historically, primarily for safety reasons, prescribed burning in these temperate ecosystems has been undertaken during autumn (Luke and McArthur 1978), however to meet new burn targets managers are now applying fire whenever weather conditions allow. As a consequence prescribed fires are occurring across a broader range of seasons and, potentially, with increased frequency (i.e. reduced intervals between successive burns). Understanding the implications of such changes in the fire regime for biodiversity is therefore critical (Bradstock *et al.* 2010; Penman *et al.* 2011).

As a group, invertebrates are numerous, diverse, and play important functional roles in ecosystems (Beattie 1995; Raven and Yeates 2007). Through their role in the breakdown and decomposition of organic matter and the release of materials to the soil environment, invertebrates have a positive influence on the availability of nutrients for plant growth and on soil physical properties. In Australia there have been a number of studies on the effects of low-intensity prescribed fire on invertebrates, particularly in regard to the interval between such fires (fire frequency); with fewer examining the season of burn. Following two short rotation (three-year interval) low-intensity fires in spring in Victoria, Collett *et al.* (2003) found that arthropod diversity had increased following the second fire, caused by greater evenness of individuals among taxa rather than any change in taxon richness. Three fires over an eight-year period had no cumulative impact on springtails and earthworms (Collett 1999)

or on richness or composition of beetle communities (Collett and Neumann 1995), but the effects of individual fires were quite variable. In contrast, two autumn fires over a five-year period produced a significant decrease in springtails, mites and earwigs and an increase in ant activity (Collett 1998). From studies based in Western Australian, Majer (1980, 1985) concluded that spring burning may be more detrimental to the soil-surface fauna than autumn burning. Some impacts however may be cumulative and take many years to manifest themselves. Examining the effects of seven fires over a 20 year period in sclerophyll forest in New South Wales, York (1999a) showed significantly lower ordinal diversity of surface-active and litter-inhabiting invertebrates in frequently burnt sites compared to unburnt sites.

With changing management practices involving the use of fire, concern has been recently expressed about the potential impacts of altered fire regimes on invertebrate diversity in both Mediterranean woodlands (Quartau 2009) and Australian temperate forests (New *et al.* 2010; York 2012). This paper utilises a long-term fire experiment to build on existing research; evaluating both the independent and combined effects of changed frequency and season of planned fire on litter-dwelling terrestrial invertebrates.

Methods

The study incorporates five areas (known locally as the 'Fire Effects Study Areas', FESA) within a 25 km radius in the Wombat State Forest, about 100 km north-west of Melbourne, Victoria, south-eastern Australia. The areas have an underlying geology of Ordovician sedimentary rock, and are at elevations ranging from 590 to 760 m above sea level. Topography varies from mostly flat (slopes 0-4°) to hills of low to moderate relief (slopes up to 21°). The climate is temperate, with annual rainfall in the range 814-901 mm, with the majority falling in winter and spring (Tolhurst and Flinn 1992). Native vegetation of the study areas is open to tall-open forest (tree heights 10 to >30 m, projective foliage cover 30-70%; Specht 1981). Dominant trees are Messmate Stringybark *Eucalyptus obliqua*, Narrow-leaf Peppermint *E. radiata* and Candlebark *E. rubida*. The understorey is characterised by a sparse shrub layer up to four metres in height (e.g. *Acacia* spp.), and ground layer of Austral Bracken (*Pteridium esculentum*) and native perennial grasses, forbs and rushes. Open to tall-open forests such as these are likely to be burnt more frequently under ongoing commitments to extensive use of prescribed fire on Victoria's public land (DSE 2012).

The study was established in 1985, and used a randomised block design involving a long-unburnt control (reference state) and four prescribed fire treatments randomly allocated within each of the five study areas (total of 25 treatment areas). The four fire treatments involved a factorial combination of two fire seasons (autumn or spring), and two fire frequencies (nominally every 3 or 10 years); that is, Autumn High-frequency (AH), Autumn Low-frequency (AL), Spring High-frequency (SH), and Spring Low-frequency (SL). Nominal prescribed fire intervals of three and ten years were chosen to represent, respectively, the shortest interval for sufficient recovery of surface fuels to carry a fire in these forests, and the likely return interval of prescribed fire based on local fire management practice. Prescribed fires in all treatments in this study were considered to be of low intensity (Tolhurst & Flinn 1992). Mean inter-fire intervals ranged from 2.7–5.7 years in the High-frequency treatments, and 8.5-16 years in Low-frequency treatments (see Bennett *et al.* 2013 for further detail).

To sample topographic variability, three plots (ridge, slope and gully) were established in each of the five burn treatments in each of the five areas; giving 75 plots overall. In 2012, twenty 2000 cm^3 samples of surface litter were systematically collected along 2 x 18 m orthogonal transects at each plot. Samples were bulked and sieved on site using a litter sifter (Upton & Mantle 2010); with a single sample for each plot returned to the laboratory. Invertebrates were extracted over four days using Tullgren funnels at the University of Melbourne. Samples were stored in 70% alcohol and identified to Order or equivalent using a binocular dissecting microscope and appropriate taxonomic keys.

Effects of prescribed fire treatments on invertebrate abundance were tested using Analysis of Variance (ANOVA) in Genstat 16th Edition. A factorial plus added control model with area as a random factor, treatment as a fixed factor, and plot nested within treatment by area, was used to examine the overall effects of prescribed fire (Control versus Fire treatments), as well as the effects of prescribed fire season (Autumn versus Spring) and frequency (High versus Low), and their interactions.

Results

In total 276,314 individuals from 23 broad taxonomic groups were collected. A number of groups were poorly represented and/or unlikely to be effectively sampled using litter extraction, with data for 15 groups sufficient to undertake analyses (Table 1). Overall, there was a significant effect of fire frequency on total invertebrate abundance (P = 0.009) with both Autumn High-frequency (AH) and Spring High-frequency (SH) treatments resulting in a substantial decline in mean invertebrate abundance (Table 1).

Table 1. Summary statistics of invertebrate abundance and ANOVA results for comparisons of five burning treatments (AL: Autumn Low-, AH: Autumn High-frequency; C: Unburnt; SL: Spring Low-, SH: Spring High-frequency). B: significant burn treatment effect, F: significant burn frequency effect (P<0.05), ns: not significant. – indicates groups poorly represented and/or unlikely to be effectively sampled using litter extraction (not tested).

When individual groups were considered, there were 3 basic patterns of response (Figure 1). Firstly, for seven groups (cockroaches, centipedes, diplopods, bugs, ants, wasps and barklice) there was no effect of fire treatments on their abundance at plots, suggesting that numbers of these groups were not

impacted by fire in any season or at any frequency. Secondly, for three groups (spiders, springtails and woodlice) there was an effect of the burning treatment, suggesting fire (in any season and at any frequency) lowers their abundance. Thirdly, for five groups (mites, amphipods, spiders, beetles and larvae), there was a significant effect of fire frequency on their abundance. No season of fire effects were apparent for any group.

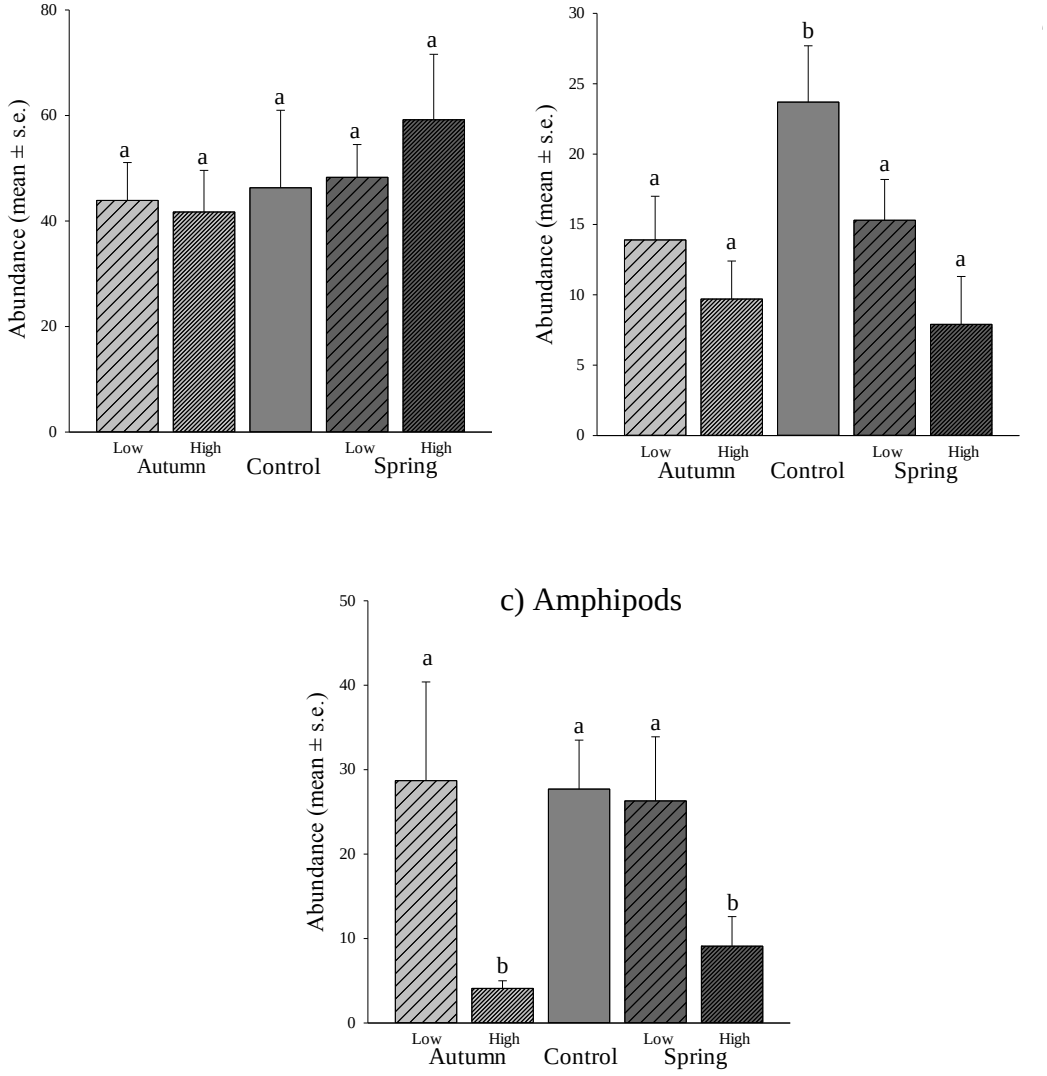

Figure 1. Examples of the three basic patterns of response. a) No effect of fire treatments on abundance e.g. ants. b) Significant effect of the burning treatment, irrespective of season and frequency e.g. woodlice. c) Significant effect of fire frequency e.g. amphipods. Columns with the same letters do not differ significantly, while those with different letters are significantly different in mean abundance (SNK post-hoc test). No season of fire effects were apparent for any group.

Discussion

Recent catastrophic wildfire events in Mediterranean-type ecosystems, including in Australia (Cameron *et al.* 2009), California (Keeley *et al.* 2009) and Greece (Pyne 2008), have led to increasing pressure on governments to mitigate fire risk (Teeter 2008; Teague *et al.* 2010). Fire prescriptions often target surface fuel loads in an attempt to reduce the intensity and spread of future wildfires (e.g.

McArthur 1967; Gould *et al.* 2007). In Australian dry forest systems however, leaf litter can accumulate quickly, often reaching pre-fire levels within 3 years (Penman and York 2010). Maintaining low fuel levels in strategic locations, and/or increasing annual area burnt by prescribed fire, will inevitably lead to increases in the frequency of fire and changed season of burning, as land managers seek to maximise burning opportunities. While sclerophyll forests, woodlands and heaths are dominated by plant species with adaptive responses than enable them to survive periodic burning (Gill 1981; Noble and Slatyer 1981), the impact of fires on terrestrial invertebrates is poorly understood. Because low-intensity fires are often patchy in nature and invertebrates can seek shelter within the soil and in unburnt habitat refuges, it has been suggested (Majer 1980; Campbell and Tanton 1981; Abbott 1984) that periodic fires used for fuel management purposes have few long-term effects on most soil and litter invertebrates. Little is known, however, about the effects of the repeated use of fire over long time scales; particularly as frequent fires can reduce spatial and structural heterogeneity and could have long-term consequences for the survival of invertebrate populations (Collett *et al.* 1993).

This study investigated the impact of 30 years of low-intensity fire on a functionally important component of the forest biodiversity, litter-dwelling invertebrates. Soil- and litter-dwelling invertebrates play an important role in the breakdown of litter and soil organic matter; facilitating the decomposition process and contributing to nutrient availability (York *et al.* 2012). Results from this long-term fire study indicated three broad response patterns. Firstly, for seven groups (cockroaches, centipedes, diplopods, bugs, ants, wasps and barklice) there was no effect of fire treatments on their abundance at plots, suggesting that numbers of these groups were not impacted by fire in any season or at any frequency. York (1999a) found negative effects of frequent fire on cockroaches, centipedes and bugs, although the low numbers caught in that study warrant cautious interpretation. Secondly, for three groups (spiders, springtails and woodlice) there was an effect of the burning treatment, suggesting fire (in any season and at any frequency) lowers their abundance. Collett (1998) found that two autumn fires over a five-year period produced a significant decrease in springtail abundance, while York (1999a) reported reductions in the numbers of spiders, springtails and woodlice with frequent autumn fire. The third broad response identified concerned five groups (mites, amphipods, spiders, beetles and larvae), where there was a significant negative effect of fire frequency on their abundance. High fire frequency has previously been shown to reduce the numbers of these groups (York 1999a).

It is of potential concern that high frequency fire (every ~3 years) significantly reduces the number of mites, amphipods, beetles and insect larvae. Amphipods (landhoppers) and larvae play major roles in litter fragmentation (Schowalter 2000) while many litter-dwelling beetles are associated with decomposer fungi (Lawrence and Slipinski 2013). This suggests a reduction in rates of decomposition and nutrient cycling with more frequent fire; which has implications for both rates of post-fire litter accumulation and forest health (see Brennan *et al.* 2009). The mechanisms underpinning these responses warrant further investigation, particularly in light of proposed increases in the amount of prescribed fire to be applied to these forest systems in coming years. It is most likely that frequent fire influences litter biomass and associated moisture levels (York 1999b; Penman and York 2010), and simplifies habitat structure. Several studies have reported the importance of litter depth and structure as a control of litter invertebrate composition (e.g. Uetz 1979; Michaels and McQuillan 1995). Because of this, litter fauna may take longer to recover after fire than the soil fauna (Majer 1984) and unburnt plants, logs and patches of litter become important refuges for fauna in burnt areas (Majer 1980; Whelan *et al.* 1980; Andrew *et al.* 2000). An interesting finding concerned the lack of a season of fire effect for any group. In earlier studies at this site Collett (1993, 1998, 1999) and Collett and Neumann (1995) observed that effects of individual fires were quite variable, with outcomes for most groups more dependent on the severity of individual fires rather the season of burn. Koch and Majer (1980) have previously emphasised that an understanding of the phenology (seasonality) of invertebrate abundance and activity is needed to fully assess the potential impacts of burning. Future work on this

project will target focal groups with an emphasis on understanding responses at the feeding guild or functional group level.

Abstract
Forest fires constitute important perturbations in Mediterranean ecosystems, and preventing methods are used (e.g. prescribed burning) to avoid large scale fires during dry periods. This preliminary study aims to investigate the effects of prescribed burning on Corsican pine (*Pinus nigra* ssp. *laricio* (Poir.) Maire var. *corsicana* (Loud.) Hyl.) in field conditions. Two complementary approaches were tested: chlorophyll fluorescence and sap flow measurements. Chlorophyll fluorescence parameters allowed showing short term effects of prescribed burning, with a decrease of photochemical process on burned pines. However, at medium term, no significant difference was visible between burned and reference trees. Sap flow monitoring provided information about daily and seasonal cycles, it was greatly correlated with vapour pressure deficit, but no effect of prescribed burning was observed.

Keywords*: Prescribed burning, Pinus laricio, chlorophyll fluorescence, sap flow*

Introduction

Forest fires constitute one of the major perturbations for Mediterranean ecosystems, with real human, economic and ecological hazard. Mediterranean pines are well known for their flammability and their vulnerability to natural fires, and in Corsica (France), in order to prevent large scale fires and protect forests, prescribed burning are conducted under Corsican pine forests (*Pinus nigra* ssp. *laricio* (Poir.) Maire var. *corsicana* (Loud.) Hyl.). Today, a scientific framework is asked by forest managers to help guide this practice.
Previous studies (Ferrat *et al.* 2009; Cannac *et al.* 2009, 2011) brought beginnings of answers with laboratory experiments on needles and experimental fires in nursery, and it is now necessary to go on with tools that can be used on the field. The aim of this preliminary study is to test the potentialities of some vitality/stress indicators in quantifying impacts of a prescribed burning in a natural pine stand: chlorophyll fluorescence and sap flow measurements.
Chlorophyll fluorescence is widely used in plant physiological studies due to the ease of the field measurements and the quality of information provided. Indeed, changes of chlorophyll fluorescence are correlated with changes of CO_2 assimilation and therefore with changes of photosynthetic rate (Baker 2008), it is also a good indicator of stress (Peñuelas *et al.* 1998). Three parameters are usually monitored, the quantum yield photosystem II (ΦPSII), the maximum quantum yield of PSII (F_v/F_m) and the non-photochemical quenching (NPQ). The first are indicators of photochemical process: ΦPSII corresponds to the proportion of absorbed light used in photochemistry, and F_v/F_m is an indicator of photosynthetic performance, with optimal value around 0.83, lower value indicating a photoinhibition. NPQ is correlated to energy dissipated as heat and is studied as a mechanism of protection (Maxwell and Johnson 2000; Calatayud *et al.* 2006; Baker 2008).
These parameters are influenced by soil mineral content (Laing *et al.* 2000; Shangguan *et al.* 2000; Gough *et al.* 2004) and by drought (Shangguan *et al.* 2000; Pukacki and Kamińska-Rożek 2005;

Boureima *et al.* 2012), as demonstrated on coniferous and crop plants. They also undergo important seasonal variations (Vogg *et al.* (1998); Gielen *et al.* (2000) on coniferous; and Damesin (2003) on deciduous trees).
Sap flow is widely used to measure whole tree water use, due to its high degree of reliability and accuracy (Lu *et al.* 2004). Many studies have investigated effects of abiotic parameters on sap flow, mainly drought, with disparate results depending on the species considered (Anfodillo *et al.* 1998 for pinaceae). It is greatly influenced by climatic conditions (radiation, rain, VPD…) on different coniferous (Köstner *et al.* 1996; Simpson 2000; Iijima *et al.* 2004) and deciduous trees (Zalesny Jr *et al.* 2006; Nasr and Mechlia 2007). Ducrey *et al.* (1996), highlighted an alteration of sap flow after an important experimental heating of young *Pinus halepensis* trunk.
To our knowledge, literature regarding the effect of prescribed burning with chlorophyll fluorescence and sap flow on a natural pines stands is quite poor (Ducrey *et al.* 1996; Ferrat *et al.* 2009; Pasqualini *et al.* 2009) and generally realized experimentally and for short periods.

Methods

Study site

The study site was a mountain (900 m a.s.l.) natural pure Corsican pine stand situated in the Venaco Forest, Corsica, France (42°11'51.3"N 9°06'53.5"E). Trees were 20-25 years old, 11-17 m tall, with 13.5-18.5 cm DBH in average. Prescribed burning was performed March 29, 2012 on an usual fuel load surface (pine needles bed) of about 1500 $g.m^{-2}$, leading to a fire intensity between 50 and 100 $kW.m^{-1}$ (Trabaud 1979; Ferrat *et al.* 2011).
Measurements of chlorophyll fluorescence and sap flow were realised daily, then monthly, on burned and reference (unburned) trees.

Chlorophyll fluorescence

Measurements of chlorophyll fluorescence were realised in situ on attached needles of the previous year with a Portable Chlorophyll Fluorometer (PAM-21000, Walz, Germany), needles were dark-adapted during 30 minutes before measurement to open the reaction centres of the PSII. All of these measurements were realised at the sunrise, before the burning and daily then monthly after the burning, from March 27 to July 13, 2012. When light energy is absorbed by chlorophyll, the light not used in photosynthesis is dissipated as heat or is re-emitted as light fluorescence. Chlorophyll fluorescence is measured by exposing a leaf to light and measuring light re-emitted, different intensity/flash of light is used to measuring different parameters (figure 1). Measurement light (MB) allows measurement of the zero fluorescence level (F_o), the maximum fluorescence level (F^o_m) is measured after a saturating flash (SP), a second saturating flash is applied under an actinic light (AL) to measuring the maximum fluorescence in the light (F'_m) and the fluorescence level under actinic light, before the second flash (F_t), the zero level fluorescence (F'_o) is measured under far-red light (Maxwell and Johnson 2000).

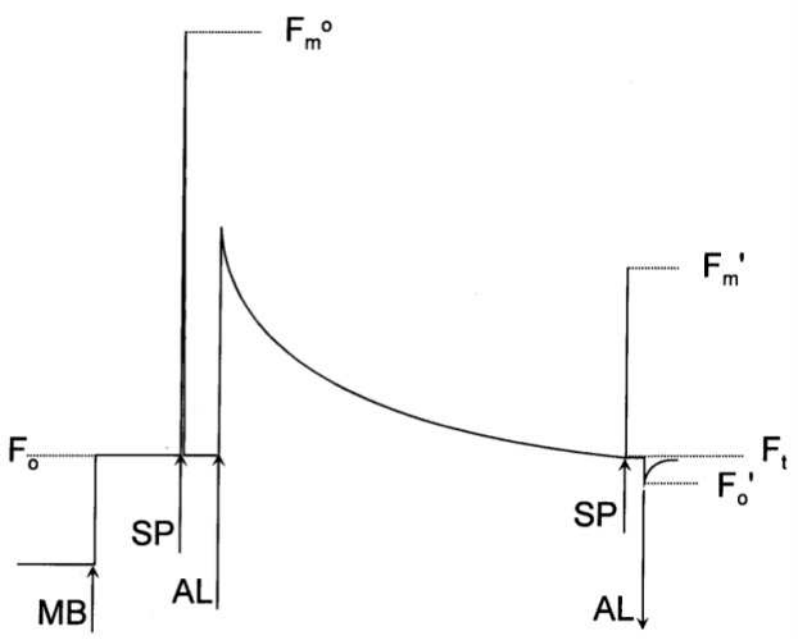

Figure 1. Sequence of a typical fluorescence trace (from Maxwell and Johnson 2000).

Three parameters were monitored: the quantum yield of photosystem II (ΦPSII), the maximum (or intrinsic) quantum yield of photosystem II (F_v/F_m) and the non-photochemical quenching. These parameters were calculated according to Maxwell and Johnson (2000), i.e.:

$$\Phi\text{PSII} = \frac{(F'_m - F_t)}{F'_m}$$

$$F_v/F_m = \frac{(F^o{}_m - F_o)}{F^o{}_m}$$

$$NPQ = \frac{(F^o{}_m - F'_m)}{F'_m}$$

with F'_m is the maximum fluorescence in the light, Ft is the level of fluorescence before the second saturating flash, F^o_m is the maximum fluorescence from dark-adapted leaves.

2.3. Sap flow

Sap flow measurements were realised with thermal dissipation probes (TDP, Dynamax, USA) according to the method developed by Granier (Granier 1985; Granier and Gross 1987). This method is based on temperature differences between two probes inserted radially into the trunk. The upper probe is continuously heated, both probes have a thermocouple. When sap flow is null, the difference between the two probes is maximal, when sap flow is high it dissipates heat produced by the upper probe by convection, and the difference of temperature between the two probes will depend on the speed of sap (Granier 1985; Granier and Gross 1987).

Depending on the thickness of sapwood, two length of probes were used (30 for DBH between 13.5 and 14.5 cm and 50 mm for DBH between 15.5 to 18.5cm) to improve the measurement (Lu *et al.* 2004). All probes were installed at East to avoid the influence of azimuth (Do and Rocheteau 2002). These measurements were recorded continuously before and after the burning from March 28 to October 30, 2012. Data were recorded in a CR3000 Micrologger (Campbell Scientific, USA) supplied by a battery charged by a solar panel. Together relative humidity and temperature were monitored, these allow computation of vapour deficit pressure (VPD, in kPa):

$$\boldsymbol{VPD = e_s - e_a}$$

$$\boldsymbol{e_s = 0.6108 \times e^{\left(\frac{17.27 \times T}{T+273.3}\right)}}$$

$$\boldsymbol{e_a = e_s \times \frac{RH}{100}}$$

with e_s is the saturation vapour pressure (kPa), e_a is the actual vapour pressure (kPa), T is the temperature (°C) and RH is the relative humidity (%).
Sap flow were calculated according to Granier and Gross (1987):

$$\boldsymbol{k = \frac{\Delta TM - \Delta T}{\Delta T}}$$

$$\boldsymbol{V = 0.0119 \times k^{1.231}}$$

with k is a dimensionless number, ΔTM is the maximal temperature difference between the two probes (°C), ΔT is the temperature difference between the two probes (°C) and V is the sap velocity ($cm.s^{-1}$).

Results - Discussion

The prescribed burning influenced all chlorophyll fluorescence measurements at short term, the maximum quantum yield of burned pines decreased strongly immediately after the burning, from 0.84 to 0.76. It increased few days later but remained always under the reference values (resp. 0.82 vs. 0.84 during summer). F_v/F_m of the reference pines remained constant during the entire measurement period (approx. 0.84, figure 2).
Quantum yield increased the day after the burning, from 0.22 to 0.37 (68% up), but there was no difference between burned and reference pines few days later. Furthermore, this parameter underwent seasonal variations with a peak (0.44) at the end of May (figure 3).
Non-photochemical quenching decreased 2 and 3 days after the burning, from 2.3 to 1.2 (48% down) then increased to the initial value the 4th day. Later, it was under the reference (65% of the reference value, May, 5), except for the last record (figure 4).

The decrease of F_v/F_m immediately after the burning could reveal an alteration of photosynthetic performances due to a thermal stress. Previous study (Pasqualini *et al.* 2009) showed a decrease of this parameter after a burning on *Pinus laricio* needles, but this decrease did not have any effect on the survival of populations. It was shown that F_v/F_m was not long term affected if the value was kept upper than 60% of reference value (Ferrat *et al.* 2009), it is in accordance with our results, as Fv/Fm was about 98% of the reference value at the end of the experiment while it was about 90% of the reference value 2 days after the burning. NPQ corresponds to energy dissipated at heat, its increase would be a protection mechanism to dissipate energy excess and photo damage of PSII (Calatayud *et al.* 2006), this mechanism has not been implemented here. In the medium term, none of these three parameters seemed significantly affected by the burning.

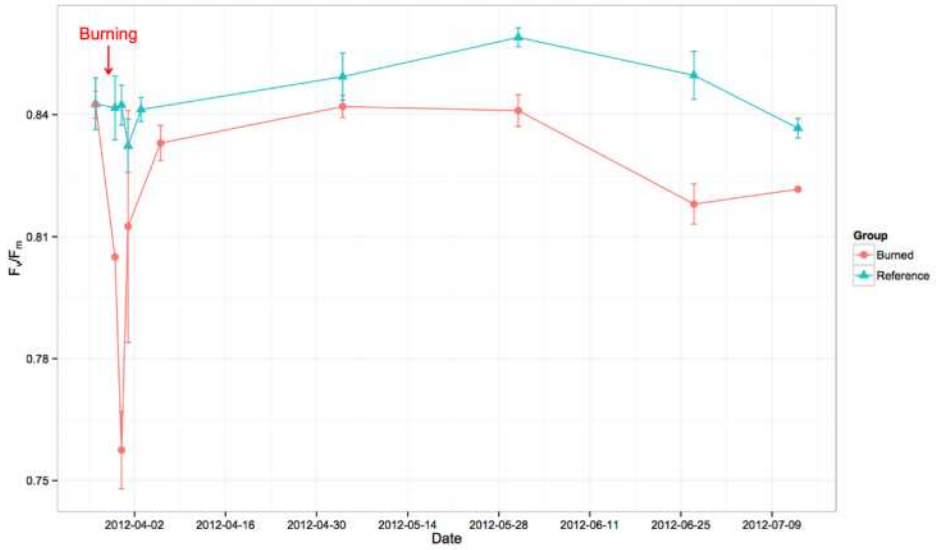

Figure 2. F_v/F_m for burned and reference pines. Means ± standard error.

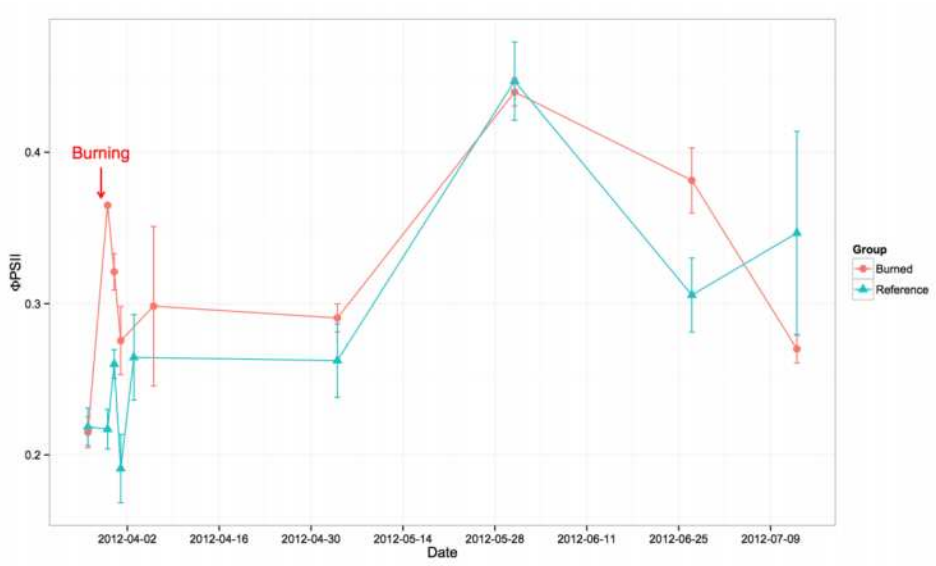

Figure 3. ΦPSII for burned and reference pines. Means ± standard error.

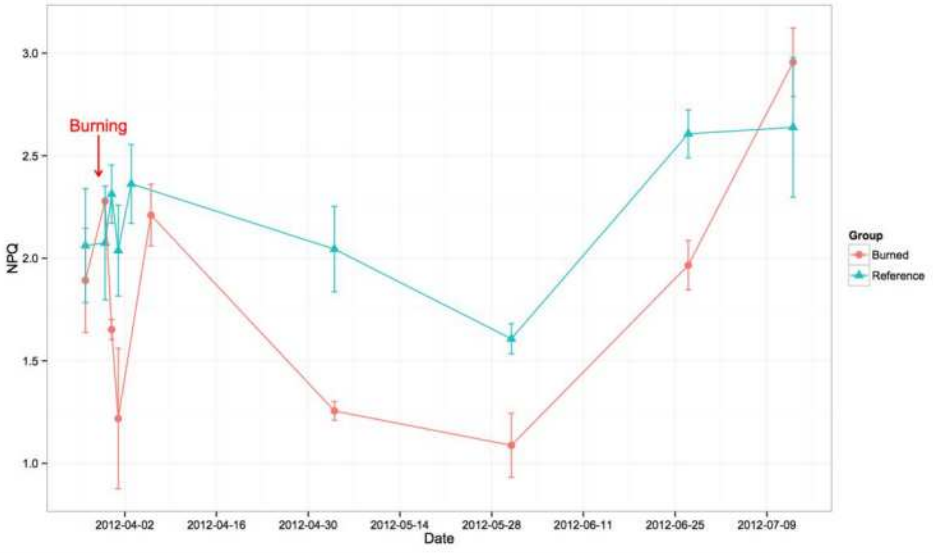

Figure 4. NPQ for burned and reference pines. Means ± standard error.

Figure 5 shows the sap velocity for two representative trees (a burned and a reference) and the VPD. Sap flow of reference tree was lightly under the sap flow of burned tree during spring (mean: 7.8 10^{-4} $cm.s^{-1}$, max: 4.39 10^{-3} $cm.s^{-1}$ for reference; mean: 1 10^{-3} $cm.s^{-1}$, max: 6.3 10^{-3} $cm.s^{-1}$ for burned) and summer (mean: 6.5 10^{-4} $cm.s^{-1}$, max: 4.5 10^{-3} $cm.s^{-1}$ for reference, mean: 8.5 10^{-4} $cm.s^{-1}$, max: 4.8 10^{-3} $cm.s^{-1}$ for burned). During autumn they were close (mean: 4.7 10^{-4} $cm.s^{-1}$, max: 2.2 10^{-3} $cm.s^{-1}$ for reference, mean: 4 10^{-4} $cm.s^{-1}$, max: 2.9 10^{-3} $cm.s^{-1}$ for burned). The global sap flow difference between reference and burned tree can be explained by difference of DBH (resp. 14 cm vs. 15 cm) and mainly by difference of probe length (resp. 30 mm vs. 50 mm). It will be important in further studies to homogenize probes for a better discrimination of sap flow trends.
Nevertheless, it can be noticed that sap flow of reference and burned trees had similar variation from the start to the end of the monitoring, the prescribed burning did not seem to affect sap flow.

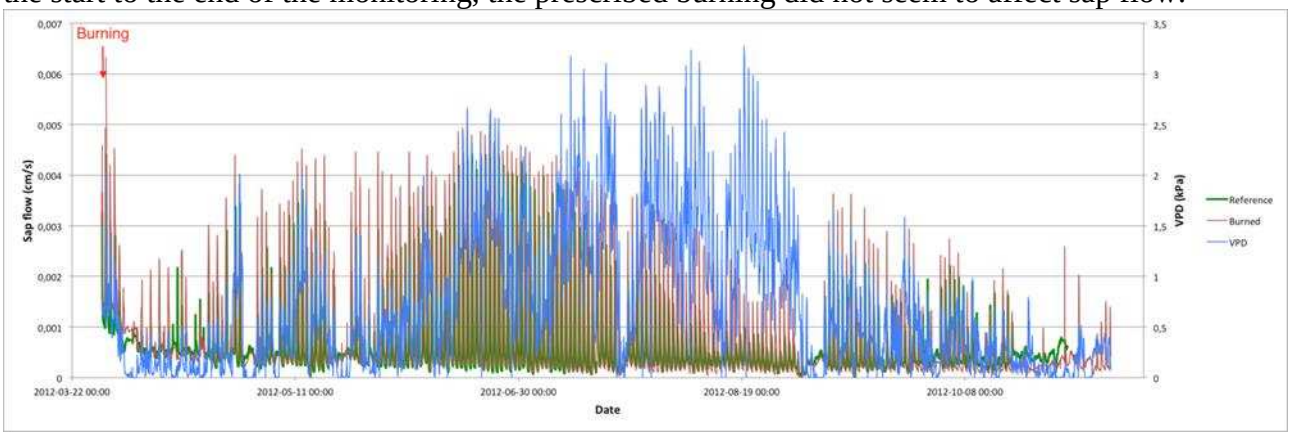

Figure 5. Sap flow velocity for burned and reference pines, and VPD.

The VPD varied daily and seasonally, it was low during spring (mean: 0.47 kPa, max: 2.66 kPa) and greater during summer (mean: 1.19, max: 3.27 kPa) and decreased during autumn (mean: 0.26 kPa, max: 1.58 kPa). Daily and seasonally variation of VPD can be explained by the great influence of relative humidity (RH) on the calculation, indeed during night and rain period RH is very high and thus VPD is very low. Temperature influences also VPD, more the temperature is important, more the saturation pressure is important and more the VPD may be important (Allen *et al.* 1998).

These data show that sap flow was greatly correlated, daily and seasonally, with vapour pressure deficit (VPD). An exception was measured during July and August, with a decrease of sap flow (from 0.004 to 0.002 $cm.s^{-1}$) while VPD was very high (over 3 kPa), this drop could be explained by low water availability during drought period (Anfodillo *et al.* 1998), and would reveal a water saving behaviour (Anfodillo *et al.* 1998; Badalotti *et al.* 2000). It will be interesting to survey this behaviour in case of severe drought.

This preliminary study has provided the beginnings of a reply regarding the effect of prescribed burning on photosynthetic and hydric parameters, and also provided information on daily and/or seasonal variation of these parameters. Chlorophyll fluorescence and sap flow measurements are promising tools to evaluate the impact of thermal stress on field, at short, medium and long term. A longer study with more replicate and complementary tools is in progress to provide more accurate answers.

Abstract
An experimental prescribed burn was conducted in February 2011 in a Quercus cerris forest in the Cilento e Vallo di Diano National Park (Southern Italy) to analyze fire effects on vegetation and soil.
Fuel fire behavior characteristics and were assessed to define the burning conditions that allowed a rate of fire spread between 0.10 and 0.22 m min-1, fireline intensity never below 50 kW m-1 and maximum flame temperatures in the litter of 600°C but the average residence time above 60°C and 300°C were 198 and 12 seconds, respectively. Litter fuel consumption ranged between 80% and 90%.
The effect of fire on vegetation was evaluated in terms of floristic composition and structure by means of phytosociological and dendrometric samplings randomly located in burned and unburned plots two years after fire. The effect of fire on soil was evaluated by determining soil chemical (pH, water content, total and extractable organic C content, total and mineral N) and microbial properties (microbial biomass, soil potential respiration) in the 0-5 cm soil at different time since fire (3 hours, 30, 94, 209 and 394 days). Moreover, water holding capacity and bulk density were measured in burned and unburned plots at first sampling.
Results on vegetation evidenced no significant differences in species richness and diversity, in both burned and unburned plots. No changes have been found in frequency and cover values of endemic species (Digitalis micrantha, Echinops ritro subsp. siculus, Lathyrus jordanii, Teucrium siculum). Woody species showed a great resilience with very low tree mortality. Sapling persistence by high sprouting rootstocks evidenced no significant difference in the abundance of some species (Quercus cerris, Acer campestre, Carpinus betulus, Crataegus monogyna) or an increase for few species (Ruscus aculeatus, Ilex aquifolium, Erica arborea, Fraxinus ornus, Sorbus torminalis, Carpinus orientalis) in burned plots.
Results on soil showed that prescribed burning did not affect soil chemical and microbial properties, so indirect effects on plants deriving on effect of fire on soil may be excluded. Our findings highlight the sustainability of prescribed burning in Quercus cerris forests and support its future use as a management tool of fire risk reduction without significant impact on vegetation and soil.

Introduction

Fire has played an important role in shaping the distribution and composition of many biomes worldwide (Keeley *et al*. 2011), including temperate forests of the Northern Hemisphere (Abrams 1992; Bradshaw *et al*. 1997). In particular, natural and anthropogenic fire regimes have been one of the main drivers in determining life traits of oak species and the structure of oak forests in both North America (e.g., Cutter & Guyette 1994; Shumway *et al*. 2001) and Europe (Clark *et al*. 1989; Mason 2000; Robin & Nelle 2014).

Oaks have several fire related traits which enable them to survive on frequent fire. Mature oaks have thicker bark than most other hardwood species (Nicolai 1986). They are capable of living for decades after bole injury. Litter displays a relatively marked flammability (Kane *et al*. 2008). Regeneration from root and stump sprouts can be enhanced by fire (Hutchinson 2008). A synergistic interaction of fire and masting may result in burned sites having high oak seedling density following a mast year (Brose *et al*. 2006; Abrams & Johnson 2013). Fires may also kill acorn predators, which may result in increased acorn viability and germination (Johnson *et al*. 2002). Acorns germinate well below the soil surface where they are protected from the heat of a surface fire. The reduced shading and competition, and prepared seedbed that result from litter removal combine to provide favourable oak regeneration conditions (Wang *et al*. 2005).

For the above mentioned reasons, prescribed burning is broadly used to manage oak forests of North Eastern America with the objective to promote oak natural regeneration, reduce invasive species, restore biological diversity, and decrease hazardous fuel build-up (Peterson & Reich 2001; Burton *et al*. 2011; Cavender-Bares & Reich 2012; Brose *et al*. 2013). Such management goals are often achieved integrating prescribed burning with other sylvicultural treatments such as thinning and shelterwood cutting (Albrect & McCarthy 2006; Brose *et al*. 2006).

Several oak species of Northern America managed by prescribed burning (i.e. *Quercus alba, Q. ellipsoidalis, Q. macrocarpa, Q. marilandica, Q. rubra, Q. shumardii, Q. stellata*), are vicariant of main European oak species, e.g., *Q. alba* vs. *Q. petraea*, *Q. macrocarpa* vs. *Q. robur*, *Q. stellata* vs. *Q. cerris* (Box & Manthei 2005), with which share similar ecological traits and regeneration strategies. However, the use of prescribed burning for forest management goals has been relatively recent in Europe in comparison to North America (Fernandes *et al*. 2013).In particular, very little knowledge exists regarding prescribed fire behaviour and its ecological effects in deciduous oak forests of Europe. In order to assess the ecological sustainability of this management practice, investigations are needed to reduce undesirable fire effects on the ecosystem components, such as tree seedlings mortality, soil degradation and floristic impoverishment (Franklin *et al*. 2003; Hutchinson *et al*. 2005; Neary *et al*. 2010; Williams *et al*. 2012).

With these aims, an experimental prescribed burning was carried out in 2011 in a *Quercus cerris* forest of the Cilento e Vallo di Diano National Park, Southern Italy (Ascoli *et al*. 2012). Since this forest is located in a Site of Community Importance (IT8050002 included in Annex I of the Directive 92/43/EEC), ecological monitoring was particularly important in order to evaluate the effects on biodiversity and to exclude possible negative impact to holly (*Ilex aquifolium*) and ruscus (*Ruscus aculeatus*), being both species protected by a regional law.

In particular the specific objectives of the present study are: i) to characterize fuels and fire behaviour observed during the experimental prescribed burning; ii) to assess short term effects of fire on understory plant species diversity, oak regeneration andprotected plant species ; iii) to analyse fire effects on soil chemical and microbial properties.

Methods

Study area

The study site (40°17’10’’N; 15°16’51’’E) is located in the National Park of Cilento, Vallo di Diano and Alburni, Sothern Italy (Figure 1), about 20 km apart from the sea in a hilly area. The site is 455 m a.s.l., with a SW aspect and an average of 40% slope. The climate is mesotemperate humid with mean annual temperature of 14.7°C (ranging from 6.3°C in January to 23.6°C in August) and annual precipitation of 825 mm with a dry period in summer with less than 100 mm. (Gioi meteorological station, 684 m a.s.l., 22 km apart from the study site).

Soil is Calcari-Vertic Cambisols and geologic substrate is Marls and Calcarenites of the Stream Trenico of the Chattian (FAO 1998; di Gennaro, 2002).

Vegetation is characterized by *Quercus cerris wood* 14-16 m high with an average cover of 80% and a low scattered presence of *Sorbus domestica*, *Ostrya carpinifolia* e *Fraxinus ornus*. The woody understorey is dominated by *Carpinus orientalis, Crataegus monogyna, Ilex aquifolium, Ruscus aculeatus* and *Erica arborea,* whereas the main representative herbs are *Festuca exaltata, Echinops ritro subsp. siculus, Digitalis micrantha.*

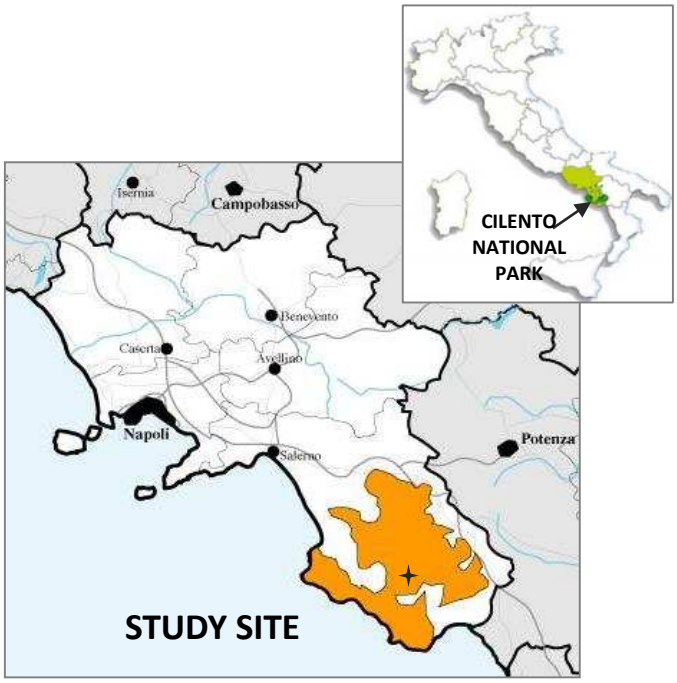

Figure 1. Study site location

Fuel and prescribed fire characterization

The prescribed burn was conducted in winter 2011 on an area of 0.7 ha. Fuel characteristics were assessed few days before burning. Dead fine (< 6 mm) surface fuels were constituted by *Q. cerris* litter, cured grasses and dead woody material. Live grasses and forbs, and elevated live woody fuels such as *Erica arborea*, were sparse. Dead surface fuels were harvested in six 1 m^2 quadrats and dried in the laboratory to determine the fuel load. Fuel bed depth and cover of dead fuels were also measured every 0.5 m along six linear transects (10 m).Dead fine fuel moisture was assessed at the time of the burn by collecting 5 litter samples. Fresh samples (50 g each) were weighed in the field by a portable scale, and then dried in laboratory.

Fire behaviour was assessed at a microplot scale (Fernandes *et al*. 2001) by measuring the arrival time of the fire front at the vertices of a triangle and computing the rate of spread according to the trigonometric method of Simard *et al*. (1984). Five equilateral triangles (2 m side) were visualized using 2 m rods placed at each triangle vertex. The time of arrival of the fire front was measured using K-Type thermocouples (0.4 mm) positioned at each triangle vertex within the litter fuel (5 cm from the soil surface), and connected to a data-logger buried one meter apart. Flame temperature was measured every second during all combustion phases. Flame height was assessed by two observers which used as a reference scale the increment markers(0.5 m)painted on each rod. Fireline intensity was calculated using the Byram (1959) formula applying a high heat content of 20000 kJ kg^{-1}. Air temperature and moisture, and wind speed and direction were assessed every time fire was spreading through a triangle using a portable weather stations positioned at midflame height at a distance of 5 m upwind the triangle. In total, 5 rate of spread observations and 15 time-temperature profiles were collected. Fuel consumption was assessed soon after the fire by harvesting remaining charred fuels in a 1 m^2 quadrat within the triangle.

2.3. Vegetation sampling

The effects of prescribed burning were assessed in summer 2013 to analyze the following parameters: floristic and structural composition, plant community sintaxonomy, species richness, species density, demography and regeneration of structural species. Plant community was sampled by the phytosociological method (Braun-Blanquet, 1964) on sampling area of 100 m^2 for sintaxonomical characterization. Moreover the phytosociological method was applied on 1 m^2 sampling plots along randomly located transects to analyze the effects of burning application on plant biodiversity. In total, 40 plots were surveyed in both burned and control sites. Thesurvey was carried outin accordance with theBraun-Blanquet scale and then converted in Van der Maarel (1979) scale in the data matrix.

The data matrix (60 species x 80 relevés) was analyzed by Principal Component Analysis (PCA) with algorithm Euclidean distance contained in SYN-TAX package (Podani, 2001) to test the degree of floristical similarity between burned and control plots. The software EstimateS (Colwell, 2013) was used to calculate rarefaction curve of richness estimators and biodiversity for sample based data (40 burned plots and 40 control plots). The nomenclature of species follows Pignatti (1982), Med Check list (Greuter *et al*., 1989), and Conti *et al*. (2005, 2007).

Stand structure (tree species density, basal area, height, and status: alive, dead, fallen, fire scar) was also assessed. Trees with a diameter at breast height >5 cmwere measured in a circular plot of 20 m in diameter. Tree regeneration with a diameter <5 cm and a height >30 cm was assessed in a circular plot of 8 m in diameter. Regeneration with a height <30 cm was assessed in the same plot used for phytosociological relevés. Regeneration was characterized by stem density, height and status (live/dead; seedling, sapling, post-fire sprout). For each plot, environmental data such as slope, litter cover and depth, bare soil, rocks, herb and shrub cover and height) were also recorded to evaluate their potential effects. A total of 40 plots were surveyed in both burn and control sites. Statistical analysis was performed to evaluate significant differences of individual number (test Chi^2) and average height (test U-Mann-Whitney) between burned and control plots.

2.4. Soil collection and analysis

To evaluate the effect of prescribed burning on soil properties that could affect oak, soil samples were collected at 0-5 cm depth in 6 randomly selected sub-plots (40 x 40 cm) of burned and unburned plots at different times since burn (3 hours, 30, 94, 209 and 394 days).

In the first sampling, in both control and burned plots, soil water holding capacity and bulk density were determined by gravimetric method (USDA, 2004). At each sampling time sieved soil samples (2-mm mesh) were analysed for chemical (water content, pH, total organic C, extractable organic C, total N, ammoniacal N and nitric N) and microbial properties (microbial C and soil potential respiration).

Water content was measured by gravimetric method (Allen, 1989). Soil pH was determined by potentiometric method on air dried soil:water suspension with a 1:2.5 ratio using a calibrated electrode (Hanna Instruments mod. HI1230). Total organic carbon content was measured on air dried soil by humid oxidation method (Springer and Klee, 1954). Extractable and microbial C were determined on fresh soil by chloroform-fumigation extraction method (Vance *et al*., 1987). Total N was determined with NCS Elemental Analyser (ThermoFlash EA 1112). The ammonium and nitrate contents were determined by potentiometric method (Beck, 1993) on fresh soil stored at 4 °C until measurement, by using specific potentiometric electrode for ammonia (ORION, Mod. 9512BNWP) and one specific for nitrate (ORION, Mod. 290A) after Castaldi and Aragosa (2002). Soil potential respiration, indicating microbial activity, was determined measuring, by gas chromatography, CO_2 evolved from samples incubated in standard conditions (25 °C, 55 % of water holding capacity, in the dark) for one hour (Kieft *et al*., 1998).

Results

Fuel characteristics and prescribed fire behaviour

Pre-fire fuel cover was 100%.Mean fuel bed depth was 8 cm. Dead fine fuel load ranged between 3.4 and 5.7 t ha^{-1}. During the burn, mean fine dead fuel moisture content (dry weight basis) was 38% (Table 1).Weather conditions are reported in Table 1.

Table 1– Mean weather, fuels and fire behavior characteristics observed during an experimental prescribed burning in Quercus cerris litter fuels. Photos shows prescribed fire behavior and fuel consumption.

Weather	
Air temperature (°C)	16
Air moisture (%)	43
Wind speed (km h^{-1})	6
Days since rain (days)	5
Fuel load	
Litter fuels(t ha^{-1})	4,24 ± 0,34
Cured grasses + fine dead woody(t ha^{-1})	2,44 ± 0,46
Fuel moisture	
Litter (%)	38 ± 5
Duff (%)	132 ± 19
Fire behaviour	
Ignition pattern	Backfire
Rate of spread (m min^{-1})	0,17 ± 0,04
Flame height (m)	0.1-0.3
Fireline intensity (kW m^{-1})	25 ± 5,7

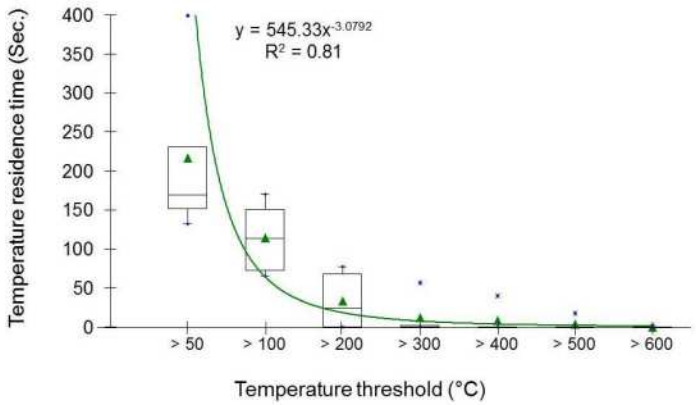

Figure 2. Flame temperature residence time above threshold temperatures measured at the soil surface during a prescribed burning in Q. cerris litter fuels.Boxes show the first and third quartiles; the black line is the median.Green triangles are the mean.Negative exponential function, its equation and R2 are also displayed.

Fire rate of spread varied between 0.10 and 0.22 m min^{-1}. Fuel consumption ranged between 80 and 90% of the pre-fire mean fuel load (see figure in Table 1). Maximum flame temperature ranged between 159°C and 601°C. Average residence time above 60°C and 300°C were 198 and 12 seconds, respectively. Figure 2 shows the flame temperature residence time above threshold temperatures measured at the soil surface. The temperature decay displayed a negative exponential function.

Vegetation

On the basis of phytosociological relevés the studied forest formations can be classified as part of mesotemperate *Quercus cerris* wood, referring to the association *Lathyro digitati quercetum cerridis* Bonin and Gamisans 1976 and subassociation *festucetosum exaltata* (Rosati *et al*.2005). These forestsare distributed in the clay-marl and sandstone areas of hilly and mountain between 400 and 850 m a.s.l. and are referred to suballiance *Ptilostemo-Quercenion cerridis* (*Teucrio siculi-Quercion cerridis*). Burned and control area show a great homogeneity in the floristic composition especially

highlighted by the high number of species frequency V (at least 80% of the relevès). In the phytosociological relevés all the species characteristic of association (*Lathyrus jordanii*, *Carpinus orientalis*, *Ptilostemon strictus* and *Melittis melissophyllum*), were found while between the characteristics of sub-association *Erica arborea* and *Drymochloa drymeja* are very common.

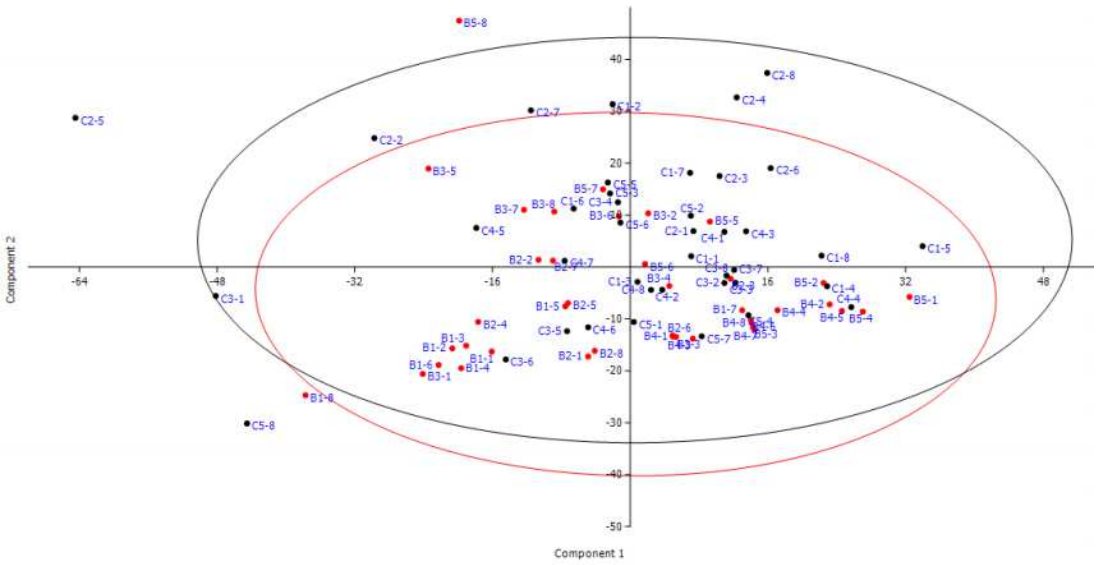

Figure 3. Principal Component Analysis of sampled 80 plots in burned (red) and control (black)area.

The prescribed burning did not affect the understory floristic composition as showed in the Figure 3. The PCA obtained by the analysis of a data matrix (60 species x 80 relevès) does not show a clear separation of burned and control plots along the axis 1 and 2 (explaining35%of the total variability). The ellipses enclose 95% of the variability and are strongly overlapping.

Prescribed burning did not affect the understory plant biodiversity. The rarefaction curve of richness estimators and biodiversity for sample based data (40 burned plots and 40 control plots) showed a similar pattern of variation with a not significant distance. In fact, considering the 95% confidence limits, the curves are superimposed (Figure 4A). No changes were found also in species density as reported in Figure 4B that evidence the same values in the average species number in both treatments.

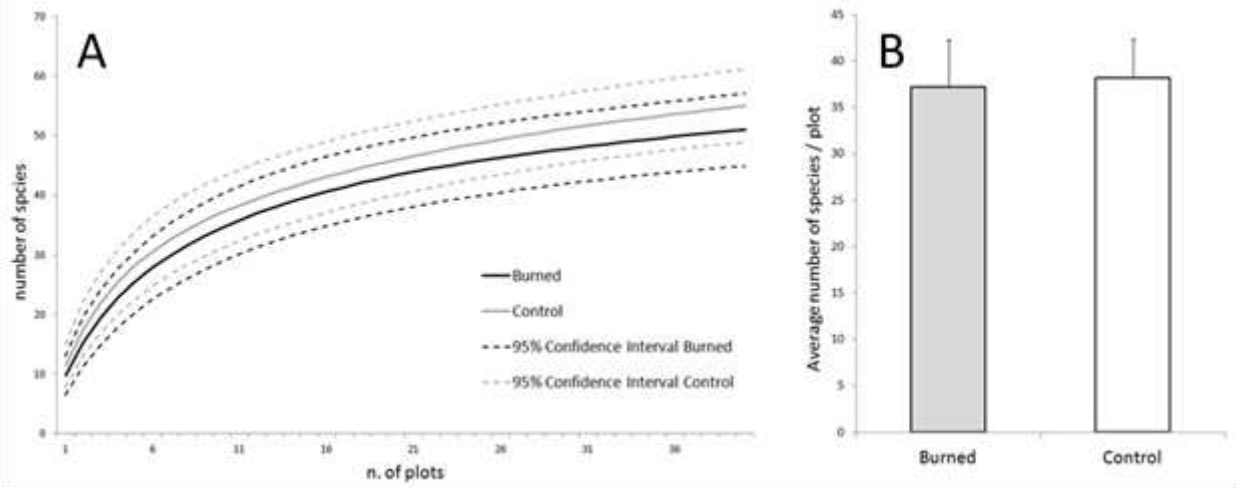

Figure 4. Rarefaction curve of species richness (A) and Average number of species/plot in burned and control area (B).

The analysis of the regeneration was carried out on all tree species present in both seedling and the sapling state. As showed in Table 2 the burning treatment produced a different effect in relation to life trait of species. In particular, *Erica arborea*, *Fraxinus ornus*, *Ilex aquifolium*, and *Sorbus torminalis* evidenced a significant increase of individual number in burned area while *S. domestica* show a decrease.

Table 3. Total number of individuals and average height of woody species in burned and control area. ***For each species significant differences between burned and unburned are reported (n.s.= not significant; *= p<0,05; **= p<0,01; ***= p<0,001).***

	Number of individuals			Average height (±STD)		
Species	**Burned**	**Control**	**test X^2**	**Burned**	**Control**	**U test**

Ilex aquifolium	65	20	***	0.58 (±0.26)	0.58 (±0.31)	n.s.
Quercus cerris	177	202	n.s.	0.43 (±0.24)	0.40 (±0.10)	**
Sorbus domestica	6	15	*	0.50 (±0.00)	0.47 (±0.12)	n.s.
Sorbus torminalis	27	7	***	0.51 (±0.16)	0.55 (±0.17)	n.s.

The ability to survive burning treatment with vegetative regrowth was found particularly interesting both in the structural species *Quercus cerris* but especially in some species of conservation interest as *Ruscus aculeatus* and *Ilex aquifolium*. These species responded to burning by resprouting from both the stem and the rhizome (Figure 5).

Figure 5. Regrowth after prescribed burning in Quercus cerris seedlings (right) and Ilex aquifolium (left).

3.3. Effects on soil

Results show that soil samples collected in control and burned plots did not affect soil water holding capacity or bulk density (Table 4).

Soil chemical and microbial properties determined at different times in burned and unburned plots showed that sampling time is the main factor affecting properties of soil compared to fire (Table 5, Figure 6). In fact, all parameters were significantly ($P<0.05$; two-way ANOVA) affected by sampling time, except for soil pH and total N, probably because of temporal variation of climatic conditions. By

contrast, only nitric N appeared significantly (P<0.05; two-way ANOVA) affected by fire. It has to be underlined that accidental changes of some parameters (pH, water content and nitric N), observed only much time after prescribed fire (Table 5), did not appear due to fire treatment. It is not surprising that no effect on soil was found because litter surface temperature was higher than 100°C only for 114 seconds. Similarly, Tecimen and Sevgi (2011) found no effect on C or N fractions if soil from *Quercus* forests (*Q. petrea*, *Q. robur*, *Q. frainetto* and *Q. cerris*) was heated until to 100 °Cfor 1-4 h, whereas a loss of C content and an increase in ammoniacal N were observed at higher temperature.

Table 4. Mean values (±standard deviations) of water holding capacity and bulk density of soil determined in the first sampling (February 2011) in burned and unburned plots of Q. cerris stand.

Treatment	Water holding Capacity(%)	Bulk density (kg m^{-3})
Control	41.5 (±11.0)	0.94 (±0.2)
Burned	45.7 (±16.0)	0.95 (±0.2)

Table 5. Mean values (± standard deviations) of soil pH, water content, total N (N_{tot}), ammoniacal N (NH_4^+-N) and nitric N (NO_3^--N) in burned and unburned plots of Q. cerris stand at different sampling times. For each sampling date significant differences (one-way ANOVA) between burned and unburned are reported (* P<0.05: ** P<0.01).

Sampling date (times after fire) Treatment	pH	Water content (% d.w.)	N_{tot} (μg g^{-1})	NH_4^+-N (μg g^{-1})	NO_3^--N (μg g^{-1})

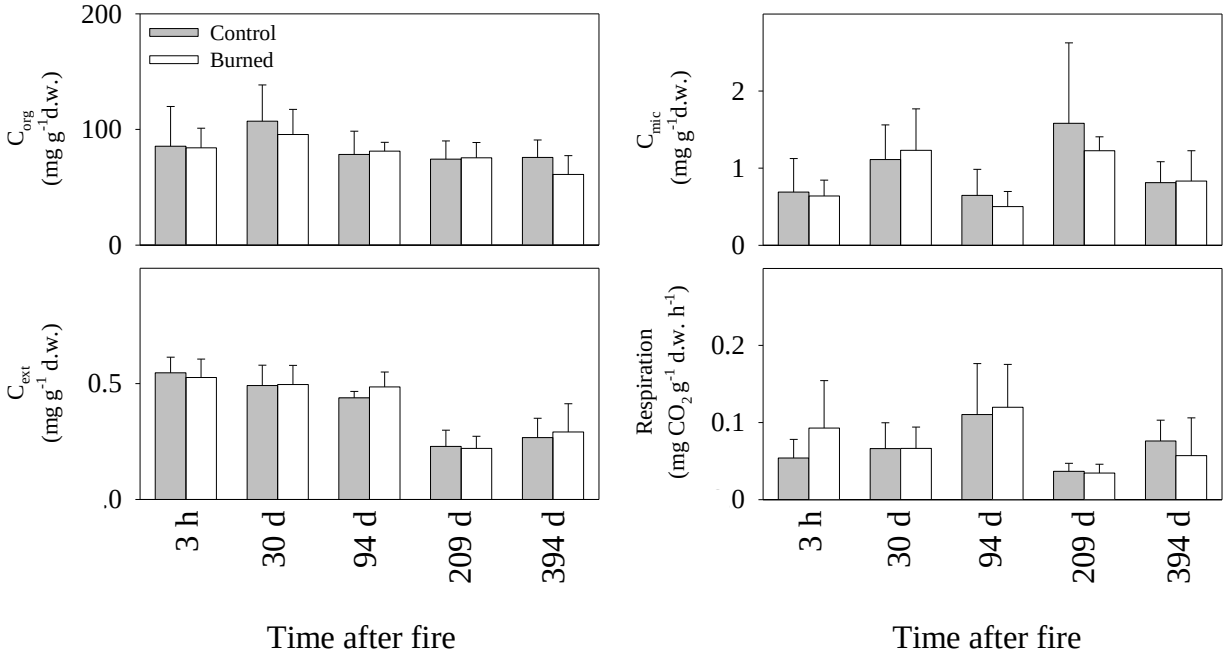

Figure 6. Mean values (+ standard deviations) of soil total organic C (C_{org}), extractable organic C (C_{ext}), microbial C (C_{mic}) and respirationin burned and unburned (control) plots.

Conclusion

In the studied Quercus cerris forest (*Lathyro digitati quercetum cerridis-subassociation festucetosum exaltata*) the prescribed burning application did not affect vegetation and soil during the two year after treatment. No significant changes occurred in floristic composition, species richness and density. The structural species Quercus cerris and some interesting protected taxa (*Ruscus aculeatus and Ilex aquifolium*) evidenced a high regeneration ability by regrowth of killed stem through resprouting new young shoot.

Moreover changes in soil chemical and microbial parameters due to fire were generally not significant and smaller than those occurring during the year, suggesting that fire-induced changes do not overcome the natural temporal variability of these parameters.

Our first results highlight the sustainability of prescribed burning in *Quercus cerris* forests as a management tool both in fire risk reduction and quercus cerris regeneration. Further monitoring activities should be continued to know the impact on all ecosystem components in the medium and long term and to evaluate the most appropriate burning prescriptions and time of frequency application.

Fire as a tool to manage pollination services

Julian Brown[a], Fiona Christie[a], Alan York[a]

Abstract
As a tool of land management and conservation there are a number of applications for which fire is poorly developed. One of those applications is the management of ecosystem services such as pollination and pest control that are provided by mobile organisms. Pollination in particular is an ecosystem service that requires improved management, in response to global declines in pollinators that present a threat to the plants that are dependent on them for reproduction. Much recent attention has been given to the effects of land use and land management generally on pollination, but little to fire as a particular form of land management. Here we develop a conceptual model describing hypothesised causal chains linking fire to pollination, and then report the initial findings of a study investigating fire effects on pollination as informed by this model for an orchid species native to Australia.

Keywords*: pollination, Caladenia tentaculata, fire, succession.*

Introduction

Fire is a tool with a wide variety of applications in land management and conservation. One potential application that has received little attention is as a means to manage ecosystem services provided by mobile organisms, such as pollination and pest control. Fire can influence the population and community dynamics of mobile organisms (Whelan *et al.* 2002), so it might be used to manage the services they provide. There is an urgent need to improve management of pollination services as recent declines in pollinators across the globe (including fire-prone regions) raises concerns over the loss of pollination services to crops and wild plant populations (Potts *et al.* 2010; Vanbergen and IPI 2013). Pollinators and consequently pollination services are affected by habitat conditions at the landscape-scale (Kremen *et al.* 2007) and fire is a relatively inexpensive tool for managing habitat at this scale. Recent research has indeed demonstrated the role of fire in structuring pollinator communities through habitat alteration (e.g. Potts *et al.* 2003a, b, 2005, 2006). However, pollination rate can be determined by factors other than pollinator population and community dynamics (Kremen *et al.* 2007); so it is important to consider whether fire might influence pollination through additional pathways to avoid unintended consequences of management. No single study has considered all the possible pathways through which fire might influence pollination.

A conceptual model describing hypothesised causal chains linking fire to pollination is developed here to guide research into the effects of fire on pollination. A general model of the effects of land use and land management on pollination has recently been developed (Kremen *et al.* 2007) and underpinned a recent quantitative model of pollination services across landscapes that performed well when evaluated against independent data (Lonsdorf *et al.* 2009). Within this tested framework the conceptual model of interactions between fire (as a particular component of land management) and pollination services is developed by combining the body of research in pollination ecology underlying Kremen *et al.*'s model with the relevant body of research in fire ecology. Kremen *et al.* propose that land use/management influences pollination by affecting the target plant to which pollination services are of interest (at the individual, patch, and population level), the plant community (with which the target plant interacts in competition or facilitation through shared pollinators), the pollinator community, and the biotic and abiotic factors that influence these groups. The model developed here (Figure 1)

describes the mechanisms (Blue boxes) linking fire (Orange box) to groups (Green boxes) to pollination (Yellow box). The mechanisms linking fire to groups can be direct (e.g. direct mortality) or indirect (e.g. alteration of nesting sites) effects that are immediate and/or occur along a time-since-last-fire trajectory (Dafni *et al.* 2012).

Kremen *et al.* (2007) highlight the importance of both local-scale changes in groups and their aggregation into landscape structure in influencing pollination. That is, there are multiple spatial scales at which changes in groups can influence pollination, which might be of particular relevance to fire management of pollination services. For example, flower visitation by bumblebees is related to the abundance of co-flowering plants within an area of 100-500 m^2, but not at larger or smaller scales (Thomson 1981; Johnson *et al.* 2003). Flower visitation by bumblebees is related to bumblebee habitat conditions within an area several orders of magnitude larger, corresponding to the bumblebees' home range (Westphal *et al.* 2006). The implication is that the size of a fire might determine its impact on pollination by determining the degree to which different pathways influencing pollination are affected; a fire that is 500 m^2 might alter competition or facilitation for pollination with little effect on pollinator populations, whereas a larger fire might impact both.

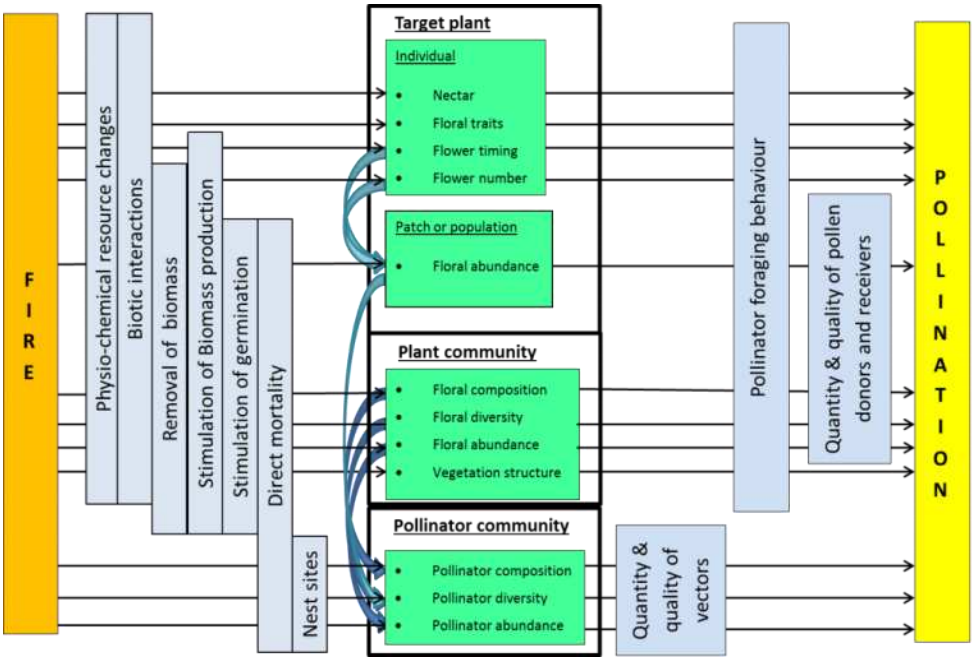

Figure 1. Conceptual model outlining hypothesised pathways of the relationships between fire and pollination. Fire may influence groups (Green boxes) through a range of mechanisms (Blue boxes). Groups may influence pollination directly (black arrows) or indirectly via a number of biotic interactions (blue arrows) through a second set of mechanisms (Blue boxes).

This model has been used to guide a PhD research project (J. Brown) into the effects of fire on pollination in a species of the Orchidaceae family (*Caladenia tentaculata*). There is a need to learn about fire effects on pollination in orchids because many inhabit fire-prone environments across the globe (Naveh *et al.* 1994; Swarts and Dixon 2009; Lamont and Downes 2011) and fecundity is generally limited by pollen (Trembley *et al.* 2005). A group of particular concern in Australia is the sexually-deceptive orchids that achieve pollination through mimicry of the sex pheromones of female insects. They occur in some of the most flammable ecosystems in the country (e.g. heathy woodlands) and are one of the most pollen-limited orchid groups (Tremblay *et al.* 2005; Phillips *et al.* 2009). The critically threatened status of a number of sexually-deceptive orchids has been attributed to the highly specialised, and so sensitive to ecological change, pollination system characteristic of this group (Swarts and Dixon 2009). Many sexually-deceptive along with other groups of terrestrial orchids are

stimulated to flower by fire (Jones 2006; Coates and Duncan 2009; Duncan 2012), and the promotion of flowering and emergence through regular burning is a common management recommendation for these plants (Cropper *et al.* 1989; Lunt 1994; Coates *et al.* 2006; Coates and Duncan 2009). However, the effects of fire on pollination through any of the possible pathways is unknown, so there is no way of predicting the effect of regular burning on pollination and determining to what extent this will depend on fire size. Reported here are the findings from the pilot study of a PhD project (J. Brown) investigating the effects of fire on pollination in the sexually-deceptive orchid *C. tentaculata*.

Methods

Study System

The study landscape was an area of approximately 15,000 km^2 in south-west Victoria, Australia (Figure 2). The area encompassed the Grampians National Park and numerous forests on public land between the National Park and the South Australian border. The native vegetation consists of sclerophyllous heaths, shrub lands, and woodlands interspersed with open grasslands (Gibbons and Downes 1964; Dodson 2001). The area has a Mediterranean-type climate (hot dry summers and mild wet winters), and has experienced recurring fires throughout the Holocene (reviewed in Dodson 2001). Prescribed fire is currently applied to vegetation on public land in an attempt to protect lives and property and achieve ecological objectives (DEPI 2013a, b). The area was chosen because the orchid and its pollinator have been detected at a number of localities in this area (Bower 2009), there is a broad range of fire histories, and minimal topographic variation between sample locations. In order to cover a wide range of post-fire successional stages this research was based on a chronosequence of 52 heathy woodland sites ranging from several months since last fire to several decades since last fire.

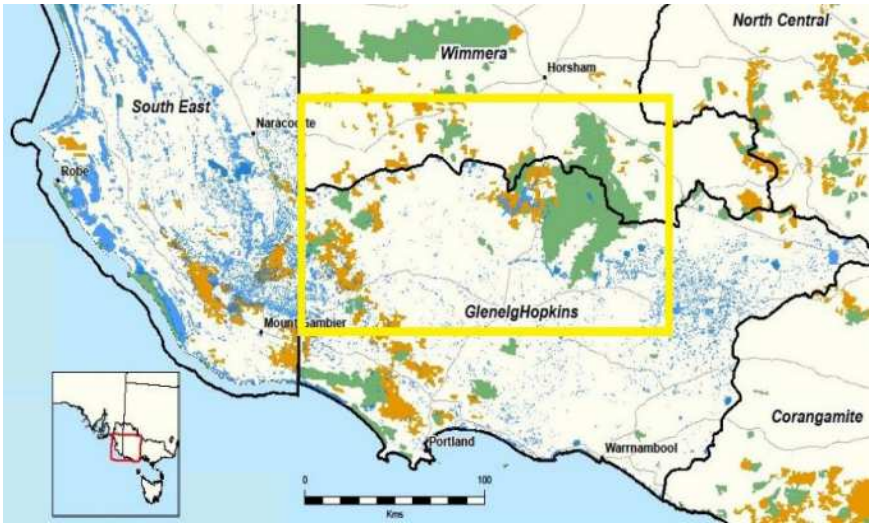

Figure 2. Area (yellow rectangle) of south-west Victoria within which all samples were collected. Green and brown areas are native vegetation (National Park and State Forest respectively), blue areas water bodies, and white rural and residential.

The native orchid *C. tentaculata* has been chosen for this study for a number of reasons. It is stimulated to flower by fire (Jones 2006; Duncan 2012). It is also known to be pollinated by a single species of parasitoid wasp from the thynnine subfamily – *Thynnoides pugionatus* – by sexual deceit (Peakall and Beattie 1996; Jones 2006). Both plant and pollinator are widespread and common in south-east Australia (Jones 2006; Bower 2009), allowing for relatively large sample sizes.

Data collection

The main response variable of interest was the visitation rate of *T. pugionatus* to *C. tentaculata* flowers. The pollinators of *C. tentaculata* respond rapidly to the presentation of its flowers (Peakall and Beattie 1996), so at each of the 52 sites four *C. tentaculata* flowers (growing in pots) were placed at a single location for 10 minutes and the number of times pollinators made contact with (visited) the flowers was observed (sexually-deceptive orchids typically exhibit one-to-one relationships with their pollinators and the pseudo-copulatory flower visiting behaviour is distinct [Gaskett 2011], such that pollinators could be identified by observing visitation). This was done multiple times at each site to allow for the development of a model that accounts for the probability of detecting the pollinator (i.e. number of visits being greater than zero) given its presence. Also obtained at each location was the time-since-last-fire (TSLF) at the site (sites 55 years or greater were classified as 55 years old which corresponds roughly to senescence for heathy woodlands [Cheal 2010] and the limits of accurate fire records for this region) from GIS layers provided by the Department of Environment and Primary Industries, temperature (since this is known to influence wasp activity) at the time of pollinator sampling, and for the recently burnt sites (less than three years before the time of sampling) the distance to the nearest edge of the burnt site (i.e. distance to nearest unburnt vegetation).

2.3. Data analysis

Only observations made above the critical temperature threshold for wasp activity of 17°C (determined using repeat observations at sites to model the probability of detecting the pollinator given its presence as a function of temperature, which is not presented here) were used for the analysis presented here. Zero visits were observed at a large proportion of the sites, so logistic regression was first used to model pollinator presence/absence (i.e. greater than zero visits/zero visits respectively) as a function of TSLF, and simple linear regression was used to model the maximum number of visits observed at each site where pollinators were present (that is, excluding sites where no pollinators were observed) as a function of TSLF. For the logistic regression, R^2 was calculated using the method developed in Nakagawa and Schielzeth 2013). For the subset of the data corresponding to recently burnt sites, simple linear regression was used to model the maximum number of visits observed at each site as a function of distance to the nearest edge of the burnt site. All analyses were performed in the R statistical environment (R Development Core Team 2011).

3. Results

The model of pollinator presence/absence as a function of TSLF was a poor fit to the data ($R^2 = 0.00$). When the maximum number of *T. pugionatus* visits to *C. tentaculata* observed at each site was modelled as a linear function of TSLF, the model explained a negligible amount of the variation ($R^2 = 0.02$). The relationship between the maximum number of visits and TSLF is shown in Figure 3 below, and it can be seen that unusually high visitation values were observed in two very recently burnt sites and one long unburnt site, but that lower values were observed across all sites (thus explaining the poor model fit).

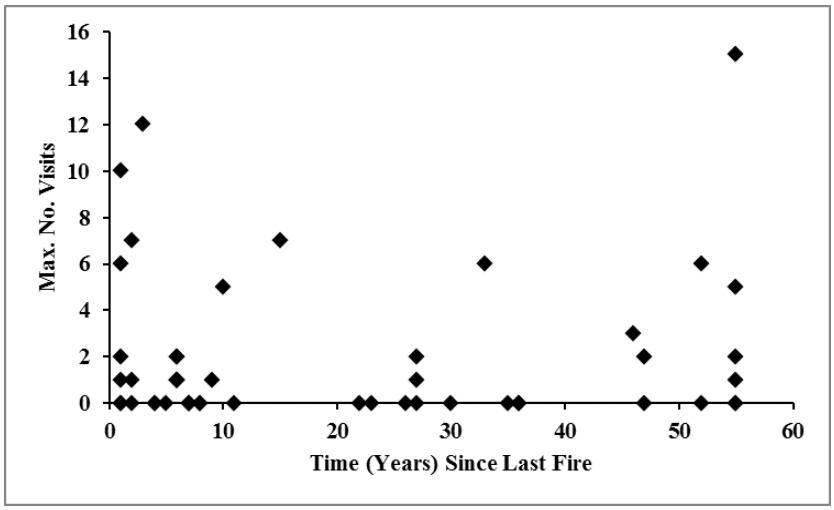

Figure 3. Show the maximum number of visits to C. tentaculata flowers by thynnine wasps at each site as a function of the number of years since the last fire at each site.

The model of the maximum number of visits to flowers at recently burnt sites as a linear function of distance from the nearest edge of the burn site was also a poor fit to the data ($R^2 = 0.00$). Figure 4(a) shows that this can be attributed to an extreme outlier. With this outlier removed (Figure 4(b)), model fit improved substantially ($R^2 = 0.45$). Inspection of Figure 4(b) suggests that inclusion of polynomial terms would further enhance model fit, though there were not enough observations to allow the addition of further parameters.

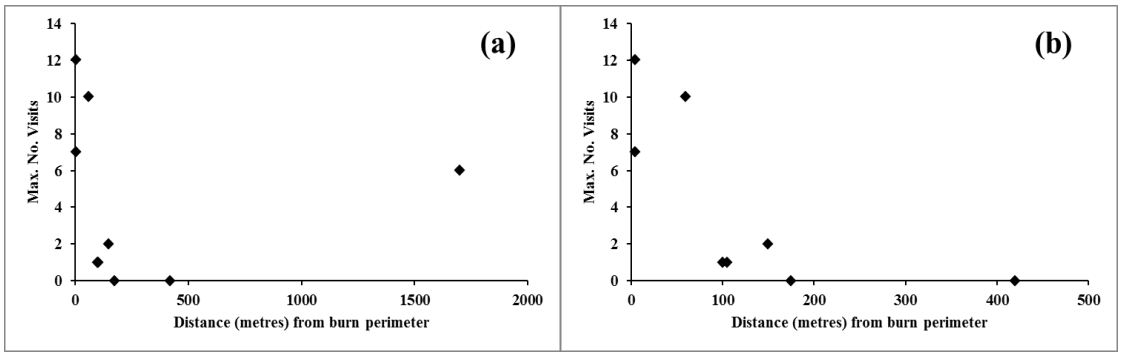

Figure 4. Shows the maximum number of visits to C. tentaculata flowers by thynnine wasps at (a) each recently burnt site and (b) each recently burnt site except for the outlier site, as a function of the distance of the flowers from the nearest edge of the burn site

Discussion

Statistical models developed here were generally poor fits to the data. Pollinator presence or visitation rate showed no clear relationship with TSLF, and visitation rate in recently burnt sites only showed a relationship to distance from the nearest edge of the burn site when an outlier was removed. The value of this pilot study lies in the potential explanations for the failure of fitted models to explain observed variation.

The outlier in the data pertaining to the recently burnt subset of sites is interesting. It lay approximately 1,700 m from the burn perimeter, which is well beyond the distance from the perimeter where the model without the outlier predicts zero visitation. It has been suggested that some thynnine wasps (the subfamily to which *T. pugionatus* belongs) might be capable of travelling up to 1,600 m, but most are

thought to be restricted to distances of 800 m (Ridsdill-Smith 1970) and the greatest distance *T. pugionatus* has been observed to travel between *C. tentaculata* flowers was 58 m (Peakall and Beattie 1996). Thus, either the observed outlier extends the known foraging range of thynnine wasps, or the wasps were resident in the recently burnt site. The TSLF GIS layer used in this analysis does not include information about variation in fire severity within fire perimeters, which may provide faunal refugia that allows fire-sensitive animals to be present immediately after fire (Whelan *et al.* 2002; Penman *et al.* 2007). Alternatively, the wasps are capable of rapidly recolonizing from surrounding unburnt vegetation or surviving the passage of fire of any severity.

Although models were generally poor fits to the data, the patterns observed are interesting in the context of the conceptual model developed in the introduction. From the patterns shown in Figure 3 and Figure 4(b) it would appear as though when *C. tentaculata* flowers in the early post-fire environment (as it tends to do) it is capable of attracting more visits from its pollinators compared to other post-fire seral stages (except perhaps for very long unburnt sites), provided it is not too far from unburnt vegetation. In other words, small fires centred on the orchid may enhance pollination, but as fire size increases the pollination benefits may eventually disappear such that visitation is equal to or less than what is experienced in later seral stages. Thus, the size of a fire may be important in determining its impact on *C. tentaculata* pollination. However, this requires more formal testing as the data presented here are suggestive at best.

Although this tentative model is yet to be tested, it is interesting to consider the underlying mechanisms. Petit and Dickson (2005) found that the pollination rate of a sexually-deceptive orchid decreased as the amount of vegetation within close proximity increased, which they attributed to increased difficulty for pollinators in locating orchid flowers. In the heathy woodland system studied in the present paper, vegetation structure is low in the early post-fire environment, gradually increasing to a maximum in mid successional stages, and then declining again late in succession (Cheal 2010; Brown 2013). Thus, the highest potential (depending on other factors such as perhaps distance from burn edge) pollination rates would be expected in recently burnt sites, and then again much later in succession, which is what was observed in the present study. A decrease in visitation in recently burnt sites with increasing distance from unburnt vegetation might occur if pollinators are incapable of inhabiting or otherwise avoid recently burnt sites, entering only when enticed by a signal (in this case indicating the possibility of a mating opportunity, since the orchids are sexual mimics) that presumably decreases in strength with greater distance from the source (the ability of an insect to detect a sex pheromone decreases as a logarithmic function of distance from the odour source [Andersson *et al.* 2012]). Further work is required to investigate these possible mechanisms in the study system.

The next stage of the PhD project is to explore some of the possible interpretations of the data presented here. The main focus will be on determining the relationship between visitation and distance from the edge of the burn site. Observations will be made of visitation to *C. tentaculata* flowers placed at a number of fixed distances from the fire perimeters of a number of recently burnt sites, and attempts will be made to control for burn severity. Processes operating at different spatial scales will also be explored. In particular, relationships between *C. tentaculata* pollination and vegetation structure (and co-flowering heterospecifics) measured within close proximity to the orchid, and between pollinator activity and seral stage composition at the landscape scale. Together the findings from this research will contribute to the knowledge base required to effectively use fire to manage *C. tentaculata* and other sexually-deceptive orchids with fire-stimulated flowering, which are among the most threatened in Australia (Victoria Flora and Fauna Guarantee Act 1988).

Abstract

Fire is one of the most drastic disturbances in forest ecosystems, particularly in Mediterranean ecosystems. Global change, including climate change and land use changes, is strengthening the rising of frequency and intensity of them. The knowledge of the resilience of the main Mediterranean ecosystems would allow defining policies and actions to protect the most vulnerable species.

One of the problems that the concept of resilience presents it is to be a concept associated to the dynamic of the ecosystem and there is no definition to quantify in a normalized and standardized way. This work propose an original methodology that involves the definition of type curves of recovery based on a time series of NDVI data, from Landsat satellite images, and the analysis of the potential changes in the taxonomic composition of the ecosystem after fire. We present the analysis of two areas affected by forest fires in the southeast of the Iberian Peninsula. It involves representative plant communities in this region, specifically esparto-grassland, esparto and rosemary shrubbery, and Aleppo pine forest.

Keywords*: resilience, site quality, landscape ecology, forest dynamics.*

Introduction

Fire is one of the main drastic disturbances in forest ecosystems, mainly in Mediterranean ecosystems, and plants have developed traits to cope with fire. Resilience has been defined as the capacity of an ecosystem to respond to a disturbance by resisting damage and recovering in a relatively short period of time in plant communities. The resilience is a function of the composite resiliences of the assemblage of species populations (Keeley 1986).

Global change, climate change and changes in land use or land cover, modified fire regime in South-eastern Spain in the last three decades (Pausas 2004). The changes promoted an increase in the number and recurrence of wildfires, its intensity and severity, burned surface and the period of fire risk. Those changes in fire regime could induce changes in the climax stage of plant community and/or ecosystems, relegated to secondary stages in the succession or, even, to paraclimax stages (San Miguel Ayanz *et al*., 2012). It implies a decrease in productivity and a reduction in plant diversity, in addition to variations in spatial distribution and vegetation structure. Forest management based on natural disturbances could maintain and restore ecological resilience (Drever *et al*., 2006) which should be taken into account in planning and policies to protect the less resilient species and improve it.

Tools helping decision makers should include analysis of resilience and adaptive resource management based in scientific knowledge. The concept of resilience is associated with ecosystem dynamics and different approaches have been developed for concrete cases of study, however, there is still a lack

regarding to obtain a normalized and standardized method to quantify relative resilience. The main objective of the current framework was to develop a tool for landscape-scale monitoring and prediction of vegetation resilience, related to management objectives.

Methods

Study area

This work was carried out in two areas burnt in 1994 in the municipality of Hellin (province of Albacete). Before fire, mature and natural Aleppo pine forests (*Pinus halepensis* Mill) and esparto-grasslands (*Macrochloa tenacissima* (L.) Kunth) covered the study area. The study area was characterized as a semiarid type and the potential natural vegetation was a shrubland of *Quercus coccifera* L. (*Rhamno lycioidis - Quercetum cocciferae* sigmetum) (Rivas-Martinez 1987). After fire, the vegetation was mainly composed of Aleppo pine, esparto grass and rosemary (*Rosmarinus officinalis* L.). Physical and climatic characterization of the study areas is shown in Table 1.

Table 1. Physical and climatic characterization corresponding to the analysed areas. Rainfall and temperature were calculated for the last 30 years

Experimental design

Resilience concept includes multiple aspects, such as taxonomic composition and pre-fire community structure changes, changes in ecosystem functions and impacts of processes rates (Holling, 1973). In this work it is formulated a methodological approximation to the resilience concept, centered on the study of plant community composition changes (successional stages) and on structure changes (recovery dynamics). In addition, those changes are analyzed in terms of plant community external factors, as fire severity and site quality. Here, the site quality concept is approximated by the amount of vegetation before the fire.

In particular, the study of changes in the taxonomic composition of communities after fire has been carried out based on pre-and post-fire cartography and forest inventories (Table 2). Structural changes in vegetation have been determined from the estimation of the recovery dynamics based on the amount and greenness of the vegetation. For that end, it has been proposed the assessment of the temporal evolution curves of the *Normalized Difference Vegetation Index* (NDVI) in the burnt areas. We use seventeen Landsat images, all of them distributed in the period 1992-2011. The acquisition dates of all Landsat images used were in spring, to avoid potential seasonal changes in NDVI due to phenological variations. Landsat images were also used to determine fire severity in terms of the *differenced Normalized Burn Ratio* (dNBR) (Key and Benson, 2006). For each pixel in the image of the study areas a record with all the fields from the databases showed in Table 2 was assigned. This information was used to analyse the changes in the taxonomic composition of communities, to define site quality and resilience.

Results

The vegetation present in the area was classified into five general plant formations and two plant sub-types in order to analyse their different post-fire behaviours (Table 3).

Table 3. Plant formations in the study area

		Plant formation	Name	Description
90%	68%	Formation 1	Esparto grassland	Mainly esparto grassland
		Formation 2	Grass-shrub	Land associated with scrub grassland. Scrub surface does not exceed 20%.
		Formation 3	Shrub	Predominance of shrubs and suffrutescent plants.
	32%	Formation 4	Aleppo pine open forest	Aleppo pine high pole wood forest (canopy cover fraction 10 %)
10%		Formation 5	Aleppo pine dense forest	5.1. Aleppo pine high pole wood forest (canopy cover fraction 30 %)
				5.2. Aleppo pine high pole wood forest (canopy cover fraction 60 %)

Taxonomic composition changes

Changes in land cover were analysed. Table 4 shows the changes in the percentage of soil coverage by each plant formation before (PRE) and after fire (POST). These results have been analyzed based on fire severity, site quality, and physiographic factors as slope and aspect. Table 5 summarizes these external factors. Site quality has been assimilated to the amount of vegetation before the fire and discretized into five levels, with the AAA category the highest quality, and the BB the category of lowest quality. Likewise, we have established four levels of severity: high, moderate-high, moderate and low.

Table 4. Vegetation before and after fire, percentages of land cover changes according to the taxonomic composition (Table 3)

POST / PRE	Esparto grassland	Grass-shrub	Shrub	Aleppo pine open forest	Aleppo pine dense forest	**% Before fire**
Esparto grassland		93		7		**5**
Grass-shrub	17	35	2	42	4	**29**
Shrub	16		80	4		**34**
Aleppo pine open forest		75		15	10	**23**
Aleppo pine dense forest	8	2	20	18	52	**9**
% Post-fire	**10**	**43**	**10**	**25**	**11**	

Recovery dynamics post-fire vegetation

From NDVI time series, until eight different patterns or curve types of the dynamics of regeneration of the vegetation structure were identified and defined. The eight characteristic patterns are regarded as 'recovery curves' Figures 1-2 grouped the individual behaviours of all analyzed pixels. In particular, Figure 1 shows for the less mature plant formations (i.e. Esparto grassland, Grass-Shrub and Shrub) these recovery curves in relation to post-fire vegetation, site quality conditions and fire severity, factors which modulate the recovery dynamics.

Table 5. Pre and post fire vegetation, site quality, fire severity, altitude and dNBR.

Pre-fire vegetation	**Post-fire vegetation**	**Site quality**	**Altitude (m)**	**Severity**	**dNBR**
Esparto grassland	Grass-shrub	BB	530 ± 30	Low	160 ± 30
	Aleppo pine opened forest	BB	461 ± 15	Low	197 ± 10
Grass-shrub	Esparto grassland	B	630 ± 90	Low	220 ± 70
	Grass-shrub	B	530 ± 80	Low	240 ± 70
	Shrub	A	690 ± 60	Mod-Low	330 ± 60
	Aleppo pine opened forest	B	530 ± 40	Mod-Low	280 ± 80
	Aleppo pine dense forest 30%	AAA	780 ± 30	Mod-Low	370 ± 80
Shrub	Esparto grassland	B	530 ± 50	Low	200 ± 50
	Shrub	B	530 ± 50	Low	220 ± 70
	Aleppo pine opened forest	AA	585 ± 15	Mod-Low	354 ± 7
Aleppo pine opened forest	Grass-shrub	B	550 ± 70	Low	200 ± 60
	Aleppo pine open forest	B	570 ± 70	Low	260 ± 80
	Aleppo pine dense forest 30%	B	580 ± 50	Low	220 ± 50
Aleppo pine dense forest 30%	Shrub	BB	510 ± 15	Low	144 ± 24
	Aleppo pine dense forest 30%	A	514 ± 7	Mod-Low	283 ± 4
Aleppo pine dense forest 60%	Esparto grassland	B	640 ± 110	Baja	260 ± 130
	Grass-shrub	BB	470 ± 20	Low	202 ± 8
	Aleppo pine opened forest	AA	500 ± 50	Mod-Low	360 ± 170

	Aleppo pine opened forest	AA	730 ± 30	Mod-Low	380 ± 90
	Aleppo pine dense forest 30%	B	770 ± 18	Mod-Low	280 ± 9
	Aleppo pine dense forest 30%	AAA	680 ± 60	Mod-High	400 ± 100
	Aleppo pine dense forest 60%	AA	696 ± 24	Mod-Low	350 ± 60

Discussion

Immature formations mainly predominate in the study area, which is coherent in a semiarid climate. Indeed, there is no climacic vegetation (*Rhamno lycioidis-Quercetum cocciferae* sigmetum) in the area, regressive climax only. About 33% of the pre-fire vegetation changed to regressive stages of autosuccession, one third of vegetation remained in the same successional stage after disturbance and other 33% developed in a more mature successional stage. Surface of Esparto grassland increased based in changes of its spatial distribution. In most of Esparto grasslands before fire, we recorded regeneration of Aleppo pine after fire. However, shrublands and open marginally in Aleppo pine forest before fire regenerated as Esparto grass. In a similar way, surface of shrubland increased after fire. We

found similar surface of Aleppo pine forest pre and post-fire. The low site quality in semiarid Mediterranean stands promoted an unstable equilibrium. In this case, fire severity is a key variable influencing recovery after fire.
Related to the dynamics of the structure recovery, patterns are related to the post-fire vegetation. Aleppo pine dense forest with a canopy cover fraction of 60% showed three different patterns being the resulting post-fire vegetation the same. For the same vegetation formation and canopy cover fraction, curve 44 in comparison with curves 1 and 32, would correspond to vegetation with higher greenness. Moreover, low quality site areas showed the 1998 and 1999 drought effect, as can be seen in the 16, 31, 28 and 41 curves.

Conclusions

The methodology is suitable for the evaluation of the evolution of regeneration of forests after fire. The first results of this study allow us to distinguish areas with different "characteristic curves". This kind of study is interesting for decision making, aimed to optimize resources and improve the management of burned areas. Forest external factors, such as fire severity, site quality or physiography are determinants to post-fire resilience. This contribution is a first step to develop a methodology based on both, fire and recovery sensitive to contextualize short and medium-term change with respect to any potential or desired pre-wildfire stand condition.

Abstract
Forest fires represent a major threat to Lebanon's forests. More precisely, *Pinus brutia* forests, which occupy relatively large areas in Lebanon, are affected by frequent fire events. Lebanon's National Strategy for forest fire management highlighted the need to facilitate natural forest regeneration and undertake reforestation activities in areas where regeneration is not possible. Accordingly, this study aimed at assessing post-fire regeneration of *Pinus brutia* in the Mediterranean region of North Lebanon. A total of 540 samples of 1x1m² were collected on 18 different sites affected by fires throughout the past 20 years. The density of seedling regeneration was calculated for each plot. The highest regeneration density (10.33 seedlings/m²) was observed on plots that were sampled one year after fire. The regeneration density decreased by 68% on plots sampled four years after fire when compared to plots sampled one year after fire. Also, the plots that were sampled five years after fire showed a 93.8% decrease in regeneration density. This continuous could be attributed to a high mortality rate due to prevailing severe weather conditions and human disturbances. The results highlighted the need to implement efficient post-fire management measures within the first four years after a fire event to decrease the mortality rate of young pine seedlings and to assist in the successful recovery of fire affected sites.

Keywords*: forest fires, post-fire natural regeneration, Pinus brutia*

Introduction

Lebanon's forest cover is a unique feature in the semi-arid environment of the Mediterranean. Lebanon's forests play an important role in supporting high biodiversity and providing a variety of environmental goods and services. Nevertheless, several biophysical and anthropogenic factors have shaped biodiversity in Lebanon (MOE/UNDP, ECODIT 2011).
Increasingly, fire occurrence risk was observed in association with high maximum temperatures and long dry seasons (Salloum and Mitri, 2014). Forest fires represent a major and continuous threat to Lebanon's forests (Mitri *et al*., 2014). In this context, monitoring post-fire regeneration of *Pinus brutia* is expected to support National efforts in restoring healthy ecological conditions of burned forest lands by providing useful and insightful information about the status of natural regeneration after fire (Mitri and Fiorucci, 2012).
Lebanon's National Strategy for forest fire management clearly indicated the need to facilitate natural forest regeneration and undertake reforestation activities in areas where regeneration is not possible (MOE/AFDC, 2009). Until present, Lebanon lacks comprehensive studies for assessing trends in post-fire forest regeneration. Accordingly, the aim of this study was to assess post-fire regeneration of *Pinus brutia* in North Lebanon.

2. Study area and dataset description

Lebanon is situated on the eastern shores of the Mediterranean. The country is characterized by its Mediterranean climate with warm and dry summer and cool and wet winters. Forests in Lebanon cover around 139,376 ha which accounts for 13.3 % of the Lebanese territory. Coniferous forests occupy 31

% of the total forest cover (MOE/UNDP/ECODIT, 2011). More specifically, pine forests including *Pinus pinea*, *Pinus brutia*, and *Pinus halepensis* are mostly found on the western slopes of the Mount Lebanon chain and they are constantly affected by fire events.
During the year of 2013, sampling of *Pinus brutia* fire affected forests was conducted on 8 different fire sites located between 500 m and 1000 m above sea level in North Lebanon (Table 1). A total of 540 samples of 1x1m² were collected and the number and height of seedlings was recorded for each sample. Historical weather data showed that around 95% of the annual precipitation fall between October and April. The average rainfall in this region has an average 1210 mm per year (MOE/UNDP/ECODIT, 2011).

Table 1. Characteristics of fire affected sites

Year of fire	Slope percent	Elevation (m)	Aspect
1993	30	703	North East
2004	5	710	West
2006	45	722	South
2007	30	794	North west
2007	10	416	South west
2008	15	642	North East
2009	30	670	South east
2012	45	1139	North east

Methods

3.1. Field sampling

The field sampling comprised surveying 20x20m plots. Each plot comprised three different locations of sampling across the slope (namely, top, middle, and bottom). A total of 30 samples of 1m² were collected within each plot using the belt transect sampling method. The length of the belt transect was 20 meters and the sampling interval was 5 meters. A quadrat of 1 m x 1 m was placed on each side of the line at the interval level. Accordingly, the number and height of individual seedlings were collected.

3.2. Statistical analysis of field data

The calculation of the regeneration density was developed based on the number of seedlings per square meter (Equation 1), an approach that was also used by Titsoni (1997).

$$\frac{\Sigma \text{ number of seedlings}}{\text{Total number of plots}} \qquad \text{Equation 1}$$

Consequently, the variation in the post-fire regeneration density of *Pinus brutia* based on descriptive statistics, and the average regeneration density was calculated for each year. ANOVA-stepwise analysis was applied to investigate significant changes in regeneration density and height of seedlings throughout the years.

Results and discussion

The highest regeneration density (average of 10.33 seedlings/m²) was recorded on plots that were surveyed one year after fire. This could be attributed to seed availability on site and lack of long-term natural stresses and human disturbances (Figure 1).

Sites surveyed three years after fire showed a decreased density by 68% (7.11 seedlings/m²) when compared to the results of sites surveyed one year after fire. Following the same comparison approach, sites sampled five years after fire showed an abrupt decrease in the regeneration rate (0.44 seedlings/m²), while sites sampled six years after fire showed only 0.22 seedlings/m². These gradual decreases in regeneration density could be attributed to both environmental and anthropogenic conditions including severe climatic conditions, human disturbances, and the effect of local environmental characteristics of the sites. Other factors such as fire characteristics (fire severity), could also affect regeneration density of *Pinus brutia* (Pausas *et al*., 2008).
Finally, the results from plots sampled twenty years after fire showed a regeneration density of 1 seedling/m². This could be attributed either to insignificant variation in regeneration density or to a continuous enrichment of young seedlings from the surrounding forested areas (Tsitsoni, 1997).

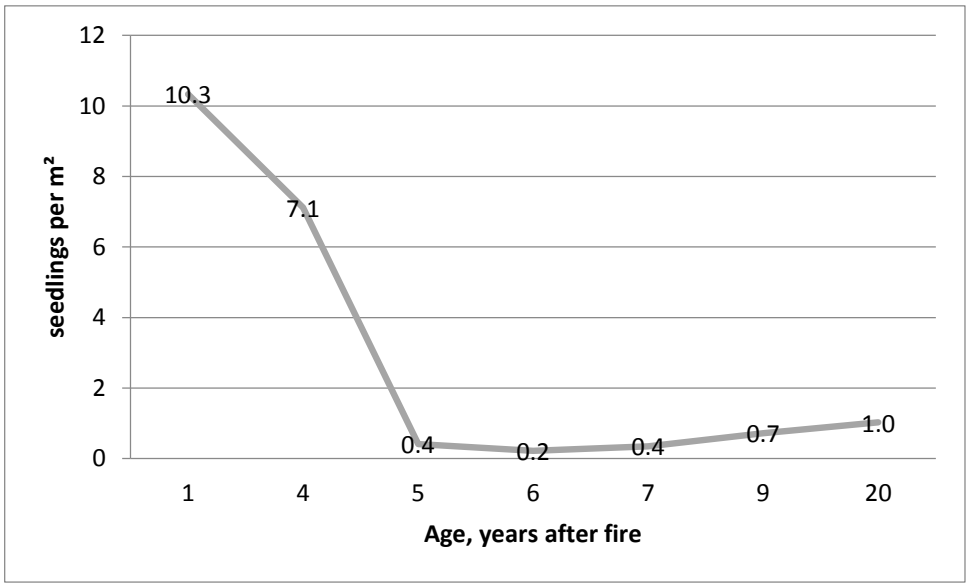

Figure 1. Multi-temporal rate of regeneration density of Pinus brutia

The regression analysis showed post-fire average height increment of 9.26 cm (Figure 2), while other studies in the Mediterranean showed an average growth of 5-20 cm per year (Neyisci, 1989; Thanos *et al*., 1989; Spanos, 1994; Spanos el al., 2000).

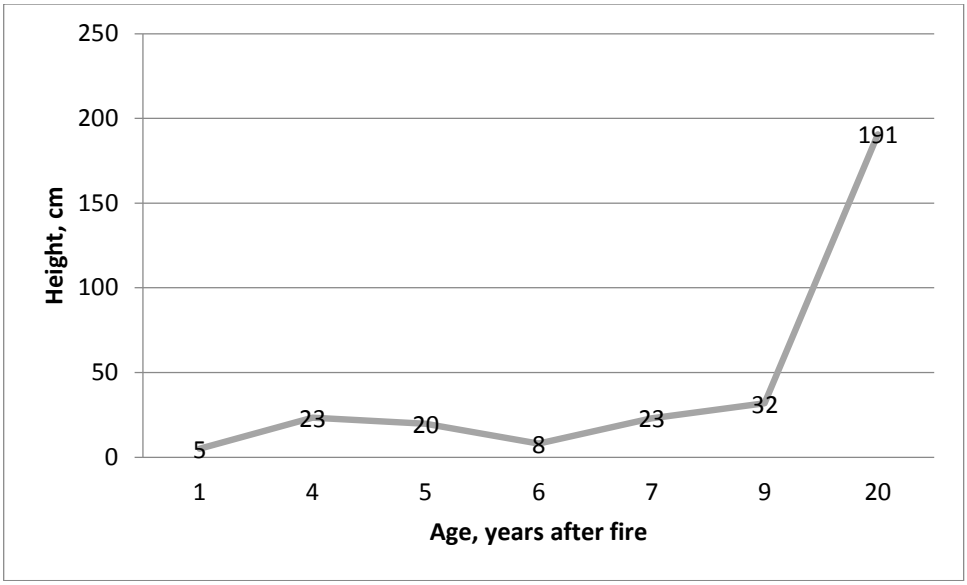

Figure 2 Post-fire variation of average seedling height

Conclusions

The highest regeneration density (10.33 seedlings/m²) was observed on plots that were sampled one year after fire. When compared to plots sampled five years after fire, the regeneration density abruptly decreased to 0.44 seedlings/m².

In the light of these findings, it is essentially important to invest more post-fire restoration efforts in assisting natural regeneration in order to promote natural recovery of pine burned forests. The implementation of certain protection measures during the first two years after a fire event is expected to facilitate a higher survival rate of established seedlings. This is expected to be a cost saving initiative in comparison to costly reforestation campaigns.

Future work will involve conducting further studies to understand the different factors that affect the natural regeneration of pine forests in Lebanon as an attempt to come out with improved post-fire management initiatives.

Natural and anthropogenic fire regimes in boreal landscapes of Northwest Russia

Andrei Gromtsev , Nikolai Petrov

Forest Research Institute, Karelian Research Centre, Russian Academy of Sciences,
11 Pushkinskaya St., Petrozavodsk, Russia, gromtsev@krc.karelia.ru, nvpetrov@krc.karelia.ru

Abstract
Patterns in the natural fire regime in different types of geographical landscape and its present-day transformations are considered. Surveys were carried out in the north-west of the Russian boreal zone at the junction of two North-European physiographic domains – Fennoscandian Shield (Fennoscandia) and East-European (Russian) Plain. The resultant data disclose the history of fires and their landscape-related characteristics over the past millennium. The frequency and intensity of wildlife fires may differ drastically among landscapes – from 1-2 in a century to 1-2 in a millennium. Multiple intermediate variants fill the range between these two poles. It is demonstrated that conservation of pristine forests with their spontaneous dynamics in protected areas is possible only under a natural fire regime. The total and average size of fires has been gradually decreasing. In the study area, e.g. the indices have over the past half a century ranged within 100-10 000 ha, and 5-20 ha a year, respectively. Humans have significantly increased the frequency of forest fires. The patterns identified can be quite confidently extrapolated to the whole boreal zone of European Russia. The characteristics of geographical landscapes (the range, ratio and spatial arrangement of their types) and land use history must however be taken into account.

Keywords*: boreal landscapes, natural fire regimes, current situation*

Introduction

Various aspects of the natural development of European boreal forests as related to fires are discussed in a great number of publications, including the authors' own (Gromtsev 1996, 2002, 2008, etc.). It is obvious the topic is of high interest to researchers. Fires (lightning-ignited) used to be the weightiest ecological factor shaping the structure and dynamics of pristine forests. Man-induced fires are now an equally important factor.
In an overwhelming majority of cases systematized data on natural fire regimes in Russia were obtained either by dating fire scars on trees or from archives. In the first case retrospective analysis is limited to 250-350 years (maximum age of the oldest tree generation). In the second case only very strong fires were recorded, but were not referenced to specific locations and ecotopes. Furthermore, averaged data for a region or habitat with no connection to the landscape features of boreal areas are usually given. They however also focus on individual sites without linking the situation to specific characteristics of boreal landscapes. Let us analyze the successions of spontaneous boreal forests in different types of geographical landscape in the second half of the Holocene and follow the major trends in them.

Study area, methodological background, and methods

Surveys were carried out in the north-west of the Russian boreal zone in the drainage basins of Lakes Ladoga and Onega, and west of the White Sea. Administratively, the central position in this region is occupied by the Republic of Karelia (total area ca. 15 mln ha excluding the water area of the named waterbodies). The area lies at the junction of two North-European physiographic domains – Fennoscandian Shield (Fennoscandia) and East-European (Russian) Plain (Fig.1). Hence, the study

area features a high diversity of geographical landscapes, even in terms of the relief (from flat marine plains to crystalline uplands rising higher than 1000 m above sea level).
Different types of geographical landscape were surveyed using the classification and map prepared in advance (Tab.1). The landscapes were distinguished by genetic types of relief, degree of paludification, and prevalent forest vegetation (prior to human impact on the forest cover). The classification was based on the zonal and the typological principles. The former differentiated the territory into the northern, middle and southern taiga subzones. The latter implied that contours similar in all landscape-forming traits but spatially discontinuous were combined into one 'type'. An average area of a landscape contour was ca. 100,000-150,000 ha. Over 30 landscape types have been identified and comprehensively studied (forests, wetlands, flora and fauna, land use history, etc.). Both the natural and the human-induced change of the landscape biotic components was studied. As applied to fires the main methods were: 1) stratigraphic analysis of peat deposits with dating of fire layers according to the peat deposition rate (ca. 1000 cores were treated); 2) recording of charcoal underneath the forest floor and the remains of burnt tree trunks with simultaneous analysis of the forest cover composition and age structure (ca. 5 000 pits); 3) dating of fire scars on trees (several hundreds records); 4) analysis of various archival materials (since mid-19th century) and modern fire statistics (covering the past 60 years).

Table 1. Classification of landscapes (example of the Republic of Karelia)

Predominant habitats	Degree of paludification		
	heavy >50%	moderate 20-50%	low <20%
I. Lacustrine, glacio-lacustrine and marine (m) plains			
Spruce	1/1,5[A]	2/4,0	-

[B] - less than 0,5%

Results

The resultant data disclose the history of fires and their landscape-related characteristics over the past millennium. Distinct fire layers (FL) were detected in deposits at different depths. The deepest-lying FL was at 2.85 m, and a charred organic-mineral layer – at 3.7 m. The layers are roughly dated to 5.5-7.5 Ka B.P. Searching for older FL involves sampling from deeper peat deposits (down to 10 m), few of which have been found in our landscape profiles. Thus, fires were a common ecological factor influencing the forest cover in the Holocene. Note here that only the fires reaching into peatland habitats are considered. Their traces can be clearly identified in the field. Fires confined to dry areas were identified separately by fire scars on trees and stags, or by charcoal underneath the forest floor.

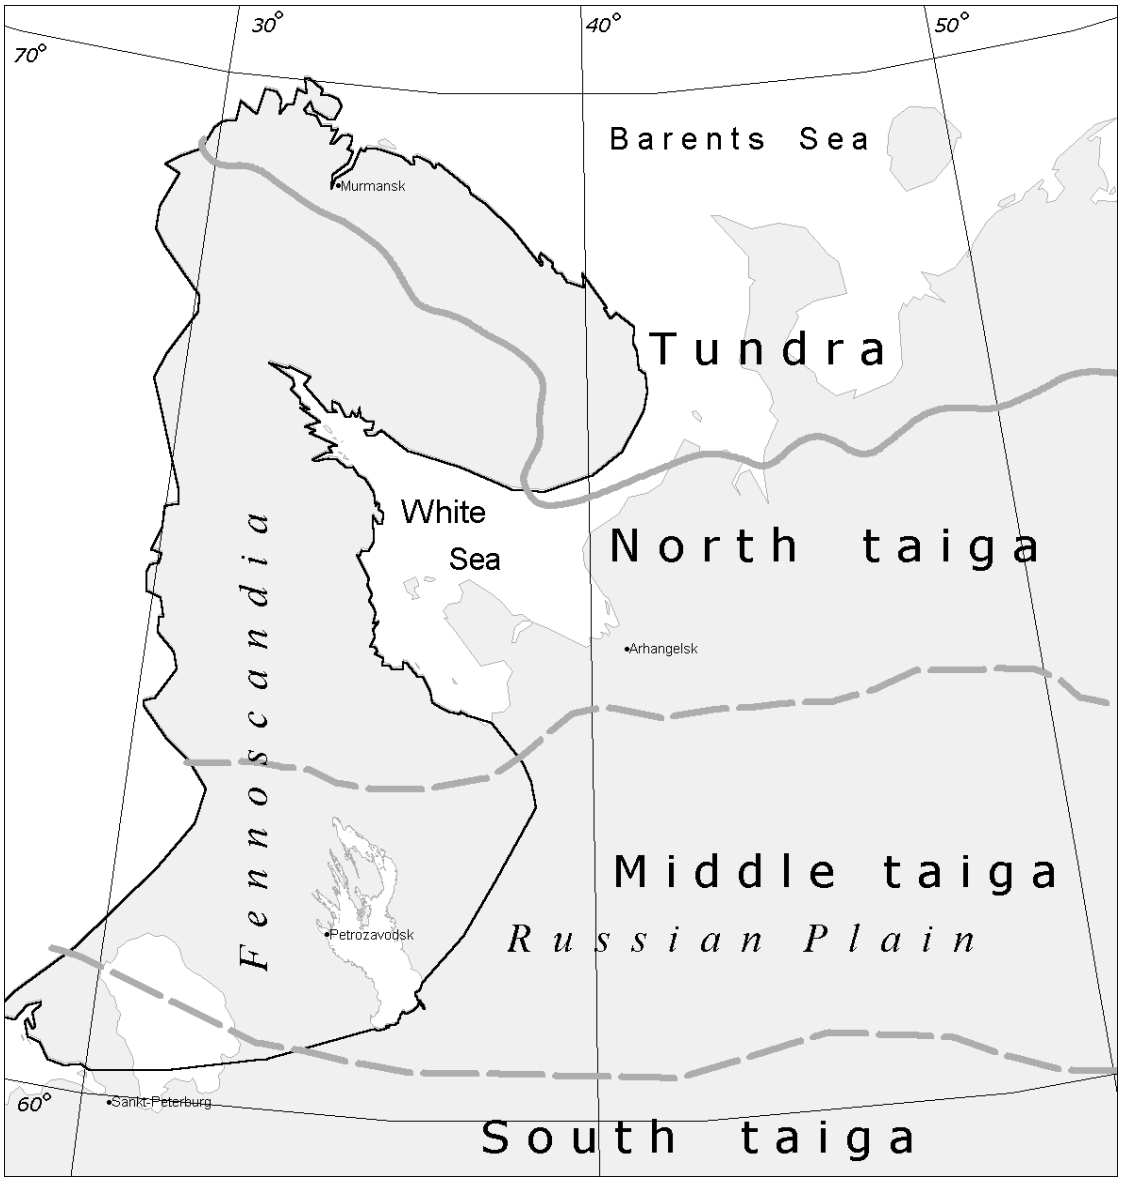

Figure 1. Taiga zone of the Western European Russia

Landscape-related patterns of the fire regime are quite vivid. The fire regime is more or less specific to each landscape type. The overall situation is however quite predictable – the number of FL was the lowest in landscapes of different genesis and paludification clearly dominated by spruce forests. Landscapes of different genesis and paludification dominated by pine forests were the most susceptible to fires (Tab.2).

Table 2. Frequency of forest fires in different types of geographical landscapes (data from the stratigraphic analysis of peat deposits, only the most illustrative types of landscapes are included)

Thus, some 'spruce' landscapes were affected by fires approximately once or twice in a thousand years. They were apparently catastrophic events induced by abnormal weather (droughts). Such stand-replacing fires destroyed nearly totally large spruce forests on mineral land. The only refugia were wet sites with flowing water, swamps, etc., from where the surviving spruce dispersed to the surrounding areas. These landscapes are a kind of a model of top fire resistance. The conditions there are least favorable for fire emergence and spread. The landscape biotic components have been affected by fires only sporadically, but with all-embracing effect.

Some 'pine' landscapes experienced stand-replacing fires (when even part of wetland habitats burnt down) 1-3 times every 300 years. Running understory fires in pine forests on dry sandy soils were even more frequent (sometimes twice a century). These habitats are a showcase of fire vulnerability. The conditions there are the most favorable for fire emergence and spread. The biotic components of these landscapes have grown adapted to frequent fire impact. Their structure and spontaneous dynamics have been controlled by fires for millennia.

Multiple intermediate variants filled the range between these two poles of the natural fire regime.

Fires as an ecological factor. Primary taiga forests in the Russian taiga zone represent, with very few exceptions, different stages and patterns of pyrogenic succession series. Prior to the commencement of human activities boreal forests had represented different stages of secondary successions – from pioneer vegetation groupings on naturally emerging burnt areas or areas of wind-fallen forest to climax forest communities. A whole spectrum of phytocenoses at different stages of the secondary succession lay between these two extreme variants. The boreal territory in general was however dominated by coniferous communities approaching their climax. The situation changed abruptly only after stand-replacing fires, which were real natural catastrophes. Leaving alone the modifications in the forest cover induced by the global climate change in the late Holocene one can claim that changes in primary boreal ecosystems were of a cyclic nature. They followed the pattern: pre-climax – catastrophe (fire or windstorm) – series of regeneration stages – pre-climax.

The pyrogenic factor has for millennia controlled the forest formation process. Fires destroyed dead organic matter, affected the forest vegetation properties of habitats, enhanced the formation of specific faunistic complexes, etc. In the absence of fires the structure of primary taiga forests underwent transformation in which the forest-forming tree species ratio changed towards shade-tolerant species. Coarse non-decayed litter deteriorating the soil suitability for forest vegetation was accumulated. The productivity of forest areas decreased, and their structure was simplified, including the less mosaic pattern of the landscape forest cover, etc. Corresponding modifications occurred in the biota in general.

Fires are a powerful natural factor that has ensured renewal and homeostasis in spontaneous forest ecosystems for at least several millennia. Preservation of primary boreal forests in protected areas in their primeval state can only be achieved if a certain fire regime that has established in the boreal landscape in the post-glacial period is maintained.

Human-induced modification of natural fire regimes. Natural fire regimes have been profoundly modified by humans. In the boreal zone of Europe this process commenced at different times and in different scope. Formally, human impact on natural fire regimes in the European part of Russia's boreal zone began some 5-10 Ka B.P., as people colonized the territory after glacial retreat. Obviously, with the arrival of ancient hunters and fishermen lightning was no longer the only cause of ignition. The number of fire outbreaks grew sharply over the past centuries due to the wide use of slash-and-burn agriculture and widespread selective forest felling. Thus, 19th century sources already state that at least 90 of 100 fires were caused by slash-and-burn (fire spreading beyond the sites). Generally speaking, humans significantly increased the frequency of forest fires. Until the last century they had spread spontaneously, restrained only by natural firebreaks (hydrographic network), or stopped due to weather (rainfall).

The total and average size of fires has lately been gradually decreasing. E.g., in the Republic of Karelia (area almost 15 mln. ha of area in total) the indices have over the past half a century ranged within 100-100 000 ha (Fig.2), and 50-2500 fires per year (Fig.3). Some large fires affected an area of several thousands hectares (one ignition is 2013 burnt over 6,000 ha). These cases are however exceptional. An average fire in the past decades rarely exceeds 10 ha due to timely detection and quick localization by modern technology.

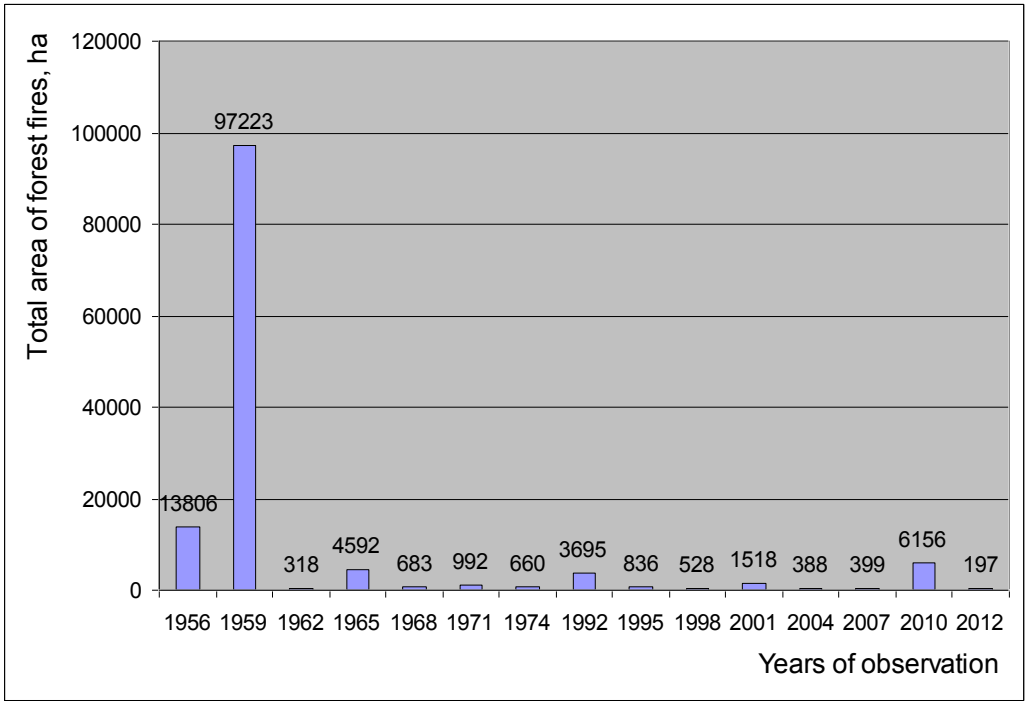

Figure 2. Total area affected by fires in the Republic of Karelia (selected data are presented)

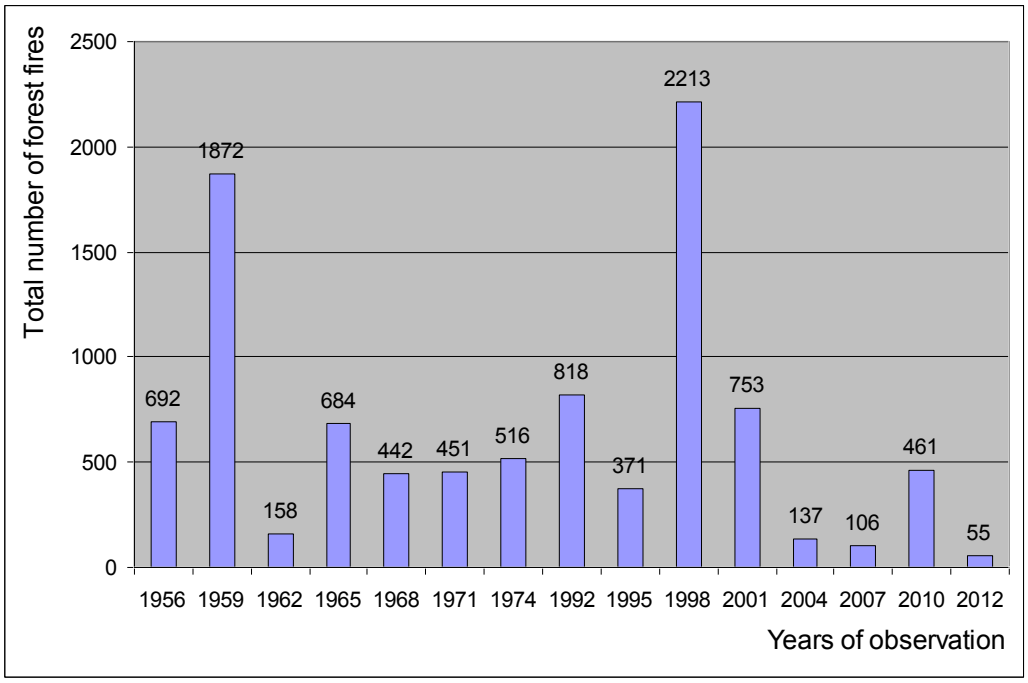

Figure 3. Total number of fires in the Republic of Karelia (selected data are presented)

Variation of the total area, number and average size of fires is due to the summer weather alone. Fires are expressly taken under control and eliminated by specialized agencies, using aircraft where needed. Thus, natural fire regimes have been fundamentally changed, mainly through a reduction in the size of a fire – from tens and hundreds of thousands hectares in primeval landscapes to some tens of hectares now. Human impact has dramatically increased the frequency of outbreaks. As mentioned above, it ranged from 1-2 in a century to 1-2 in a millennium depending on the landscape. The number has now grown to a total of several thousands a year. Yet, all the indices still correlate quite clearly with the landscape characteristics, and can vary by a factor of tens of times. Conservation of pristine forests with their spontaneous dynamics in protected areas is possible only under a natural fire regime.

Conclusions

The patterns identified can be quite confidently extrapolated to the whole European part of boreal forests in Russia. The characteristics of geographical landscapes (the range, ratio and spatial arrangement of their types) and land use history must however be taken into account.

Abstract
Fires in Central European lowland forests are nowadays numerous but efficiently suppressed and hence usually very small. Poland is one of the countries with highest annual number of forest fires in the region, with as many as 9–10 000 individual fire events per year (with record of 17 000 fires in 2003), however of relatively limited size, with 0.5–0.95 ha being mean values of area burned in a single forest fire. Main fire season in Poland lasts from March to September and is driven largely by weather conditions and litter humidity, with people being the dominant source of ignition. Active forest fire prevention and suppression is carried both by the regular fire services and State Forest Administration – the main forest manager in Poland due to the ownership structure of forest land in the country (>80% state-owned). In Białowieża Forest, one of the best preserved lowland forest ecosystems in temperate Europe fires happen at present rather incidental, alike in the rest of the country are effectively controlled and thereby affect very small areas (0.5 ha). However numerous stands with fire scarred trees, stumps and snags, especially in the conifer dominated areas, can be found; indicating substantial fire presence in the past. The first tree ring fire history records from that area evidenced frequent fires in Pinus sylvestris-dominated forests during the 17th up to early 19th centuries, with dramatic decrease in fire presence over the last 150+ years, most likely linked to changes in human fire use and forest management. We conclude that there is a large need for fire history and fire ecology studies in Central Europe due to high population density and strong dominance of flammable conifers in forests of that region. Extended knowledge about past disturbance dynamics and reference conditions may be essential for future sustainable forest management and nature conservation throughout this part of European continent.

Introduction

Fires in Central European lowland forests are nowadays numerous but efficiently suppressed and hence usually very small (Szczygieł *et al.* 2009*a*; Schmuck *et al.* 2011). However, that region has evidenced a significant rise in the number of forest fires in the recent decades (Szczygieł *et al.* 2008, 2009*a*,*b*), alike the whole European continent (Schelhaas *et al.* 2003).
Although fire has been proven to be one of the key elements of European lowland forest ecosystems during the Holocene (e.g. Hannon *et al.* 2000; Rösch 2000), the knowledge on fire ecology in that region is limited (Bradshaw *et al.* 1997; Hille 2006; Niklasson *et al.* 2010). Forest fires in that part of Europe are still associated with threat and large economic losses (Ubysz and Szczygieł 2002; Ubysz *et al.* 2006; Szczygieł *et al.* 2009*a*), which may impede the acceptance of fire as one of the important natural factors shaping forest structure and dynamics throughout the region (*cf.* Faliński 2001).
Given the significant share of fire-prone coniferous forests and the observed increase in fire activity throughout Central Europe, projected climate change and its possible influence on forest fire risk in

the near future (Badeck *et al.* 2003; Schelhaas *et al.* 2003, 2010; Szczygieł *et al.* 2008, 2009*a*; San-Miguel-Ayanz *et al.* 2011), extended knowledge on the ecological role of fire in forest ecosystems of that region is valuable.

Poland is one of the largest countries in Central-Eastern Europe (Szczygieł *et al.* 2009*a*), with the total country area of approx. 312.7 th. km^2 and total population of approx. 38.5 mill people, reflecting high population density of 123 people/km^2 (GUS 2014). Over 9 mill ha, accounting for ca. one third of the country area is covered by forests (San-Miguel-Ayanz *et al.* 2011; Zajączkowski *et al.* 2014), which locates Poland among the countries with substantial forest cover in the region (San-Miguel-Ayanz *et al.* 2011). Polish forests are largely dominated by coniferous forest habitats on sandy soils (51%) and coniferous stands (approx. 70% of the forest area), with *Pinus sylvestris* L. (Scots pine) being the dominant tree species (approx. 60%). Stands younger than 80 years cover approx. 70% of the forest area, with age class 41–60 yrs accounting for as much as 26.0%. Over 80% of forests in Poland is owned by the state (Zajączkowski *et al.* 2014).

Active forest fire prevention and suppression in Poland is carried both by the regular fire services and State Forest Administration (LP = Lasy Państwowe, State Forests National Forest Holding) – the main forest manager in the country, administrating 77.3% of the forest area (Zajączkowski *et al.* 2014), obliged to conduct forest fire prevention by the Forestry Act (1991).

In Białowieża Forest, one of the best preserved lowland forest ecosystems in temperate Europe (Faliński 1986; Peterken 1996) fires happen at present rather incidental, alike in the rest of Poland are effectively controlled and thereby affect very small areas (ca. 0.5 ha) (E. Zin and M. Niklasson, unpubl.). However numerous stands with fire scarred trees, stumps and snags, especially in the conifer dominated areas, can be found (e.g. Faliński 1986); indicating substantial fire presence in the past. This has been also confirmed by the first tree ring fire history reconstruction in that area (Niklasson *et al.* 2010).

To conclude on past and present fire regimes in temperate forest zone of lowland Central Europe we used Poland as a case study and applied both: (1) literature review (including actual fire inventory reports throughout the last decades) on current data concerning present fire activity in the country and (2) tree ring fire history record from two locations in Białowieża Forest, obtained by dendroecological analyses of tree ring samples from *Pinus sylvestris*, spanning over the period 1650–2010.

Methods

To achieve data on the present forest fire activity in Poland we did literature review. Additionally, selected actual fire inventory reports throughout the last decades were reviewed in the National Information System on Forest Fires database (available online at https:// bazapozarow.ibles.pl/ ibl_ppoz/faces/index.jsp). To summarize data on the annual number of forest fires, burnt area in forest fires and mean area burned in a single forest fire in Poland in 1990–2013, we used the following publications: Szczygieł and Piwnicki (2011); Piwnicki and Szczygieł (2011, 2012); Zajączkowski *et al.* (2014). The first one may be found in Schmuck *et al.* (2011). The three latter ones are available online at http://www.gios.gov.pl/monlas/raporty.html (Annual Reports: 2011, 2012) and at http://www.lasy.gov.pl/informacje/publikacje/ informacje-statystyczne-i-raporty/raport-o-stanie-lasow/raport-o-stanie-lasow-2013/view (Annual Report: 2013), respectively.

Tree ring fire history data from two locations in Białowieża Forest were obtained by dendroecological analyses of wood samples from *Pinus sylvestris*, spanning over the period 1650–2010. Exact fire dates were identified by cross dating of fire scars according to the standard dendrochronological techniques. Details on field and laboratory procedures are given in Niklasson *et al.* (2010).

Results and discussion

Present-day forest fire activity in Poland

Poland is one of the countries with the highest annual number of forest fires in Central-Eastern Europe (Szczygieł *et al.* 2009*a*), with as many as 9–10 000 individual fire events per year, however of relatively limited size, with 0.5–0.95 ha being mean values of area burned in a single forest fire in the recent decades (Tab. 1).

Although most of the burnt area occurs nowadays in the Mediterranean part of the European continent (Schmuck *et al.* 2011), Poland still has accounted for as much as 60% of all forest fires in Central-Eastern European countries in 1999–2001, with as many as approx. 240.5 th. fires which burned approx. 465 th. ha. In that period larger burnt area has been noted only once, in 1996, when the highest value has been recorded in the Ukraine (Szczygieł *et al.* 2009*a*). In the recent past (1990–2013) the highest number of forest fires in Poland occurred in 2003, with the record value of 17 088 fires. The largest area (43 755) burned in Polish forest fires in 1992 (Tab. 1). This has been a year with a disastrous fire situation (Szczygieł *et al.* 2008, 2009*a*), when the two largest, catastrophic forest fires in Poland in the recent history have occurred. In the Potrzebowice Forest District in north-western Poland more than 5 000 ha have burnt, whereas the Rudy Raciborskie fire in Upper Silesia (south-western Poland), being the largest forest fire in the country since 1948, has damaged over 9 000 ha in Forest Districts: Rudy Raciborskie, Rudziniec and Kędzierzyn (Hawryś *et al.* 1998, 2004; Dobrowolska 2008; Szczygieł *et al.* 2008).

As weather conditions and litter humidity are the main drivers of the fire risk in Poland (Ubysz *et al.* 2006; Szczygieł *et al.* 2009*b*) the anticipated changes in temperature and precipitation patterns may considerably increase the burning hazard in the near future (Schelhaas *et al.* 2010). In fact, a significant rise in the forest fire activity in Poland has been already observed over the last decades due to the increasing trend in temperature and decreasing precipitation (Ubysz *et al.* 2006; Szczygieł *et al.* 2008). Furthermore, mild winters and shortening of the snow cover period have prolonged fire season (Szczygieł *et al.* 2008), that nowadays lasts from March–April to September (Ubysz *et al.* 2006; Piwnicki and Szczygieł 2011, 2012; Szczygieł and Piwnicki 2011; Zajączkowski *et al.* 2014). In 2011–2012 the highest forest fire risk has been recorded in April, May and June (Piwnicki and Szczygieł 2011, 2012), whereas in the last year in April and July (Zajączkowski *et al.* 2014). Nevertheless the effective fire suppression system in Poland may successfully prevent the increase in annually burnt forest area (Szczygieł *et al.* 2008). Mean area of a single forest fire in 1990–2013 was 0.93 ha (Tab. 1) – a value considerably lower than the average for earlier periods, given by Szczygieł *et al.* (2008): 3.25 ha in 1948–1950, 2.35 ha in 1951–1960, 1.78 ha in 1961–1970, 1.43 ha in 1971–1980 and 1.41 ha in 1981–1990. However, extreme weather conditions in certain years (like e.g. 2003) may still significantly increase the forest fire activity and hence the mean forest fire size (Tab. 1).

The main cause of fires in Poland are people as natural, lightning-ignited fires account for about 1% only. It has been also observed, that the number of forest fire outbreaks has been larger on holidays than on workdays (Ubysz and Szczygieł 2006). Arson cases have represented as much as approx. 40% of forest fire causes throughout the recent past (Szczygieł *et al.* 2009*a*; Piwnicki and Szczygieł 2011, 2012; Szczygieł and Piwnicki 2011; Zajączkowski *et al.* 2014). Fire spreading from nonforest areas due to the burning of grasslands has been another important cause of forest fires in Poland (Rydzak and Trebecki 2009; Szczygieł *et al.* 2009*a*). This practice, although illegal according to Polish legislation (Nature Conservation Act 2004), has been traditionally aiming at improving grazing conditions by removal of old plant remains and post-fire fertilizing effect (Rydzak and Trebecki 2009; Szczygieł *et al.* 2009*a*). The decrease in number of fires caused by setting grasslands ablaze has been observed in the most recent years only (Rydzak and Trebecki 2009; Szczygieł and Piwnicki 2011; Zajączkowski *et al.* 2014), likely as an effect of educational campaigns by the State Forest

Administration (Rydzak and Trebecki 2009; Szczygieł and Piwnicki 2011) and/or of people's concern for EU-subsidies, that could have been eventually withdrawn (Szczygieł *et al.* 2009*a*).

Table 1. Data on forest fires in Poland in 1990–2013 (Sources: Piwnicki and Szczygieł 2011, 2012; Szczygieł and Piwnicki 2011; Zajączkowski et al. 2014).

Fire prevention together with creating and maintaining fire protection infrastructure are obligatory tasks of the Polish State Forest Administration (LP = Lasy Państwowe, State Forests National Forest Holding), as defined by the Forestry Act (1991). Current fire prevention and suppression measures applied by the State Forest Administration, besides education activities for the public, include construction of fuel- and fire breaks, silvicultural operations, fire observation system, communication

and alarm network, water supply points and professional fire suppression equipment (Szczygieł and Piwnicki 2011). All that has amounted to the total fire protection cost (incurred by the State Forest Administration) of 294 mill PLN (approx. 71 mill EUR) in 2003–2004 (Szczygieł *et al.* 2007) and of 63 mill PLN (approx. 15.2 mill EUR) in 2010 only (Szczygieł and Piwnicki 2011). According to the Polish law State Forest Administration is not obliged to conduct active fire suppression. Nevertheless it belongs to its important activities. In 2003–2004 fire suppression carried out by the State Forest Administration has accounted for 17.2% of the total fire protection cost incurred, corresponding to the cost of approx. 8–10 mill PLN (approx. 1.9–2.4 mill EUR) annually. As many as 9% of all forest fires in that period have been supressed by the employees of the State Forest Administration alone, with no fire brigades involved (Szczygieł *et al.* 2007).
At present there is no prescribed burning practice in Polish forests as it is legally restricted (e.g. Forestry Act 1991; Nature Conservation Act 2004). In the other neighbouring countries in the temperate Europe fire use is still practiced at the experimental level only, for nature conservation and landscape management purposes (Goldammer and Bruce 2004).

Historical forest fire record from Białowieża

The first tree ring fire history records from two locations in Białowieża Forest evidenced frequent fires in *Pinus sylvestris*-dominated stands during the 17th up to early 19th centuries, with dramatic decrease in fire presence over the last 150+ years, most likely linked to changes in human fire use and forest management (Niklasson *et al.* 2010; Zin *et al.*, unpubl.).
Despite the considerable fire occurence in Central-Eastern Europe nowadays (e.g. Szczygieł *et al.* 2009*a*; Schmuck *et al.* 2011), there are hardly any annually resolved data on fire activity in temperate European forests spanning over time periods longer than the 20th and the 21st centuries (*cf.* Niklasson *et al.* 2010). As main reasons for the lack of such research in that region Niklasson *et al.* (2010) gave both the traditional perspective on fire as less important disturbance agent in the vegetation dynamics of this biome (e.g. Ellenberg 1988; Vera 2000; Timbal *et al.* 2005) and the paucity of old-growth woodlands enabling dendrochronological analyses spanning over several centuries, mainly linked to the long history of forest use and management throughout this part of the European continent (e.g. Pyne 1997; Farrell *et al.* 2000).
Białowieża Forest however, a large woodland in the borderland between north-eastern Poland and western Belarus, offers an extraordinary value for dendroecological studies. Thanks to its status as a royal hunting area since the early 1400s (Samojlik 2007) it withstood deforestation and commercial timber exploitation that made thousands of hectares of old-growth woodlands all over the continent disappear and survived until today as one of the best preserved temperate lowland deciduous and mixed forests in Europe (Faliński 1986; Peterken 1996). Considering dendrochronological recunstructions, Białowieża Forest is most likely unique among other European lowland forests. Old-growth forest stands with deadwood continuity and numerous ancient, large-size trees that are still present in that area (Faliński 1986; Sokołowski 2004) deliver annually resolved tree ring record of past stand and forest dynamics.
The first tree ring fire history record from a site located in the Polish part of Białowieża Forest (Niklasson *et al.* 2010), being to our knowledge also the first dendrochronological fire history reconstruction from the temperate forests of lowland Central Europe, has evidenced fire as a factor of major importance for the past forest dynamics. It has been proven that historical fires were recurring at very short intervals (approx. 10 years on average) over the last 350+ years (1650–2007), which favoured *Pinus sylvestris*-dominated forest. However, significant temporal changes in the past fire frequencies have been recorded at the end of the 18th century, when fire intervals have significantly increased. The complete cessation of fire occurrence has been documented since 1920s. This change in historical fire regime has resulted in a remarkable shift in tree establishment patterns, towards the dominance of fire-sensitive, shade-tolerant Norway spruce (*Picea abies* (L.) Karst.) (Niklasson *et al.*

2010) – a phenomenon described also in boreal Europe (e.g. Linder 1998; Wallenius *et al.* 2004). Furthermore, substantial human impact on the reconstructed fire regime has been suggested (Niklasson *et al.* 2010), alike in other studies from Northern European locations (e.g. Niklasson and Granström 2000; Groven & Niklasson 2005; Storaunet *et al.* 2013).
Interestingly, the second tree ring fire history record from Białowieża Forest, coming from a study site located in the Belarusian section of that area (Zin *et al.*, unpubl.), brought similar information on the historical forest fire activity over the analogous period. That site, although separated in space, evidenced comparably high fire frequency between 1650s and the first decades of the 1800s, when the onset of fire decline appeared. Similarly to the Polish location, no fires were recorded since the first decades of the 20th century (Zin *et al.*, unpubl.).

Conclusions

We conclude that there is a large need for fire history and fire ecology studies in Central Europe due to high population density and strong dominance of flammable conifers in forests of that region. Extended knowledge about past disturbance dynamics and reference conditions may be essential for future sustainable forest management and nature conservation throughout this part of European continent.

Abstract
Maps of the number, size, and species of trees in forests across the United States are desirable for a number of applications. For landscape-level fire and forest simulations that use the Forest Vegetation Simulator (FVS), a spatial tree-level dataset, or "tree list", is a necessity. FVS is widely used at the stand level for simulating fire effects on tree mortality, carbon, and biomass, but uses at the landscape level are limited by lack of availability of forest inventory data for large contiguous areas. Detailed mapping of trees across large areas is not feasible with current technologies, but statistical methods for matching forest plot data with biophysical characteristics of the landscape offer a practical means to populate landscapes with a limited set of forest plot inventory data. We used a modified random forests approach, with Landfire vegetation and biophysical predictors at 30m grid resolution. In essence, the random forests method creates a "forest" of decision trees in order to choose the forest plot with the best statistical match for each grid cell in the landscape. Landfire data was used in this project because is publicly available, offers seamless coverage of variables needed for fire models, and is consistent with other datasets, including burn probabilities and flame length probabilities generated for the continental US by Fire Program Analysis (FPA). We used the imputed forest plot data to generate a map of forest cover and height as well as existing vegetation group for a study area in eastern Oregon, and examined correlations with Landfire data. The results showed good correspondence between the two data sets (84-97% within-class agreement, depending on the variable). In future research, the new imputed grid of inventory data will be used for landscape simulation studies to determine risk to terrestrial carbon resources from wildfire as well as to investigate the effect of fuel treatments on burn probability and fire sizes.

Keywords*: imputation; forest plot data; Landfire; random forests*

Introduction

For many research applications ranging from estimation of terrestrial carbon resources to the impact of fuel treatment projects on wildfire propagation, to name a few, it is desirable to know the location, size, and species of each tree on the landscape. However, such a mapping effort is not feasible with current technologies. LiDAR and similar technologies may make such a tree-level map a reality in coming years, but in the interim, various statistical efforts can produce spatial models, known as "tree lists", suitable for a wide range of research applications.
To this end, a number of statistical methods have been evaluated in the literature, ranging from gradient nearest neighbour imputation (GNN), linear models (LM), classification and regression trees (CART), kriging, universal kriging (UK) and most similar neighbour (MSN) (Moeur and Stage 1995; Pierce *et al.* 2009). Among these, Pierce *et al.* (2009) found GNN performed best for forest structure variables in Oregon, while LMs and UK demonstrated stronger performance for both forest structure and canopy variables in Washington and California. Drury and Herynk (2011) produced a national tree list by stratifying plot data by existing vegetation type, biophysical setting, succession class, and canopy bulk

density. Because this method generally left several potential matches for each grid cell on the landscape, and because the purpose of the tree list was to model tree mortality from fire, they then identified the median bark thickness for each plot, and chose the plot with the median of the median bark thickness to assign.

This project had several specific requirements that precluded use of most of these methods. For this project, we required our tree list to be consistent with two already existing datasets. The Landfire project provides over 20 national geo-spatial layers, including topographic, fuel, and vegetation layers, on 30m grids (www.landfire.gov). These layers, in turn, are used as inputs to Fire Program Analysis (FPA), which runs national-level wildfire simulations to output burn probability and flame length probabilities on a 270m grid, accompanied by a set of modelled fire perimeters. Therefore, we leveraged the Landfire dataset as inputs to our tree list, to ensure consistency with that dataset as well as the FPA outputs. In order to model forest type, introduction of a categorical variable, existing vegetation group, into our model along with numeric variables was necessary. That limited the set of possible methodologies to classification trees. We chose random forests as our methodology, since it leverages a "forest" of classification trees in order to produce high accuracies and model complex interactions among predictor variables, two notable strengths of this methodology over other statistical classifiers (Cutler *et al.* 2007). The random forests method as used here in essence evaluates a set of forest plots, and identifies the best-matching plot for each grid cell on the landscape. Our methodology is distinct from that of Pierce *et al.* (2009) in that it has the capacity to use categorical variables and is consistent with Landfire and FPA data. Several important differences exist between our methodology and that of Drury and Herynk (2011) as well: 1) we limited our data to a single set of nationally consistent plot data, whereas they obtained a variety of fixed- and variable-plot designs from multiple agencies, 2) since tree mortality was not the primary variable of interest, we did not use it as a predictor, and 3) we wanted to identify a single best matching plot for each point on the landscape rather than utilizing the median plot in a class, retaining more variability on the landscape.

Here, we demonstrate high model accuracies for a random forests imputation run on an approximately 40,000 km^2 area of forest in the western U.S., indicating the output would be suitable for a wide range of research applications.

2. Methods

In order to test and refine our methodology, we chose a Landfire zone, Zone 9, which lies mainly in eastern Oregon, as our study area (Figure 1). The zone contains large forested areas, amounting to about 25% of the total area of the zone, or approximately 40,000 km^2.

In this random forests imputation, a set of reference observations was imputed to a set of target points (Crookston and Finley 2008). The reference observations consisted of a set of forest plot data acquired from the US Forest Service's Forest Inventory Analysis (FIA) program. Beginning in 1999, FIA has been using a standardized plot design to conduct forest surveys across the US (O'Connell *et al.* 2014). Among the variables collected at these plots that we utilized in the imputation are: elevation, slope, aspect, latitude, and longitude. The Landfire program calculates additional variables needed for the imputation and stores them in their Landfire Reference Database (LFRDB), including forest height, forest cover, and existing vegetation group (EVG) computed from a classification method devised by NatureServe (2009) for Landfire. We derived additional biophysical variables via overlays of plot locations with gridded data from the Landfire project for photosynthetically active radiation, precipitation, relative humidity, maximum temperature, minimum temperature, and vapour pressure deficit. The target points in this study consist of a grid of 30m pixels that comprise the Landfire dataset. So, in essence, we use random forests to find the best matching FIA plot for each 30m pixel, imputing an FIA plot number to each pixel.

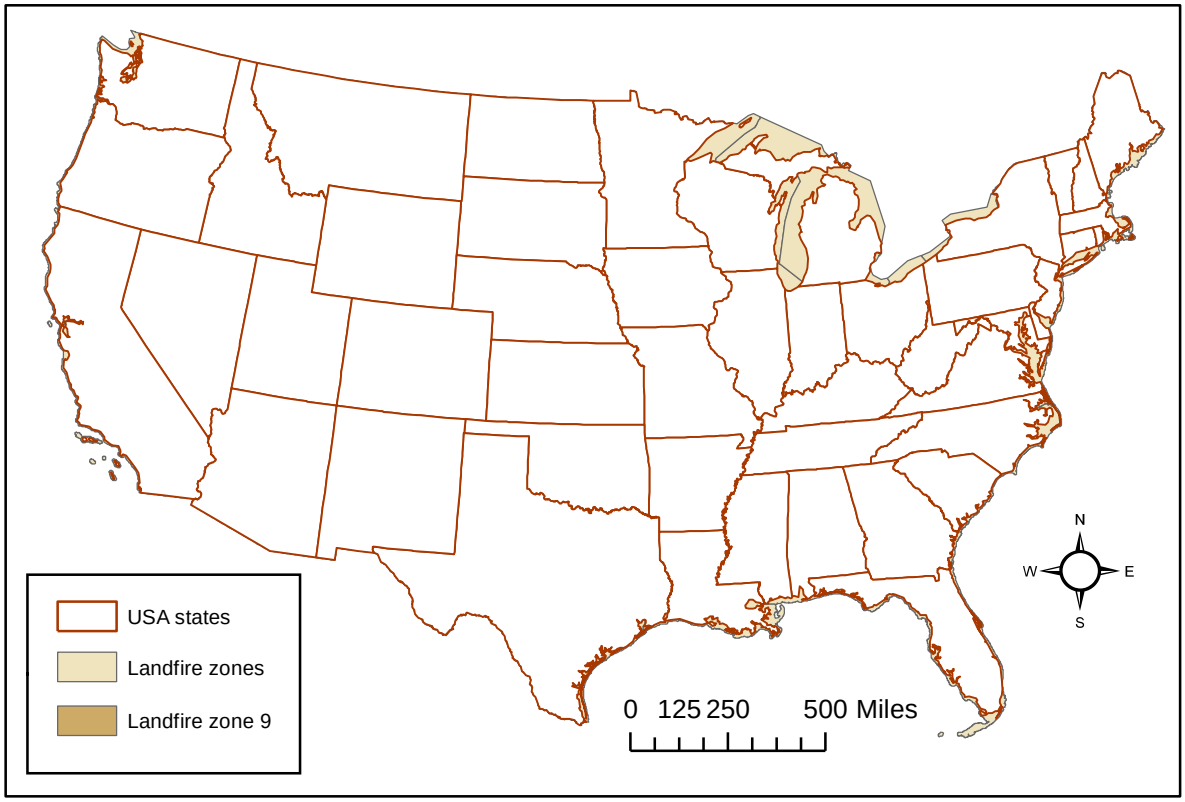

Figure 1. Location of the study area, Landfire Zone 9, in the western United States.

For this project, we retained only FIA plots that utilized the national design, were single condition (meaning they did not cross ownership boundaries or major vegetation types), and appeared in the LFRDB. Thus, we began with 15,333 plots in the western half of the continental United States, and then created a subset consisting only of the plots with EVGs appearing in Zone 9. Then, we formed the random forest model using the yaImpute package in the statistical program R. To do this, we used 250 total decision trees to predict tree height, tree cover, and EVG for each plot. To predict these, we used the following predictors: latitude, longitude, tree cover, tree height, elevation, slope, EVG, PAR (photosynthetically active radiation), precipitation, relative humidity, maximum temperature, minimum temperature, VPD (vapour pressure deficit), cosine of aspect (northing), and sine of aspect (easting). Notice that the variables we wish to predict also appear as predictors. This may appear odd, but the reason we do this is that the objective with random forest imputation is to build a model that assigns a set of predictor values to a plot associated with the response variables. Accuracy in the response variables can be heightened by also including them as predictors. The random forest method involves building many classification trees (in this case, 83 for each response variable, adding to the total 249). Each tree is formed using a subset of the plots, and the remainder (referred to as the out-of-bag observations) are set aside to assess accuracy. As Cutler *et al.* (2007) eloquently describes it, "Observations in the original data set that do not occur in a bootstrap sample are called out-of-bag observations. A classification tree is fit to each bootstrap sample, but at each node, only a small number of randomly selected variables (e.g., the square root of the number of variables) are available for binary partitioning." Binary partitioning continues until the variance in each bucket cannot be reduced significantly, or until further divisions cannot be made without reducing the number of observations in a bucket to less than 5. Each "fully grown" decision tree is used to predict the out-of-bag observations. "The predicted class of an observation is calculated by the majority vote of the out-of-bag-predictions for that observation, with ties split randomly" (Cutler *et al.* 2007).

We can obtain an overall accuracy of the model by taking the out-of-bag misclassification for each tree and considering them in aggregate to assess the overall quality of the forest model. In this case,

the out-of-bag error rates for Zone 9 were 6.99%, 1.79%, and 0.897% for forest cover, forest height, and EVG respectively, an indication of high model accuracy.
Once the forest of decision trees is in hand, we can impute new target observations to determine which reference plots are most closely associated with the targets (pixels, in this case). Our dataset consisted of 44,138,635 forested pixels. The imputation is done by evaluating the target predictor variables for each pixel through each of the 3 sets of trees associated with each response variable. Then, the plot most frequently imputed amongst all 500 trees is considered the winner. Once we obtain this list of reference plots, we can build imagery of the variables of interest associated with each imputed plot. In this case, we output raster images of forest cover, forest height, existing vegetation group, and plot number. The plot number can be used to reference the number, size, and species of trees in each plot via a lookup table.
Validation consisted of assessing within-class accuracy for the three response variables (forest cover, forest height, and existing vegetation group) using confusion matrices and the kappa statistic. Barplots were used to assess the proportion of pixels in each class in the target data versus the imputed data.

Results and Discussion

Accuracies for imputed forest height were high. Landfire maps forest height in four classes: 0-5 m, 5-10 m, 10-25 m, and greater than 25 m. The Landfire organization also computes the height of FIA forest plots in its LFRDB to tenths of a meter. We compared the height of each imputed plot to the height class mapped by Landfire for the corresponding pixel (Table 1). The resulting confusion matrix represents a type of accuracy assessment of the outputs. We do not assess the accuracy of the Landfire data itself, which has its own error rates, but we compute the accuracy of our imputation compared to the gridded target data. Within-class accuracy for forest height was 97% in Zone 9. The number of pixels in each height class compared quite favourably across the imputed plot data and the Landfire gridded target data (Figure 2).

Table 1. Confusion matrix of forest height in meters in gridded Landfire data and imputed forest plot data.

		Imputed plot				
		0-5m	**5-10m**	**10-25m**	**>25m**	**Accuracy**
Gridded Landfire	**0-5m**	1,059,777	98,042	820	13	**0.91**
	5-10m	47,313	7,842,084	6,227	63	**0.99**
	10-25m	852	66,957	23,609,236	107,949	**0.99**
	>25m	316	2,734	1,100,876	10,195,377	**0.90**
	Accuracy	**0.96**	**0.98**	**0.96**	**0.99**	**0.97**

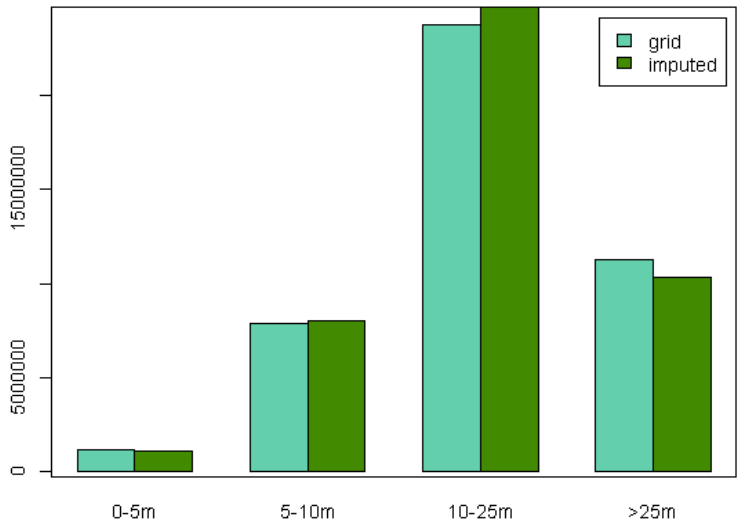

Figure 2. Barplots comparing height class of imputed forest plot data and gridded Landfire reference data. Units of the y axis are numbers of pixels.

The accuracy of the imputation was also high for forest cover. Forest cover is mapped in nine classes in Landfire (Table 2), with areas of tree cover less than 10% not considered forested. For FIA plots, forest cover is estimated to the nearest percent in the LFRDB. Overall accuracy for the zone was 86%, with within-class accuracy ranging from less than 1% in the two densest forest cover classes (80-89% and 90-100%) to 98% in a moderate cover class (30-39%). The proportion of cover classes compared favourably across the imputed forest plots and gridded target Landfire data (Figure 3). The largest discrepancies were in the sparsest cover class (10-19%), which was underestimated by the imputed plot data, and the 20-29% cover class, which was conversely overestimated by the imputed plot data. Forest cover greater than 60% was rare in the Landfire reference data.

Table 2. Confusion matrix of forest cover in percent in gridded Landfire data and imputed forest plot data.

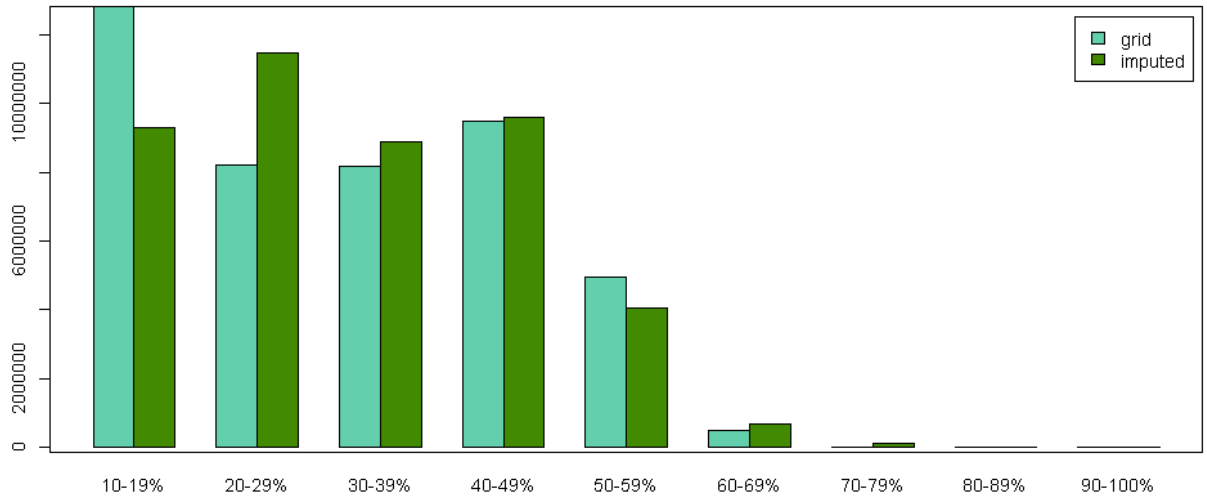

Figure 3. Barplots comparing forest cover class of imputed forest plot data and gridded Landfire target data. Units of the y axis are numbers of pixels.

The third response variable in our study was existing vegetation group (EVG). There were 14 EVGs in Zone 9 (Table 3). EVG is mapped to the gridded target data by Landfire, and also assigned to FIA forest plots in the LFRDB. Within-class accuracy of EVG was 84% for the study area as a whole. Class proportions compared favourably across the gridded Landfire data and the imputed plot data, but the most common EVG classes tended to be somewhat over-represented in the imputed plot data (Figure 4).

Table 3. Landfire Existing Vegetation Groups (EVGs) in zone 9, by numeric code and text description

EVG Code	EVG Description
602	Aspen Forest, Woodland, and Parkland
603	Aspen-Mixed Conifer Forest and Woodland

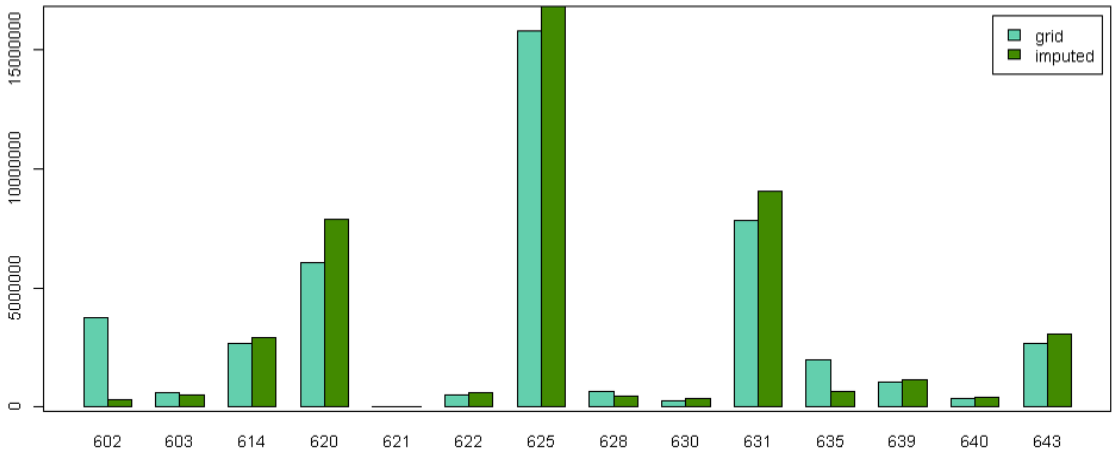

Figure 4.
Barplots comparing Existing Vegetation Group (EVG) of imputed forest plot data and gridded Landfire reference data. Units of the y axis are numbers of pixels.

In general, within-class accuracies were lower in rarer classes. This result makes sense, since it is unlikely in rare types that random forests can match all three of the response variables (forest cover, height, and existing vegetation group) when choosing from a limited pool of candidate forest plots, and must in essence choose which of these response variables is most important to match. If increased accuracy was desired in future implementations of this methodology, increasing the sample size of rare types would likely be the most effective way to boost accuracies.

Conclusions

Here, we have demonstrated that a modified random forests approach is a feasible method for imputing forest plots to a set of target landscape grids. This method produces a seamless grid of tree data at the landscape level. The modified random forests method produced high correlations between the target gridded data and the imputed plot data for the response variables of forest cover, forest height, and existing vegetation group (86%, 97%, and 84% respectively), an indication of high model accuracy. Very high classification accuracy is one of the strengths of the random forest method, along with its ability to utilize categorical as well as numerical variables (Cutler *et al.* 2007). Due to the high accuracy, the output imputed forest plot data should perform well in a number of applications, including estimation of risk from wildfire to terrestrial carbon resources, and analysis of the effect of fuel treatments on fire sizes and landscape-level burn probability.

Abstract

Globally peatlands contain ca. 550 GT of ancient carbon and there is the potential for a positive feedback between peatland degradation and global climate change. Peatlands cover a substantial area of the British Uplands and the effects of wildfire and traditional managed burning on their ecological integrity are issues of growing debate. Land-managers and conservationists continue to argue over the effects of managed and wild fire on peatland carbon dynamics. Clear differences do exist in the severity of moorland fires and wildfires, though often intense, are not necessarily severe. The aim of our project was to document variation in the severity and ecological effects of a spate of peatland wildfires that burnt during the springs of 2011 and 2012. We identified a number of fire locations that included coverage of variation in major north-south and east-west bioclimatic conditions and peatland types. Fire severity was described using a modified form of the semi-quantitative Composite Burn Index. Fuel consumption was assessed using destructive harvesting of burnt- and unburnt fuel loads. Carbon dioxide and methane fluxes were assessed using samples taken from gas flux chambers. Fire severity varied substantially both within and between individual fires. Average severity varied up to two-fold between fires but as much as three-fold within some fires. Total carbon loss varied substantially between and within wildfires. Average fire-level consumption was 0.64± 0.12 kg C m^{-2} but this estimate should be treated with caution. Consumption was best described by a mixed effects model than included random intercepts for different fires and plots within fires and random slopes for different plots. The evidence for differences in consumption between fires was weak due to the small sampling size and the substantial within plot and fire variation in fuel load. There was a linear relationship between pre-fire fuel surface load and surface fuel consumption but no obvious difference between the prescribed and wild fires in how the proportion of fuel consumed changed with increasing fuel load. Soil methane fluxes were consistently lower on burnt sites whilst carbon dioxide fluxes were generally higher. Day-night temperature fluctuations in burnt plots were frequently more than twice that seen in unburnt plots. Our results demonstrate substantial variation in fire severity both within and between individual wildfire events. Assessment of the effects of wildfires requires intensive sampling efforts and drawing robust conclusions about the implications of wildfire on ecosystem C dynamics is thus fraught with difficulties.

Keywords*: carbon dioxide, Composite Burn Index, fuel consumption, methane, soil gas flux, soil microclimate*

Introduction

Globally peatlands contain ca. 550 GT of ancient carbon (Mitra *et al.* 2005) but there is considerable concern about the potential for a positive feedback between peatland degradation and global climate change (Turetsky *et al.* 2002, Dorrepaal *et al.* 2009). Many temperate and boreal peatlands experience wildfires and when these fires ignite peat deposits substantial amounts of carbon can be released (e.g. Davies *et al.* 2013). Ecosystem recovery following such severe burns can be extremely slow due to

the destruction of below-ground plant propagules (Granström and Schimmel 1993). More pernicious fire effects, such as scorching of the peat surface or removal of ground fuel layers overlying peat deposits, are also possible but the ecosystem implications of such impacts are relatively poorly-studied. The results of Maltby *et al.* (1990) however suggest that ecosystem recovery in such cases can take decades or longer. Little quantitative evidence exists of the extent to which peatland wildfire severity varies, the fuel and fire weather drivers of variation in severity or the ecological impacts of such variation.

Peatlands cover a substantial area of the British Uplands and the effects of wildfire and traditional managed burning on their ecological integrity are issues of growing debate (Davies *et al.* 2008a). Fire is an integral part of the traditional management of heaths and moorlands and is used to create a diversity of heather (*Calluna vulgaris*, hereafter *Calluna*) dominated habitat structures that support large surplus populations of red grouse (*Lagopus lagopus scoticus*) for hunting (Tharme *et al.* 2001). Traditional burning also provides fresh growth of heather for sheep and deer grazing (Smith and Thomas 1956), creates habitats for rare wildlife (Tharme *et al.* 2001) and may help to manage fuel loads reducing the potential for large or severe wildfires (Davies *et al.* 2008a). Nevertheless, land-managers and conservationists continue to argue over the effects of fire on peatland habitat structure, biodiversity and soil carbon dynamics. With regards to the latter there remains rather little scientific information to inform best-practice fire management (Blodau 2002).

Relatively few studies have directly examined the effects of fire on soil carbon fluxes or hydrology in U.K. peatlands. For the studies that do exist, most come from a single long-term experiment at Moor House in northern England. Here Ward *et al.* (2007) recorded increased net ecosystem respiration and reduced methane emissions as a result of burning. Additionally, Worrall *et al.* (2007) observed higher water tables in plots subject to more frequent managed burns. A larger number of studies have examined the effect of fire on the production of dissolved organic carbon though the results remain difficult to interpret and somewhat controversial. Holden *et al.* (2012) point to discrepancies between plot and catchment scale experiments and suggest that the results of catchment scale studies showing increased DOC production (e.g. Clutterbuck and Yallop 2010) should be treated with some caution.

Clear differences do exist in the severity of moorland fires and we can distinguish between high severity burns, that consume surface and ground fuels, whilst igniting or scorching underlying peat (e.g. Maltby *et al.* 1990) and lower severity prescribed burns that have more limited ecosystem effects (Davies *et al.* 2010). However, wildfires, though often intense, are not necessarily severe (Bullock and Webb 1995). There is thus a clear need to describe the extent to which fire severity varies in peatland ecosystems and to understand what processes drive this variation. During the springs of 2011 and 2012 a large number of intense and severe wildfires burnt across heaths and moorlands throughout the UK. The extent of these fires, associated environmental degradation and the costs of restoration have added to increasing concern about potential feedbacks between climate, fire frequency, fire severity and carbon fluxes from moorlands (e.g. Davies *et al.* 2008a). Research on the impacts of such fires on UK peatlands is urgently needed to inform the development of fire danger rating systems (e.g. Kitchen *et al.* 2006) and to fill fundamental knowledge gaps regarding fire, peatland and global change.

The aim of our project was to document variation in the severity and ecological effects of a spate of peatland wildfires that burnt during the springs of 2011 and 2012. Here we report the results of preliminary analyses of variation in i) peatland fire severity; ii) carbon lost from direct combustion of above-ground biomass and iii) changes in methane and carbon dioxide fluxes following burning.

Methods

Study sites

Though regional Fire and Rescue Services collect some data on the occurrence of wildfire there is currently no national system in place for reporting wildfire outbreaks. We therefore worked in collaboration with land management agencies, land owners and other stakeholder groups to identify a

number of fire locations that included coverage of variation in major north-south and east-west bioclimatic conditions and peatland types (Figure 1).

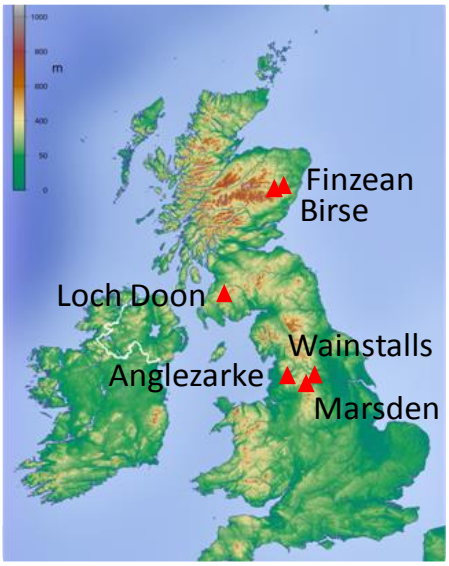

Figure 1. Location of wildfire study sites across the U.K. Sites covered a range of bioclimatic conditions and included fires in dry heath communities on shallow, stony organic soils (Finzean, Birse), active blanket bogs dominated by* Molinia caerulea *and* Sphagnum *spp. (Loch Doon) as well as wet and dry* Calluna*- and grass/sedge dominated moorland on peat soils (Angelzarke, Wainstalls, Marsden).

Each wildfire was assessed using a walk-over survey with the relevant land-owner. We created or obtained maps of the fire perimeter and carefully noted qualitative evidence of variation in fire severity. In each fire we selected three to six locations for further monitoring that best represented the range of severities we observed.

Monitoring fire severity

Fire severity was described using a modified form of the semi-quantitative Composite Burn Index (CBI; Key and Benson 2006). This method was adapted for use on treeless moorlands and bogs similarly to Schepers *et al.* (2014). The CBI uses qualitative descriptions of fire effects on a number of vegetation strata and ecosystem properties each scored on a rating of zero to three. These scores are then averaged within strata and the averages summed across strata to produce an overall severity index. Our method included assessment of fire effects on surface and ground fuel layers. We thus examined: litter/ light fuel consumption, duff/peat consumption, exposure of mineral soil, damage or loss of *Sphagnum* capitula, moss scorching and consumption, recovery of *Sphagnum*/moss species, percentage of shrubs top-killed, fine/crown fuel consumption, frequency of burnt shrubs or grass/sedge tussocks resprouting, evidence of new colonizers and the potential for changes in species composition.

CBI plots were circular, 20 m in diameter and established both as stand-alone plots in the fire interior and as paired burnt/unburnt plots close to the fire perimeter (Figure 2). For paired plots, we avoided edge-effects by ensuring the burnt plot centre was always located < 30 m from the edge of the fire. No part of any plot was < 5 m from the fire perimeter or, for unburnt plots, in obviously scorched vegetation. We were careful to ensure that burnt and unburnt plots had similar pre-fire fuel structures by locating them in the same pre-fire *Calluna* stand through careful observation of stem density and basal diameters either side of the fireline. Due to the large size of the wildfires, the substantial spatial separation of the plots and variation in pre-fire fuel structure we considered each CBI plot or paired-plot to be an independent observation in a manner similar to the "microplot" approach of Fernandes *et al.* (2000).

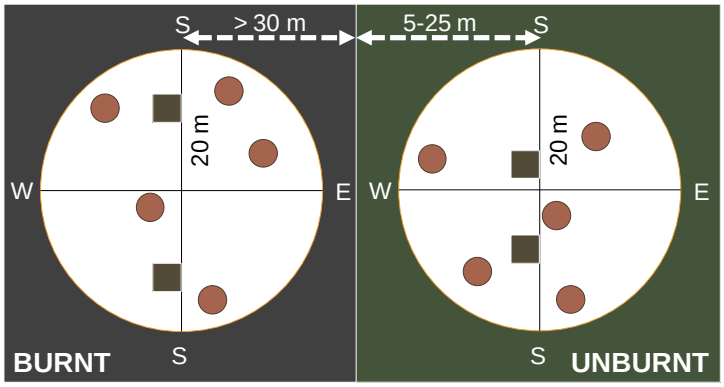

Figure 2. Layout of CBI monitoring plots showing the two fuel quadrats (squares), located at random distances along the N-S axis, and five soil gas flux chambers (circles) located at random co-ordinates in each plot

2.3. Variation in above ground carbon loss

Fuel consumption was assessed using destructive harvesting of fuel loads in two 50 x 50 cm quadrats located at random co-ordinates within the paired burnt/unburnt plots (two paired plots per fire). All above ground biomass was harvested down to the top of the peat. We harvested surface fuels (shrubs, grasses, etc.) separately from ground fuels (*Sphagnum* spp., other mosses + plant litter, grass/sedge tussock bases and duff). Fuel was also harvested in a similar manner from five gas flux chambers (diameter = 38 cm; see below) located at random locations throughout each plot. Samples were processed in the lab and dried at 80°C for 48 hours before being weighed. Fuel consumption was defined as average unburnt plot biomass minus average burnt plot biomass. Combustion completeness was defined as the proportion of fuel consumed and above-ground carbon loss was estimated by assuming all fuel components had a C proportion of 0.48 (Legg *et al.* 2010). We compared consumption and combustion completeness of our wildfires with data from 26 prescribed fires described by Davies *et al.* (2009). This comparison was however limited to changes in surface fuels (herbaceous and shrub species) as data on consumption of ground fuels were limited for the prescribed burns.

Total fuel consumption (i.e. all fuel components pooled) was analysed by making a square root transformation of the data and using a General Linear Mixed Model in the "lme4" package (Bates *et al.* 2013) of R 2.15.0 (R Development Core Team 2012). Plot and fire were defined as random effects whilst status (burnt/unburnt) and sample (chamber/quadrat ID) were defined as fixed effects. We initiated analysis using the full model (random slopes, according to status, and intercepts) and simplified the model by reference to AIC. Parametric bootstrapping was used to fit 95% confidence intervals around mean fire-level fuel consumption that accounted for uncertainty due to sampling variation in quadrats/chambers and plots.

2.4. Assessing soil carbon fluxes

Carbon dioxide and methane fluxes were assessed using samples taken from five gas flux chambers permanently located at random co-ordinates within each side of our burnt/unburnt plot pairs (Figure 2). The chambers were made of black plastic, had a diameter of ca. 38 cm and a volume of ca. 30 l. Chamber bases were buried 3-5 cm below the top of the peat. We made five measurements of the distance from the chamber top to the internal ground level in order to determine the installed chamber volume. As we were interested in variation in fire effects on the soil ecosystem we chose to contrast carbon fluxes in our burnt plots with a "zero severity burn" in the unburnt plot and in the absence of plant photosynthesis and respiration. This was achieved by removing all vegetation (surface and ground fuels) in the chambers down to the top of the peat. Any variation in flux was thus solely a result of varying fire effects on the soil. We acknowledge that the removal of vegetation can cause changes

in the production of root exudates which might alter the structure and activity of soil microbial communities. However, since the above ground components of plants were removed in both burnt and unburnt plots, we suggest any difference should be attributable to temperature pulses from the fire, scorching or heat induced alteration of peat structure. Chambers were sealed using metal lids and gas samples extracted using a syringe. The sample was then used to fill an airtight vial. Samples were extracted immediately following closure and at ten minute intervals thereafter to produce a total of five samples per chamber. Methane and carbon dioxide concentrations were analysed using a gas chromatograph and fluxes estimated by standard regression-based methods.

Due to the importance of soil temperature in determining peatland soil carbon fluxes (e.g. Updegraff *et al.* 2001) we buried iButton™ temperature loggers 2 cm below the top of the peat (and thus below overlying layers of moss, litter and duff in unburnt plots) in a random subsample of our paired plots. Two loggers were buried in each plot – one each in the burnt and unburnt subplot. Loggers recorded soil temperature hourly and were left in place for up to a month and half during August and September.

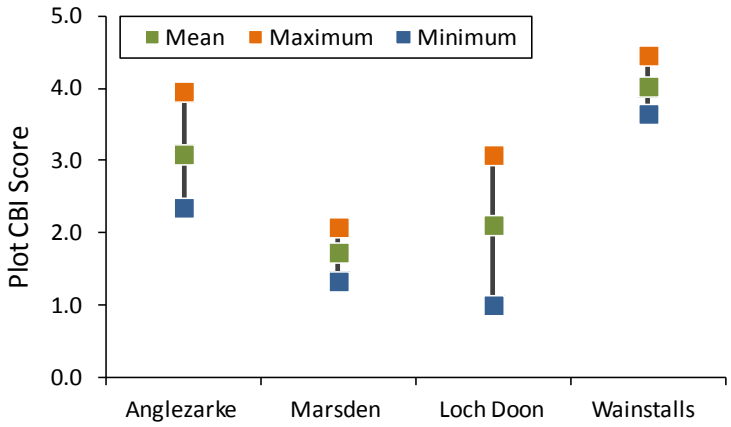

Figure 3. Variation in fire severity between and within four wildfires (data for Finzean to be analysed). Symbols show fire mean (green), minimum (blue) and maximum (orange) Composite Burn Index score.

Results

3.1. Variation in fire severity

Fire severity varied substantially both within and between individual fires. Interestingly average severity varied up to two-fold between fires but as much as three-fold within some fires (Figure 1).

3.2. Variation in above ground carbon loss

Total carbon loss varied substantially between and within wildfires (Figure 4) but average fire-level consumption was 0.64± 0.12 kg C m^{-2} across the five wildfires we studied. Average fire-level losses were relatively consistent with the exception of Finzean. Here mean carbon losses were both notably higher than other fires and the amount of variation between plots rather small.

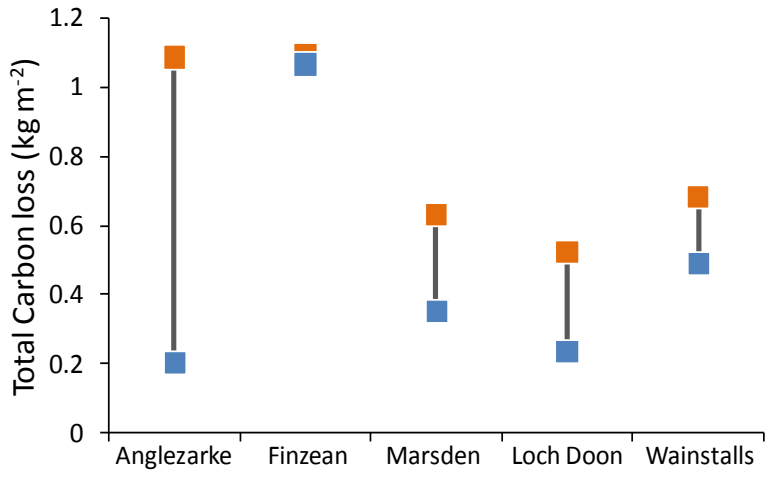

Figure 4. Variation in total (ground and surface fuels) carbon loss due to combustion across five wildfires. Blue and orange points are the minimum and maximum losses recorded respectively.

Fuel consumption was best described by a model than included the fixed effects of plot status (burnt/unburnt), quadrat ID and random intercepts for different fires and plots within fires and random slopes for different plots. The evidence for differences between fires was weak but was retained in the model as the relatively small sample size meant such differences couldn't be categorically discounted. Consumption thus varied substantially between plots within fires but there was limited evidence of a difference in average consumption between fires (Figure 2). Parametric bootstrapping was used to fit 95% confidence intervals and revealed substantial uncertainty in the prediction of mean fire fuel consumption due to sampling variation in quadrats/chambers and plots (Figure 2).

There was a linear relationship between pre-fire surface fuel load and surface fuel consumption but no obvious difference between the two types of fire in how the proportion of fuel consumed changed with increasing fuel load (Figure 6). Surface fuel consumption increased linearly with increasing fuel load up to a load of ca. 1.25 kg m^{-2}, thereafter fuel consumption appeared to reach an asymptote. This was reinforced by the apparent decline in combustion completeness with increasing fuel load. It was noticeable that the surface fuel load of the prescribed fires was, on average, higher than that found on the wildfire sites we monitored.

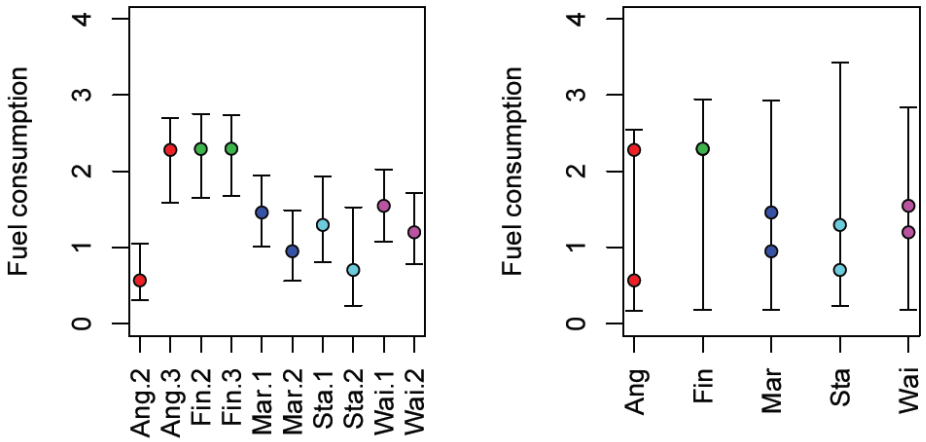

Figure 5. variation in total fuel consumption (kg/m2) between and within five different wildfires (left). Bootstrapped 95% Confidence Intervals showing uncertainty in fire mean fuel consumption due to within plot and within fire variation in fuel load (right).

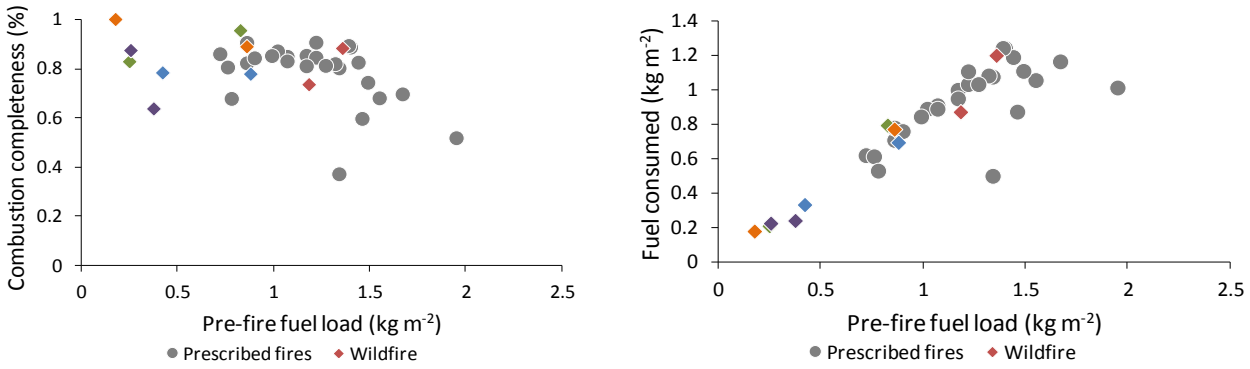

Figure 6. The relationship between pre-fire surface (herbaceous and shrub) fuel load and combustion completeness (left), and fuel consumption (right) for five wildfires (diamonds) and the 26 prescribed burns (grey circles) described by Davies et al. (2009). For wildfires each point is a CBI paired plot rather than a fire per se. Colours define each wildfire – Angelzarke (green), Finzean (red), Loch Doon (purple), Marsden (orange) and Wainstalls (blue). Note that for clarity errors are not shown here but they are likely to be large (see Figure 5)

3.3. Variation in soil gas fluxes

Both CO_2 and CH_4 fluxes were noticeably different between burnt and unburnt plots but substantial differences also existed between different fires. Methane fluxes were consistently lower on burnt sites whilst carbon dioxide fluxes were generally higher (Figure 7).

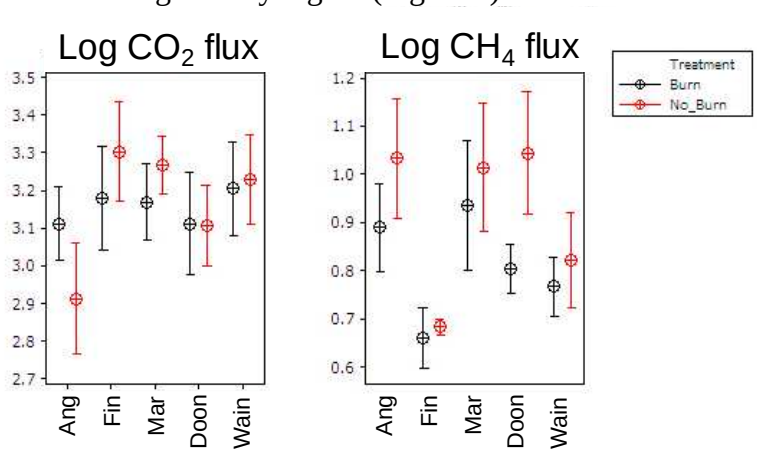

Figure 7. Variation in mean carbon dioxide (left) and methane (right) fluxes recorded in paired burnt/unburnt CBI plots across five different wildfire sites.

Substantial differences were recorded in both mean soil temperature and diurnal temperature trends between brunt and unburnt plots. Day-night temperature fluctuations in burnt plots were frequently more than twice that seen in unburnt plots (Figure 8).

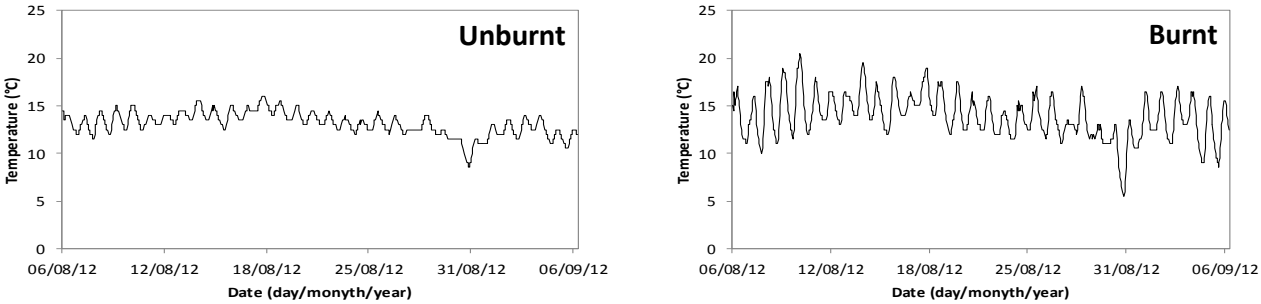

Figure 8. Example of typical patterns of diurnal soil temperature variation in unburnt and burnt plots

Discussion

Our results demonstrate substantial variation in fire severity both within and between individual wildfire events (Figure 4). Given the potential for substantial variation in fuel structure (Davies *et al.* 2008b) and fire weather (Legg *et al.* 2007) in the British uplands this is perhaps not surprising. A key finding of our work is therefore that robust assessment of the effects of wildfires requires substantial sampling effort. Variation in CBI and our estimates of fuel consumption were greater within a number of fires than that recorded, on average, between different burns. Managers needing to understand the effects of wildfires on landscapes, or researchers and policy makers wanting to quantify the effects of burning on landscape C storage, must therefore ensure that their monitoring is representative of this variation. Despite investing substantial monitoring effort in assessing fuel structure in burnt and unburnt stands the variation in fuel load encountered at both the sub-plot and fire levels mean we were unable to draw any robust conclusions about differences in consumption between fires (Figure 5). It is also clear that the estimate of mean carbon released by combustion we present should be treated with caution.

Though our monitoring captured a range of fuel structures it was clear from comparison with data from prescribed burns that this did not adequately reflect the range of fuel loads found on British peatlands (Figure 6). Broad differences in fuel consumption between and within wildfires could generally be related to pre-fire fuel composition. High levels of combustion completeness were recorded across all sites but this tended to be lower on wetter sites like Loch Doon. In such bog communities strong vertical gradients in the moisture content of standing *Molinia* litter may limit fuel consumption (Hamilton 2000). Prescribed fires in *Calluna*-dominated fuels generally consume all fine fuels < ca. 2 mm in diameter leaving behind larger, live woody stems (Davies 2006). This relationship is apparent in Figure 6 where the asymptote in fuel consumption as a function of fuel load is a consequence of the higher proportion of coarse, woody fuels in these older stands. In very severe burns this woody material may also be consumed but, the relationship we observed between pre-fire fuel load and fuel consumption (Figure 6) suggests that carbon release from the direct combustion of surface fuels only can be predicted from pre-fire fuel load for all but the most severe fires. Further analysis is needed to allow for comparison of consumption of ground fuels during prescribed burns and wildfires, and on fuel consumption during higher severity wildfires. This will allow us to determine whether, or under what burning conditions, differences in combustion processes operate and lead to altered rates of C emission.

For fires that do not lead to consumption or scorching of ground fuel layers and peat the carbon lost from combustion should, in theory, be of comparatively little concern. *Calluna* and other moorland plants such as *Molinia* and *Erica* spp. are able to regenerate rapidly both from seed and vegetatively (e.g. Hobbs and Gimingham 1984, Davies *et al.* 2010). Regeneration may, however, be delayed, lacking or follow alternative successional trajectories in older stands (Hobbs and Gimingham 1984, Davies *et al.* 2010), where fire severities are high (Legg *et al.* 1992) or where there are compounded

disturbances such as grazing and trampling by livestock (e.g. Legg *et al.* 1992). Understanding the consequences of wildfire for landscape carbon storage thus requires robust monitoring of post-fire vegetation regeneration. Assuming regeneration progresses communities back towards their pre-fire state, there are nevertheless substantial consequences of fire for carbon dynamics. Authors have provided contrasting data on dissolved organic carbon production and CO_2 and CH_4 fluxes and most of this information comes from low severity prescribed burns. Severe moorland wildfires have the potential to deliver large temperature pulses belowground, to remove insulating ground and surface fuel layers all of which may alter soil temperature (Figure 8), moisture, water table and microbial community dynamics. Previous authors (e.g. Worrall *et al.* 2007) have observed a raised water table in more frequently burnt sites and others were surprised to see reduced CH_4 fluxes following burning (Ward *et al.* 2007) at the same site. Our results mirror those recorded by for methane by Ward *et al.* (2007), albeit for wild rather prescribed fires and for a wider range of sites. There is this increasing evidence for a decline in CH_4 production in at least the first year following burning. Data on longer-term trends is now needed. Contrary to Ward *et al.* (2007), burning generally reduced CO_2 fluxes for our sites. Differences between burnt and unburnt plots were, however, very small for two of our fires and CO_2 production increased at Angelzarke. Our results suggest fire-related disturbance of microbial communities but identifying the underlying processes, and understanding site-to-site differences in response, will require further research. We also recorded substantial changes in diurnal soil temperature fluxes (Figure 8). Given that soil temperature is closely related to soil C flux (Updegraff *et al.* 2001) additional fine-temporal scale assessment of variation in C fluxes would be worthwhile.

In conclusion our data show that drawing robust conclusions about the implications of wildfire on ecosystem C dynamics is fraught with difficulties. Characterising the effects of fuel consumption is made difficult by substantial variation in fuel structure between and within individual fires and the need to understand the nature of post-fire regeneration. Wildfires appeared to have substantial effects on soil ecological processes generally leading to reduced CH_4 and CO_2 fluxes. At this point it is difficult to determine whether this is due to the direct impacts of the fires themselves or associated changes in vegetation and soil microclimate. Key objectives of our on-going research include:

- Quantifying the relationship between carbon fluxes and fire (CBI) severity
- Modelling variation in carbon fluxes to differences in fire weather
- Describing how vegetation recovery varies as a function of fire severity
- Defining the mechanisms by which fuel structure and fire weather control fire severity (see Grau *et al.* this volume).

Acknowledgements

Thanks are due to Emily Taylor, Sophie Philbrick and Roger Grau for field and lab assistance. Julia McMorrow and the England & Wales Wildfire Forum helped us obtain records of wildfires and our thanks go to all those who contributed data/information. We are particularly grateful to the owners and managers of the sites we used: Yorkshire Water, United Utilities, National Trust, Forestry Commission Scotland, Finzean Estate, Birse Community Trust, Bo Scholefield, Carl Prenton, Ian Harper, Kate Snow, Gemma Wren, Judith Patrick, Rob Soutar, Andrew Jarrott, Andrew Farquharson and Paul Chapman. This research was funded by the Natural Environment Research Council.

Fire Management

A focused analysis on lean fire management systems

Abstract
A primary role of the Incident Command System (ICS) is to learn from past incidents, particularly in the case of wildland fires. As such, a successful ICS application is critically dependent on its capability to function as a learning organization in order to continuously improve emergency response effectiveness. The objective of this study is to evaluate the potential to apply fundamental principles of the Toyota Production System (Lean manufacturing) to improve the learning effectiveness within the ICS. An in-depth review of literature and training documents regarding both systems reveals common goals and functional similarities, including the importance of continuous improvement. These similarities point to the validity of applying Lean principles to the ICS. Subsequently, a focus on systematic problem solving and the learning function of the ICS culminated in the discovery of gaps between the two systems. Finally, recommendations are made that the application of systematic problem solving including rigorous root cause analysis and effective standardization of successful problem solving countermeasures could be adapted from Lean principles in order to benefit the system.

Keywords*: Toyota Production Systems, Lean Manufacturing, Fire Management, Wildland Fire Management, Incident command System.*

Introduction

The objective of this study is to evaluate the potential to apply fundamental principles of Lean Manufacturing (LM) to facilitate continuous improvement of the Incident Command System (ICS). The ICS drives management of all major incidents including human and lightning caused wildfires in forests, grasslands, and preserved or monitored areas of the United States. The term "Lean" indicates that operational methods based on Toyota Production System (TPS) principles are in place within some model area of, or throughout the entirety of, an organization.

1.1. Wildland Fire in the United States

The inevitability of wildland fire occurrence has prompted dedicated annual seasons where precautions are taken and emphasized publically in hopes of reducing the frequency and severity of incidents. Since 2005, annual costs for wildland fire suppression have ranged from approximately one to two billion U.S. dollars for private, state, and federal land combined (National Interagency Fire Coordination Center, 2014). *Figure 1* illustrates the variation of wildland fire suppression costs form 2005 to 2013. According to the figure, suppression costs in 2013 reached $1.74B, a reduction from $1.9B in the previous year (National Interagency Fire Coordination Center, 2013). However, the National Oceanic and Atmospheric Administration (NOAA, 2012) classified 2012 as a warmer and drier year than average, which likely increased the risk of wildfires.

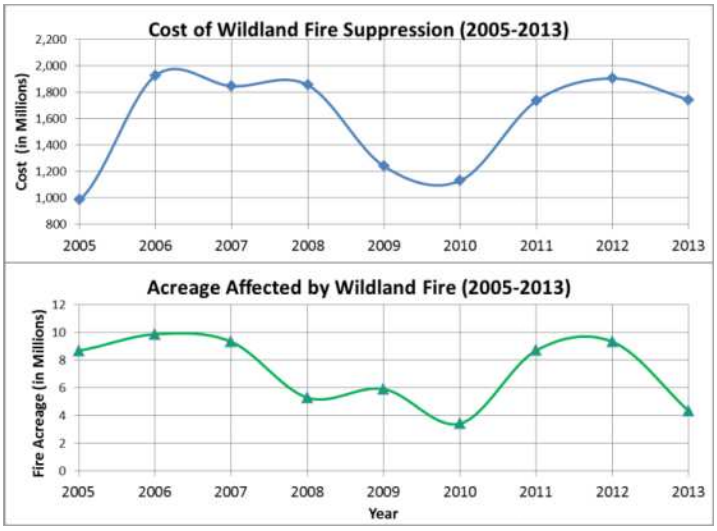

Figure 1. Wildland Fire Statistics (2005-2013) (National Interagency Fire Coordination Center, 2013).

ICS plays a key role in effectively managing hazardous incidents and preventing loss of valuable lives. To do this, ICS streamlines the overall decision making process to effectively cope with all aspects of urgency associated with wildland fire, ranging from strict monitoring of an incident to full extinguishment depending on geographic and fuel management considerations, proximity to wildland-urban interfaces (WUI), weather conditions, and available resources. .

Management Systems

Using available key references, the ICS is compared with a successful LM management system to identify similarities and differences. As main facilitators of the ICS use throughout the country, the Federal Emergency Management Agency (FEMA) and the National Incident Management System (NIMS) provide training documents, while the University of Kentucky's Lean Systems Program (UK-LSP) provides a variety of courses on LM principles and practices created through 20 years of close collaboration with Toyota. Over those 20 years, UK-LSP has served more than 20,000 people from different types of organizations including manufacturing, food service industry, healthcare and public services, as well as education.

The Incident Command System

ICS is an expert system developed in response to lessons learned during past experiences. In the fall of 1970, southern California suffered significant fires that burned over 500,000 acres, more than 700 structures, and caused 16 fatalities (Countryman, 1974). In response, the FIRESCOPE program was developed as "the first practical application of systems design to a major, complex wildland fire management operational problem." The FIRESCOPE team discovered that inefficient interagency communications and unclear organizational structures within the fire management system were regularly at fault during out of control incidents (Chase, 1980). As part of the FIRESCOPE program, the ICS evolved throughout the 1970s and was implemented as a stand-alone management response system in southern California in the 1980s (Chase, 1980). Over time, the ICS proved its effectiveness in meeting the demands of each fire based incident by uniquely scaling an organizational structure and facilitating coordination of resources (Buck *et al*, 2006). In the early 2000s, the ICS was extended nationwide through the National Response Framework (NRF) to create a uniform management system for all incidents (not just fire related) under a National Incident Management System (NIMS). Today, the ICS emphasizes the importance of systematic problem solving and a standardized planning process

to meet its objectives. These activities are supported by a dynamic organizational structure based on clear roles and standardized terminology (Deal *et al*, 2010; Emergency Management Institute, 2014).

Lean Manufacturing

The Toyota Production System was developed in response to lessons learned during past experiences, and thus, shares similar background with the ICS. The tough economic climate of post-World War II Japan led Japanese manufacturing companies to fight for their very survival. In 1950, American scientist and statistician W. Edwards Deming travelled to Japan to assist post-war recovery efforts. Deming introduced Japanese officials to the concept of statistical quality control (Deming and Orsini, 2013) and the idea that focusing on "built-in" quality rather than inspection could increase the quality of products or services without increasing costs (Deming, 1986). Deming also introduced the Japanese to the Plan-Do-Check-Act (PDCA) learning cycle, as well as his "14 Principles of Management" (Deming, 1986), both of which serve as the foundation for managing the ability to achieve and sustain built-in quality. Eventually these ideas were embraced and successfully implemented into many Japanese companie, including Toyota, who continue to apply them, eventually developing the Toyota Production System (TPS or Lean Manufacturing).

As it stands today, TPS places a great deal of importance on "providing products and services with craftsmanship, pride, zeal, history, spirit, joy, and more" (Saito *et al*, 2012) as well, the company strives to promote lifelong learning in its employees to produce well-rounded professionals who possess not only well-developed specialized technical skills but also overall knowledge and keen interest in continuously improving their work (Saito and Finney, 2014). Fujio Cho, the most respected world leader in TPS states: *a company must provide service to society, and the way a company must go about that is to produce good products honestly and consistently without compromise* (Saito *et al*, 2012), *offering service-oriented concepts to create a highly effective and efficient modern system consisting of people, information, machine and material* (Cho 1995).

The UK-LSP teaches a standard definition of what Lean should mean to an organization. The definition of "True Lean" is meticulously crafted as illustrated in the following 5 points: 1) The group by themselves, 2) use systematic problem solving, 3) to improve the work they do, 4) towards achievement of the company's targets and goals, 5) when and only when the company culture is the reason the improvement occurs (Lean Systems Program, 2013). Each point of this definition holds a certain principle of TPS. The first point focuses on the workers and places them first in the definition of "True Lean," signifying their importance in the system. The second point states that there exists a systematic method of problem solving. The third point stresses the focus on continuous improvement but only within the work that one is responsible for, not in other sections outside of their control. The fourth and fifth points outline that the company's culture is what drives the system towards achieving the measurable targets and goals set by the company. The foundation of a Lean system is standardization and revision of those standards through diligent problem solving to resolve abnormalities, to reduce/eliminate waste, and to continuously improve the system's ability to provide products or services (Lean Systems Program, 2013, Saito and Finney, 2014).

3. Discussions

The dynamic nature of the ICS mission is met using a best practices approach, which relies heavily on its ability to learn from previous incidents indicating that learning occurs not only on an individual basis, but also at an organizational level (Fiol and Lyles, 1985). The application of Lean principles and practices have been shown to greatly increase individual learning, and by extension, organizational learning (Maginnis, 2013). Because of this, Toyota has been called "the gold standard" of learning organizations (Liker and Hoseus, 2008). The PDCA learning cycle encourages the continuous improvement typical of learning systems because of its reliance on timely operational information feedback (Argyris, 1982, Spears and Bowman, 1999, Hall, 2006). The need to develop an ever-

increasingly effective learning organization provides a common goal for both LM and ICS, and indicates that the ICS could benefit in its efforts for continuous improvement by adopting Lean principles. To support this claim, we need to look closely at the ICS: their key functions and components.

Figure 2 provides a diagram of organizational structures and direction of communication flow for LM and ICS, where two-way communication and workforce education play a key role in success.

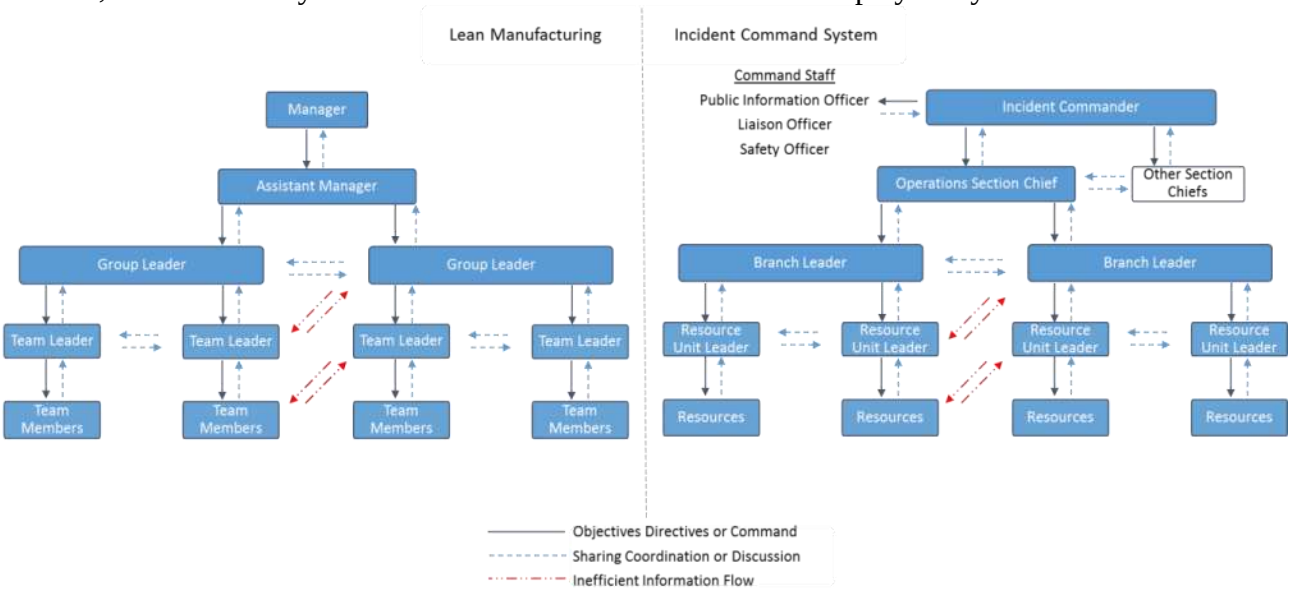

Figure 2. Comparison of structure, roles, and information flow for Lean and ICS.

Groupings within the ICS are comprised of 3 to 7 individuals per supervisor to improve management (Emergency Management Institute, 2014). Similarly, Lean systems employ the same type of control span for supervisors to have around 4 to 6 members reporting to them. Each system also has standards in place to inform workers of their role and corresponding responsibilities. In Lean systems, standardized work is developed and maintained to promote stability and recognition of abnormalities. Similarly, the ICS employs Standard Operating Procedures (SOPs) that promote the best known practices based on previous responses for the same purpose.

Figure 3 shows that the ICS problem solving method shares the same foundation of PDCA as LM problem solving, but that it differs from LM in one key aspect, the focus on problem recurrence.

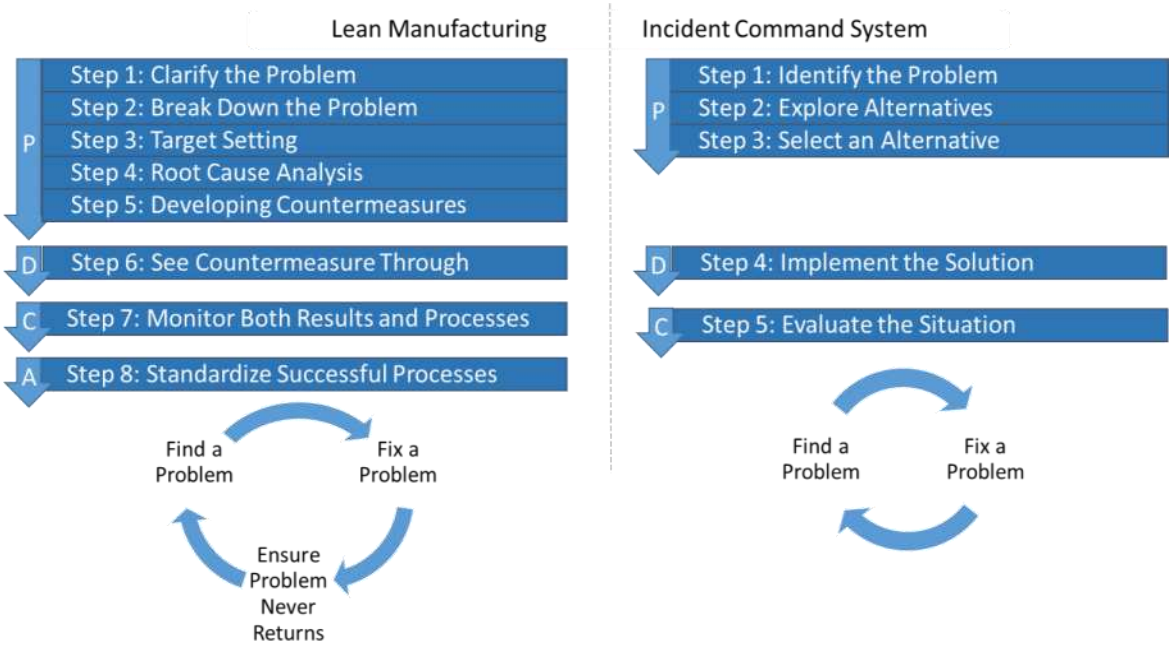

Figure 3. Comparison of Problem Solving Methods used in Lean and the ICS.

A high emphasis is placed on planning in both methods during the initial stage to better understand a problem and develop effective solutions. The ICS method has supportive materials to guide the user towards clarifying, breaking down, and setting goals for problems in the first step of its method (Emergency Management Institute, 2014). LM emphasizes root cause analysis and standardization of successful results following the PDCA to promote the cycle (finding/fixing a problem and tracing back to a root cause to prevent recurrence) (Lean Systems Program, 2013). Unsuccessful applications of LM typically result from an over-emphasis on immediate improvement which often ignores the importance of thorough problem solving and well maintained standardization (Angelis *et al*, 2011). The ICS training documents do not explicitly state standardization and incorporation as part of the current best method, but they are clearly required for continuous improvement, since resolving issues without finding the root cause will risk in recurrence of problems. The ICS process shown in *Figure 3* encourages finding and fixing problems, but will not prevent recurrence unless problems are traced to the root cause, and the results are incorporated into the standard procedures of the ICS.

Donahue and Tuohy (2006) recognized recurrence of problems in their analysis of learning capabilities within the ICS. After careful review of post incident reports, they concluded the need for the drive and ability to solve problems permanently rather than suffer them repeatedly (Donahue and Tuohy, 2006). Moynihan (2009) further explored the concepts of organizational learning in the ICS with regards to learning that takes place during the management of an incident (intra-crisis learning) and learning that takes place as reflection outside of an incident (inter-crisis learning). Moynihan also noted that the development and revision process taking place during inter-crisis learning would effectively minimize the amount of intra-crisis learning required (Moynihan, 2008).

Figure 4 demonstrates the ICS cycle of continuously evaluating how effectively it responds through each iteration of addressing incidents (Fires 1,2,3,…,n). The ICS then uses this data from each incident to improve the efficiency of response and goes on to repeat the process.

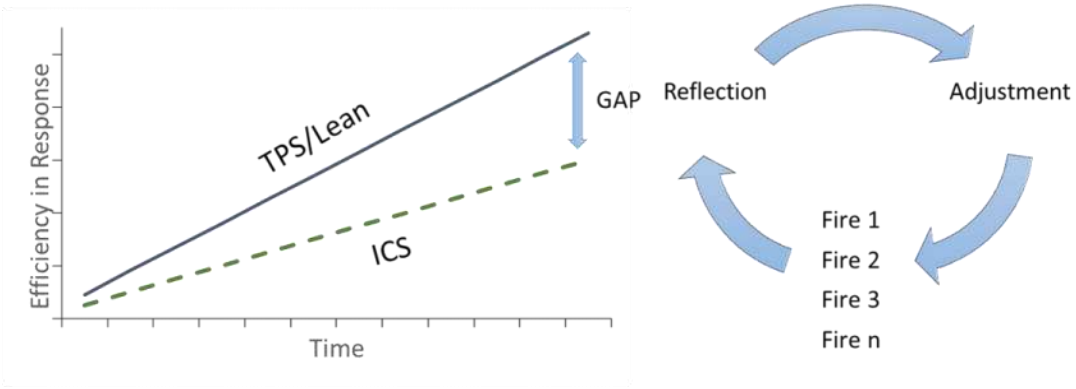

Figure 4. Anticipated Incremental Improvement of TPS/Lean organizations versus the ICS (based on Maginnis, 2013).

The figure also illustrates the anticipated gap that would occur between systems applying TPS/Lean methods and the ICS without root cause analysis and strict adherence to standardizing successful results (Maginnis, 2013).

Conclusions

The robust learning cycle present within the Lean method of PDCA facilitates continuous improvement when followed rigorously. This is due to a deeper level of learning achieved from investigations of root cause to eliminate problems (Tucker and Spears, 2002). In addition, Lean systems retain and spread information regarding improvements throughout the system by continual revision of standards and effective communication in response to problem solving successes. This also serves to drive the system towards future efforts for continuous improvement as goals have been effectively raised and set. The Incident Command System attempts to follow the PDCA cycle, but if the system struggles with problem recurrence as suggested by the literature, application of root cause analysis may be able to significantly contribute to the effectiveness of future emergency responses. Furthermore, ICS training documents regarding problem solving do not guide the user to post-problem solving efforts intended to retain and spread knowledge throughout the system. This highlights an area where loss of valuable incident based knowledge would occur, which could be remedied through more diligent revision of standards.

Many factors are understood to impact the use and effectiveness of the ICS regardless of system design itself. Moynihan (2009) stated that barriers to intra-crisis learning may result from limited time, political consequence, and weak working relationships between responders. As well, a recent comprehensive literature review published by Jensen and Waugh (2014) noted various factors regarding the application of ICS procedures within various emergency response areas. In order to improve the system overall, it is important to maintain continuous improvement efforts within areas that do use the ICS regularly, such as the firefighting community. These efforts would result in a model area of the system that demonstrates efficiency and effectiveness to lead by example and encourage further integration as a unified response community.

Abstract
The aim of this paper is to present the methodologies, a software and results developed in the European FUME program to map the rural-urban interfaces (RUI).
Three methodologies were set up for RUI mapping: two on the local scale (the community scale) and one on the global scale (the European scale).
The first local scale method was developed in a French context by IRSTEA. In this case the RUI is defined by a radius of 100 metres around each house located at a distance inferior to 200 metres from forests or scrublands. The building density was used to create four classes of housing configuration. Then the structure of vegetation was characterized and mapped to emphasize its horizontal continuity with landscape ecology metrics. The RUI map was created by a combination of housing configuration and vegetation characterisation.
The second local scale method developed by TRAGSATEC is based on three phases. First a settlement map creation with the union of a land use cover and a vegetation cover defines the housing and the landscape that surrounds them. Then a buffer is created around settlements which are located at a distance inferior to 400 m from the forest; its size depends on the difficulty in protecting the houses against fire. In the final phase the different types of RUI are defined from the type of settlement and vegetation-settlement connection around houses.
The global scale method developed by IRSTEA makes possible the comparison of the situations and the importance of RUI in the different European countries.
On the global scale, the rural urban interfaces are defined by a radius of 400 metres around houses located at less than 200 metres from forests or shrubland. The global rural urban interface map results from the combination of criteria from the Corine Land Cover database and from the soil sealing database.
A major step of the work was the development of a software named RUImap with the three different methods above.
The use of the tool could be very advantageous for fire risk analysis on RUI scale, and for local quantification of fuel charge and continuity. This information linked with the direct knowledge of the general context is very important for the local fire risk assessment.

Introduction

Each summer wildfires burn 500 000 ha of forests in the European Mediterranean regions (source EFFIS). 90% of forest fires are of human origin and most of them start in the wildland-urban interfaces. A better understanding of these spaces was obtained through numerous studies in the USA and Canada. The description and characterization of these interfaces have been developed at Irstea (Lampin C., 2009). To make operation easy and fast, an ArcGis extension was developed to create maps on a large area. A first prototype of the software was developed with funding from the FIREPARADOX Program (FP6) .The first operational version

of this tool and user's guide (Lampin –Maillet *et al*, 2010) were created in 2010 with the support from the Ministry of Ecology and published and distributed to regional services.
The framework of the European FUME (Forest fires under climate, social and economic changes in Europe, the Mediterranean and other fire-affected areas of the world) program has defined the creation of a common tool to map rural urban interfaces (RUI). It is a WUI concept for all types of interconnections between the urban area and forest areas around, or wildlands with agricultural areas and with various types of vegetation. Within RUI, buildings and human infrastructures are closely mixed with fuel vegetation and create high wildfire risk. The dynamics can be controlled by land management and planning measures.

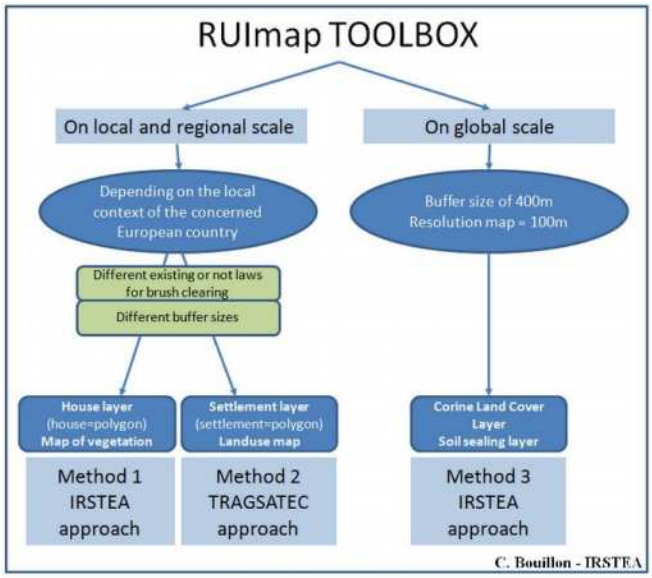

Figure 1. Schema of the tool

Three partners are involved in the creation and testing of this tool: Tragsatec, Spain; Irstea , France and the University of Sassari , Italy. Tragsatec developed a method for mapping interfaces on the local (municipal) level. Irstea developed two methods , a local method by improving the method already set (Lampin&Bouillon, 2011) and a global method, the European scale. The University of Sassari is responsible for testing and validating the results with data from three sites located in Spain, the Alicante region , in France , the Bouches-du-Rhône and in Sardinia, Italy. All developments were made with the ESRI ™ ArcGIS ™ platform and were integrated by Tragsatec in a common software called RUImap (Figure 1). Some recent uses of the methods and maps presented in this paper show a direct operational use of the results to improve the knowledge of the territory under the RUI approach and mapping.

Methods

Local scale Irstea

In the methodology developed in France (C. Lampin -Maillet , 2009), RUI is defined according to the July 9th, 2002 French Forest Orientation Law which makes brush clearing obligatory within a maximum radius of 100 metres around each house located at a distance inferior to 200 metres from forests (Figure 2).

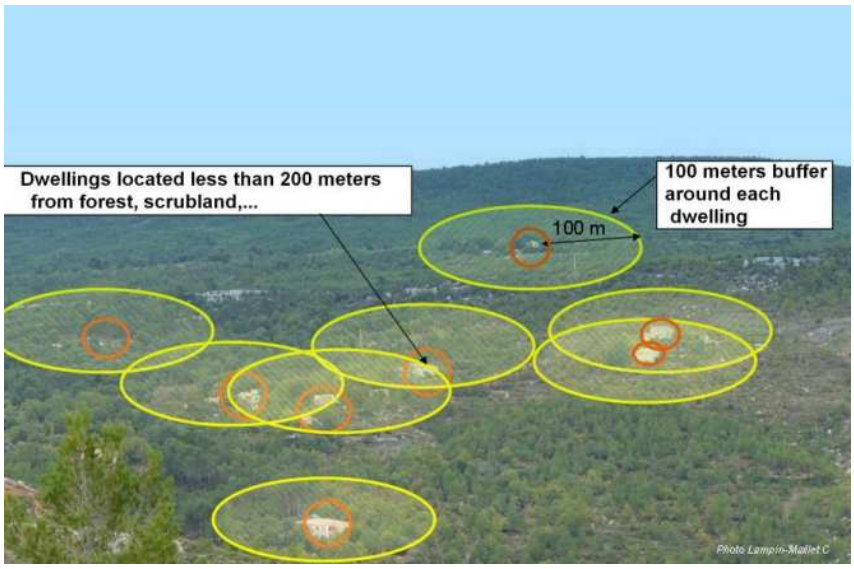

Figure 2. RUI definition

The 12 types of RUI (Figure 3) are created by integrating the density of buildings with a vegetation structure, more or less continuous. The process includes a combination of four housing configurations based on building density (isolated: from 1 to 3 buildings, scattered: from 3 to 50 buildings, dense: more than 50 buildings and very dense: more than 50 buildings at a distance of less than 15m between buildings) and three vegetation connectivity types (null, low, high) based on a landscape metrics : Aggregation Index (AI) (Turner, 1990), which can be mapped using FRAGSTATS3.3© software (McGarigal & Marks, 1994).

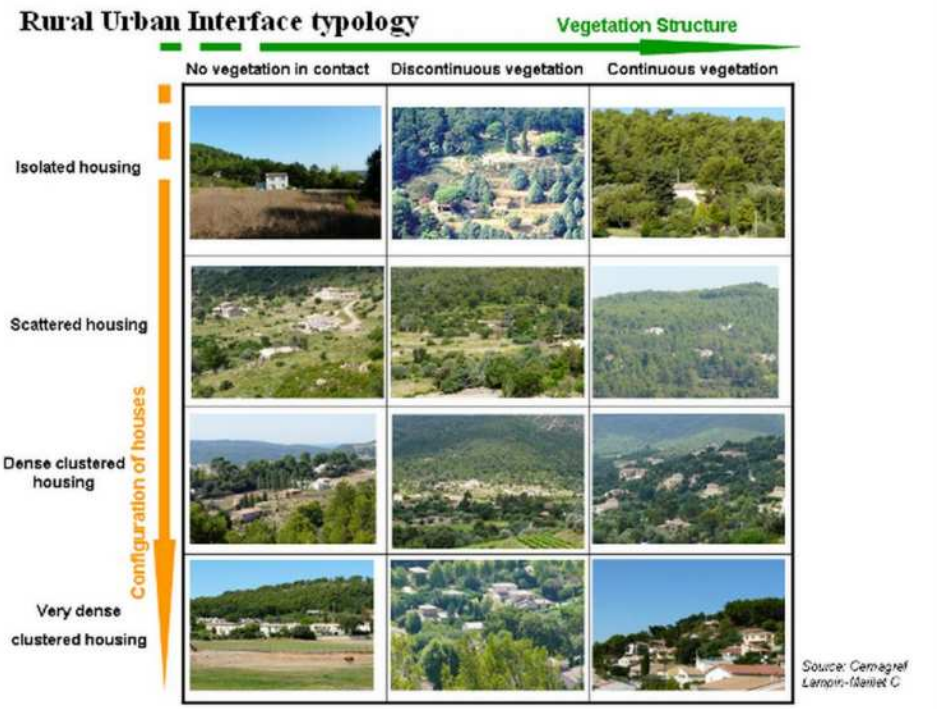

Figure 3. The 12 types of RUI

The map was created by the tool and set up with a colour code for an easy interpretation. (Figure 4)

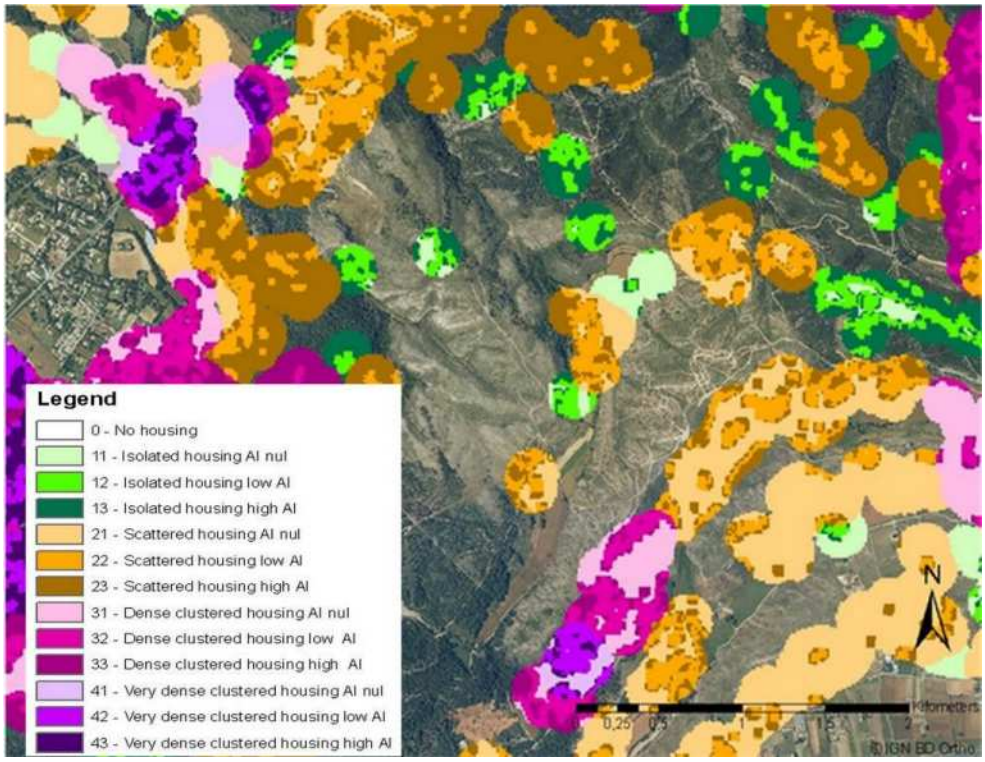

Figure 4 Local scale RUI map

Methods Local scale Tragsatec

The second local scale method was developed by TRAGSATEC. The method is based on three phases. First a settlement map creation with two layers : a land use cover (in Spain : SIGPAC) and a vegetation cover (the National Forest Map of Spain). The result of the union of the layers is a territory which is distributed in plots depending on the housing (Figure 5) - urban cores, spread buildings, isolated houses, etc... - and the different uses of land - forestry or agricultural -, taking as a basic aspect how the dispersion of the buildings is on the land and the landscape that surrounds them with the rules defined below:

- Urban area (plot > 50 ha)
- Habitat in agricultural areas (1 ha < plot <50 ha, forest < 30%)
- Habitat in forest areas (1ha < plot <50 ha, forest >= 30 %)
- Habitat dispersed in agricultural area (plot < 1 ha , forest < 30% , 3 > buildings > 5)
- Habitat dispersed in forest areas (plot <1 ha , forest >= 30% , 3 > buildings > 5)
- Habitat isolated agricultural area (plot < 1 ha , forest < 30% , buildings < 3)
- Habitat isolated forest area (plot < 1 ha , forest >= 30% , buildings < 3).

The second phase is a buffer creation. The Rural-urban interfaces only are considered in settlements which are located at a distance inferior to 400 m from the forest (according to the Regional Spanish laws). A buffer is created around the established settlements from the first phase and its size depends on the difficulty in protecting the houses against fire. In the final phase the different types of RUI are defined from the type of settlement and vegetation-settlement connection around houses, the buffer for each type of settlement is the area called the rural-urban interface.

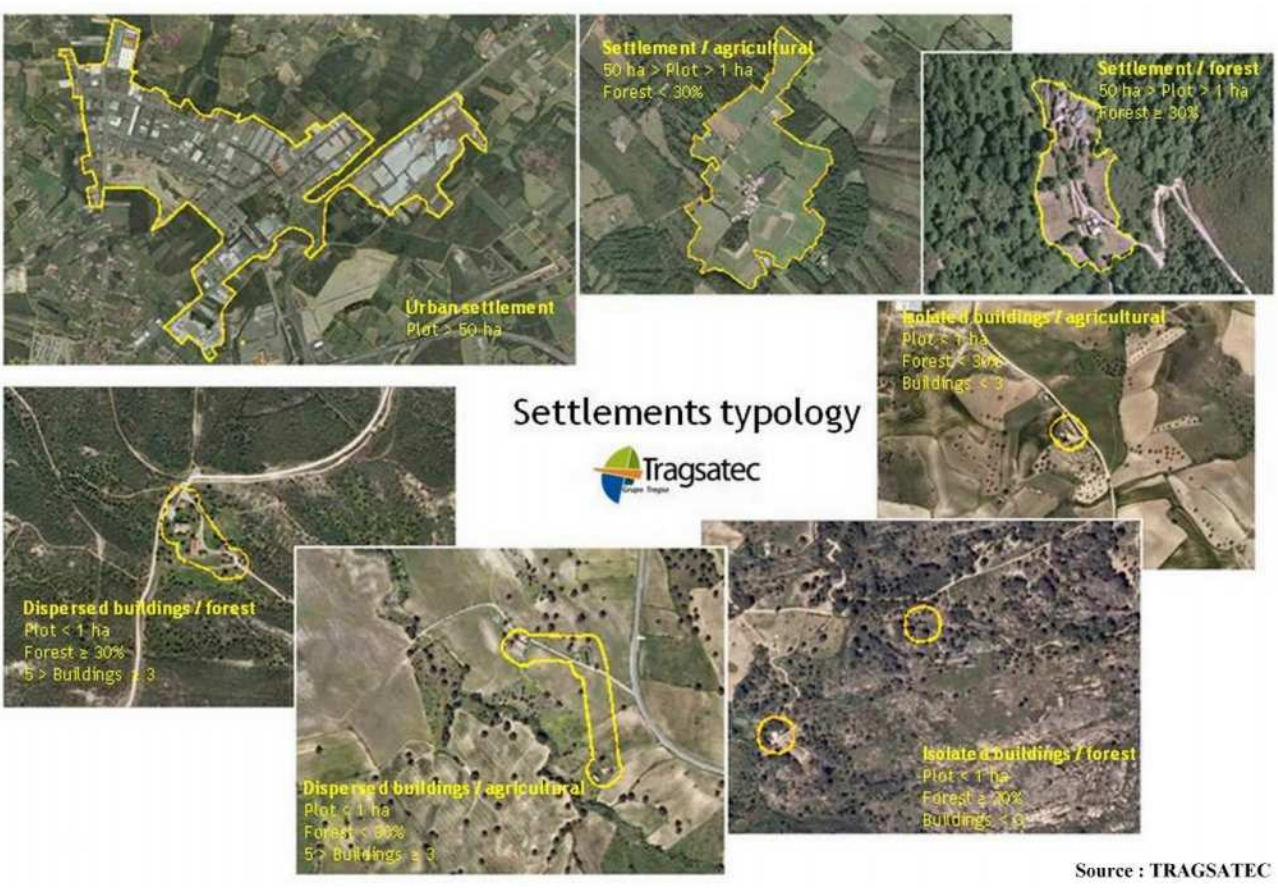

Figure 5. Tragsatec settlement typology-

The Rural-urban interfaces are considered in settlements which are located at a distance inferior to 400 m from the forest. This distance can be modified in the tool according to the laws of each country. Then the RUI map is created (Figure 6) by applying differentiated buffers, varying from 100m up to 400m, according to the type of habitat and risk.(Table 1)

Table 1- Buffer sizes

Settlement Type	Buffer size
Urban settlement	400
Settlement in forested area	300
Settlement in agricultural area	200
Dispersed buildings in forested area	300
Dispersed buildings in agricultural area	100
Isolated buildings in forested area	200
Isolated buildings in agricultural area	100

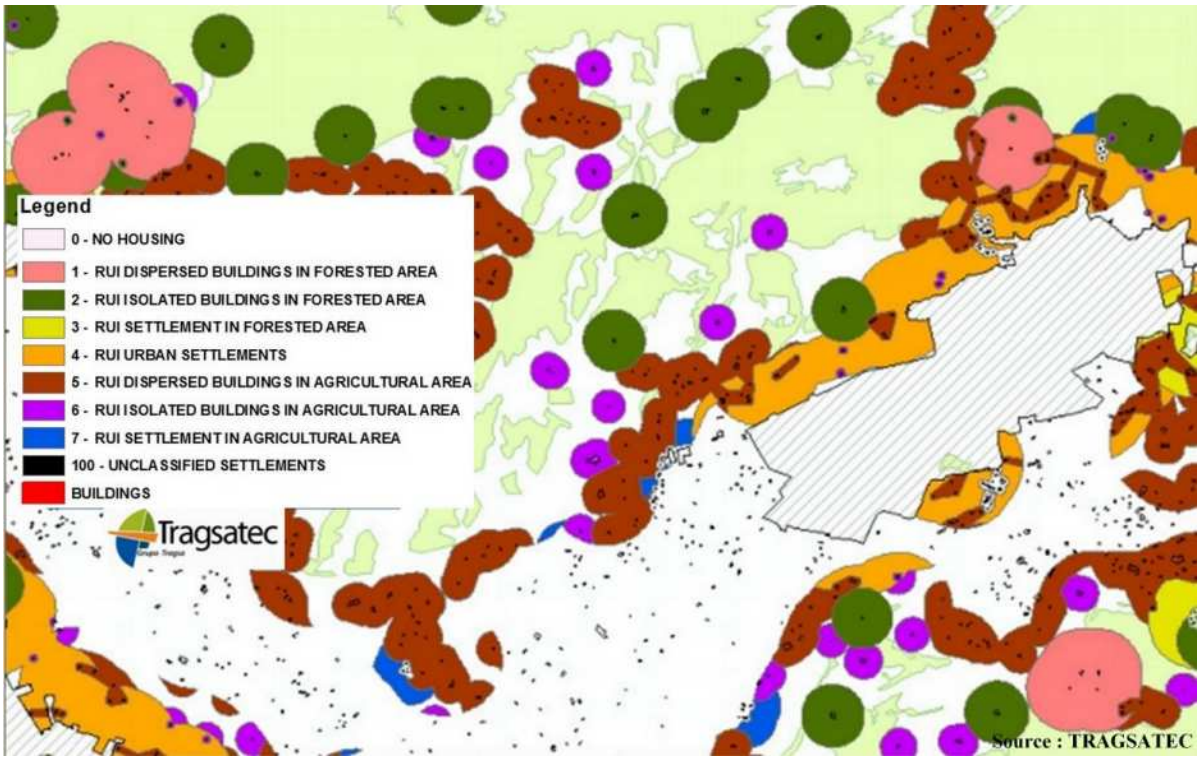

Figure 6. Map of RUI local scale - Tragsatec

2.3. Global scale Irstea

The global scale has been considered as the European level. This level of work has been taken into account in order to compare the situations and the importance of RUI in the different European countries.

The main database used is the 2006 CORINE Landcover with a pixel resolution of 100 metres. In order to characterize RUI, two main landcover types were used : vegetation and urbanization.

On the global scale, the rural urban interfaces are defined by a radius of 400 metres around houses located at less than 200 metres from forests or shrubland. The distance of 400 metres takes into account the perimeter where fuel reduction operations can be imposed on homeowners by different laws or regulations but also the possible burning of houses by spot fires.

The global rural urban interface map results from the combination of 2 criteria:

- the general land cover characterization (mineral, agricultural, sparse vegetated or forested area) resulting from the simplification of the Corine Land Cover database;
- the housing configuration (isolated, scattered, dense cluster housing) resulting from the combination of urban fabric classes of the Corine Land Cover database and from the soil sealing database.

A nine class typology was created during the process with a repartition of housing in three classes : isolated, scattered and dense, combined with different contexts : mineral, agriculture or sparse vegetation and forest. (Figure 7)

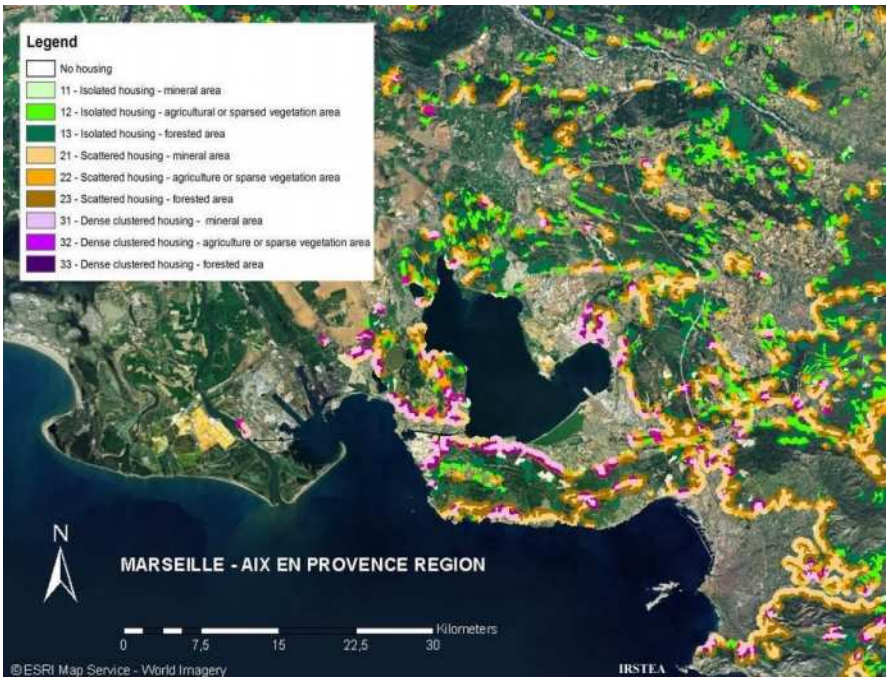

Figure 7. Global RUI map

Results

The RUImap software

This tool called RUImap (Figure 8) is an extension for ESRI™ ArcGis™. It was designed to run the three methodologies detailed above automatically and to gain in time and easiness. Each partner developed some parts of the tool. The Irstea local and global scale modules were developed with the Python programming language using ArgGis™ functions. The TRAGSATEC local scale was written in VBA language. The design and integration of the module in the final version was made by Tragsatec.

Figure 8. The RUImap software

3.2. Application of RUImap methodologies in different contexts

The methodology was used in different programs and researches in Europe. Town managers (in charge of planning, risks and expenditure) could directly apply the methods developed and use the software designed for an easy-and-direct use. The tool could quickly create easily-readable maps, show the location and categories of Rural urban interfaces. The several outputs produced by the tool were compared and a significant coherence was noticed between the different methodologies. The knowledge of the territory and some comparisons of the outputs with the real situation show a good correlation between the software results and the real RUI distribution on the territory.
The two approaches, global and local, are both useful to know, describe and map the territory on different scales and with different definitions. The general map produced by the global tool can be used to have a general view of the territorial characteristics. Then, it is possible to use the local and regional scale to focus the areas and update the analysis.
The IRSTEA and TRAGSATEC methodologies can be considered as complementary. The first method developed by Irstea analyses the residential buildings and the presence and continuity of vegetation. The Tragsatec method works on the dwellings too but it takes into account the environment in which they are located (forested, urban, agricultural). When running the local tool with both methods, more information can be collected and a more complete description of single RUI contexts can be obtained.
The use of the tool could be very useful for fire risk analysis on RUI scale and for local quantification of fuel load and continuity. The information with the direct knowledge of the general context is very important for the local fire risk assessment.

Municipality of Arcos de Valdevez, Portugal

The Portuguese National Fire Plan (2006) promoted fire prevention, population sensitization using passive means such as improvement of surveillance, detection and alert. It focused the need to protect the WUI/RUI through the establishment of defensible space of at least a hundred metres around the buildings and settlements. In this way, "WUImapping" has been used in different research projects.
The local scale methodology was used in the European project MOVE (Methods for the Improvement of Vulnerability Assessment in Europe) to define the vulnerability of the territories in order to find a more cost-effective risk management (funded by European Commission (7th Framework Programme). (Figure 9)

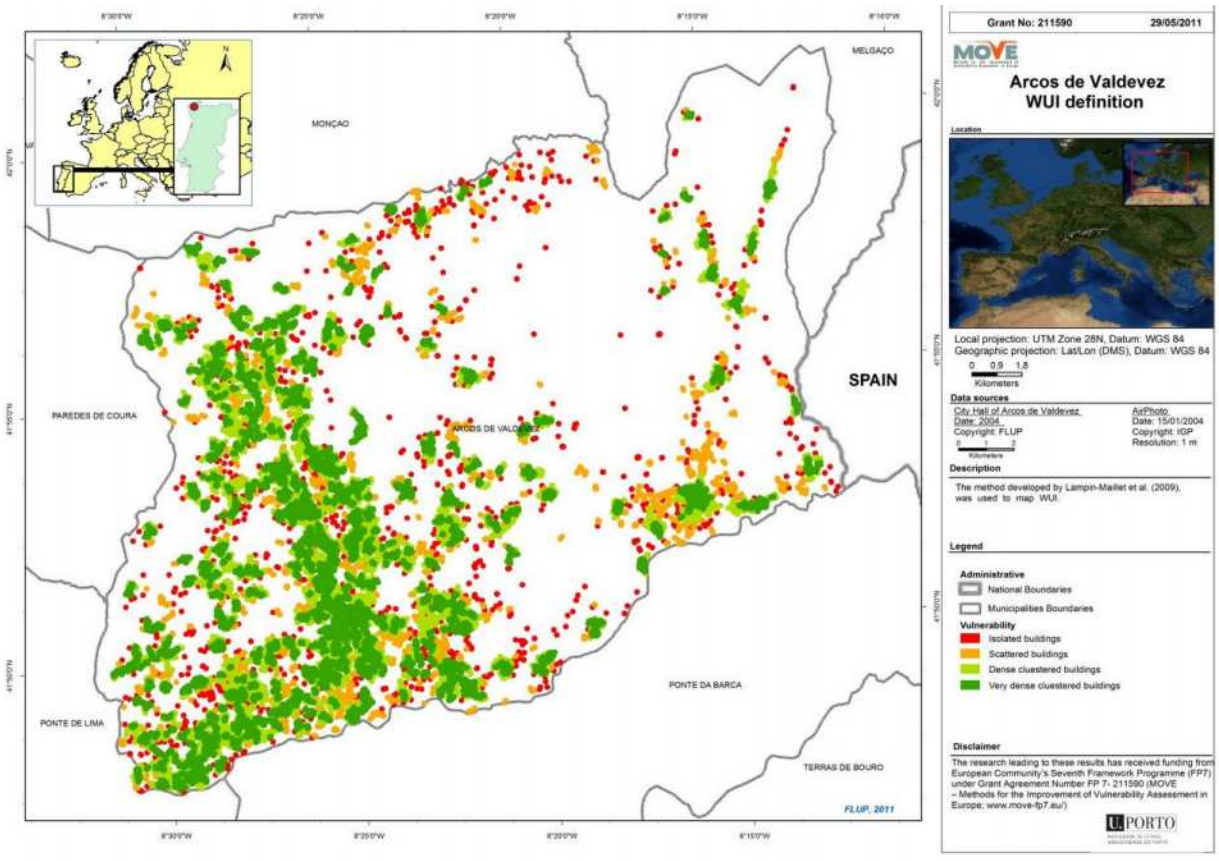

Figure 9. WUI mapping – Program MOVE

A project dealing with the implementation of a Forest Fire Risk Communication Program, will start in 2014 and will use the WUI/RUI methods in collaboration with several municipalities and stakeholders such as the Institute for Nature Conservation and Forests which is responsible for the coordination of all actions. The WUI/RUI typology will make possible a classification of the different forest fire prevention problems and will address them in a coherent way, both providing the capacity of transferability and capitalization.

Golfo Aranci area , Sardinia, Italy

Throughout most Mediterranean coastal areas, potential fire risk is really high for villages, tourist resorts, and people particularly in the summer. With a more important human presence and with extreme weather conditions, vegetation is highly flammable.
Therefore, developing planning policies is essential to find out strategies to prevent and reduce wildfire risk in WUI/RUI areas. Recently, several authors stressed the importance of estimating trends in expansion of WUI/RUI areas.
Tracking past and recent expansion trends allows to minimize their impact, to determine likely extent, location and pattern of WUI/RUI in the future, and to provide information for long-term land use planning and natural resource management. The study focuses on analysing and evaluating the temporal evolution of WUI/RUI areas in North Sardinia coastal regions in the 1954-2008 period with a great tourism development. (Figure 10)
Several simulations by Farsite(fire spread and behaviour simulator) were also performed in order to evaluate the accuracy of this approach in providing useful information for mitigating fire danger and risk in WUI/RUI areas.

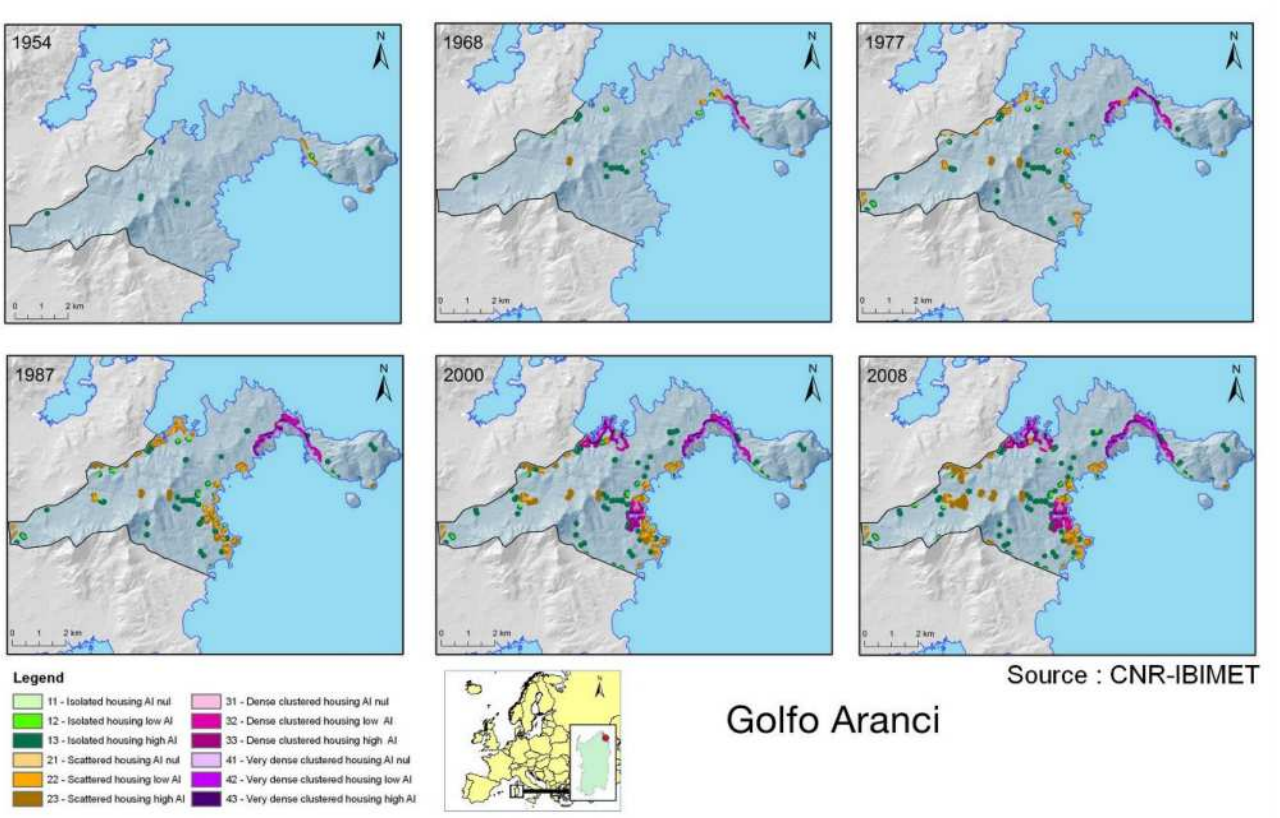

Figure 10. Evolution of the WUI/RUI 1954 – 2008 – Gofo Aranci, Italy

Oristano region, Sardinia, Italy

In the province of Oristano (central-western Sardinia), the mapping and characterization of the interface areas and the adaptation of the methodology to the Iocal context were tested in 22 municipalities, 21 are in the forestry district of Arci-Grighine, using the RUImap tool and the local scale as a methodological basis.(Lampin-Maillet *et al*.2010a and 2010b) .
An adaptation of the RUI mapping procedure was performed, as the French procedure is closely linked to their definition of the RUI and to the brush clearing law (Law Art L.322.3). This adaptation permits the application of the methodology to the Italian territory where a precise definition of the interface is still lacking and were immediate identification of areas that may be more sensitive to the problem of forest fire does not correspond to Italy. The alternative use of this input data allowed us to divide the territory into a forest area and rural area rather than in an area with a requirement / non-requirement trimming.
In the derivation of the vegetation map, the use of aerial orthophotography and of the filter (ICS Index Soil color) has revealed the fragmentation of forest vegetation with satisfying results, highlighting areas of bare soil present in some portions of the territory. BCZ (Brush clearing zone) was not used in this procedure as it is different in Italy. The change in the size of the floating window has made it mandatory to change the thresholds that define classes. AI low e high have been fixed respectively to 0-88% and> 88%.
The piedmont forest district of Arci-Grighine is an area with a high priority level in terms of land management and fire prevention actions.

Among the different RUI types Isolated and Scattered housing and AI low and high are those that require the highest security costs as they have a large surface area exposed to the fire and are difficult to reach. The map of RUI (figure 11) shows high-risk areas with very low population density and in the mountain ranges of Grighine (red) and the Monte Arci (blue). The last area was burned on July 4th, 2014 from a forest to a more dense housing RUI, causing huge damage to farms and dwellings.

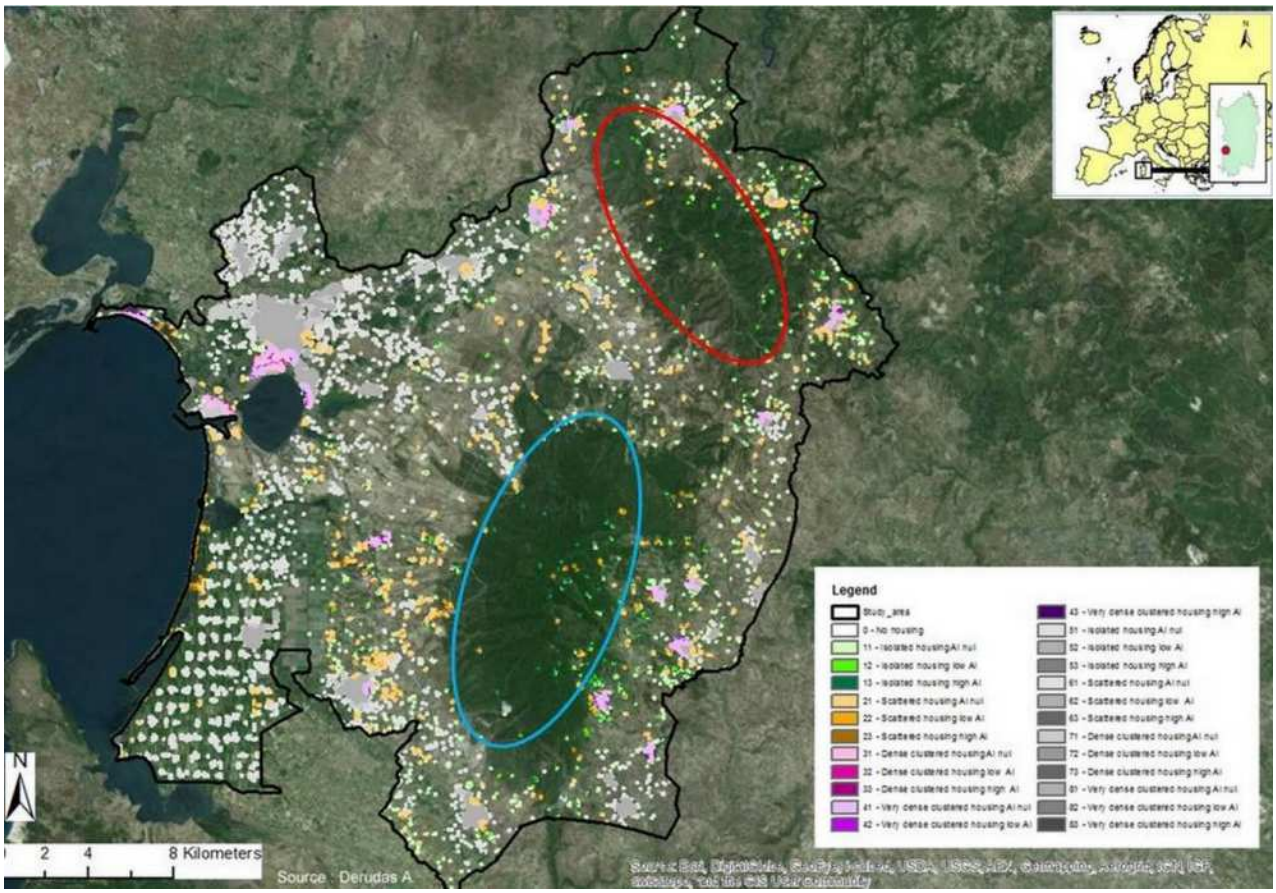

Figure 11– Priority zones to monitor, isolated houses, high vegetation aggregation

Molentargius regional park, Cagliari, Italy

The Molentargius regional park is an area of 1600 ha in the vicinity of Cagliari. The park stretches on wetland, lagoon areas (Ramsar convention) and abandoned salt flats frequented by numerous bird species.
The park area is also made of different terrestrial ecosystems with a patchwork of various vegetation: reed beds, meadows, groves and degraded scrublands interconnected with an a man-made system of some dwellings next to urbanization.
A plan was made to mitigate and lower the fire risk to human high value belongings like commercial buildings on the edge of the park.
The use of the RUImap software allowed to add information to the general knowledge of the park area, as a large part is included in an Rural Urban interface area. An analysis of the territory of the Molentargius regional park was performed (Figure 12) with the results obtained with the application of the RUImap software and the burned areas from 2005 to 2012. We can observe that most of the fires occurred in the areas where dwellings are surrounded by more or less dense vegetation.

Figure 12. RUI map and burnt area

Mimose village, Sinnai community, Sardinia, Italy

In this chapter the study uses the RUImap local methodology for mapping interface areas. This method is different from the method indicated in the guidelines issued by the Department of National Civil Protection Plan. France and Sardinia have different fire protection requirements . RUImap tool was used to point out the differences between the two countries.
The main interesting points of these RUI cartography are :
• a better knowledge of the interface areas and understanding of the dynamics;
• the identification of the most immediate at risk areas for fire operators.
• In the design phase of fire prevention :
- the identification and estimation of the areas to be cleaned;
- the assessment of the scope of the areas at risk and the consequent dividing up fire fighting teams and equipment;
- the design of the escape routes for the population as well as firebreaks or areas of cleaning required in the vicinity of the towns;
- the evaluation of suitable location basins or points for fire water supply.

The mapping urban-forest interfaces is one of the key elements for assessing the risk of fire. It is indeed a method to identify the critical present in an area and the sensitive points such as residences to be protected in case of fire, the presence of people and their assets. It is thus a valuable aid in the fight against fires through the knowledge of the spatial organization of housing in addition to being a tool to identify the people who live in urban-forest interfaces and so it is important to provide information focused on the risk of fire for preventive purposes.

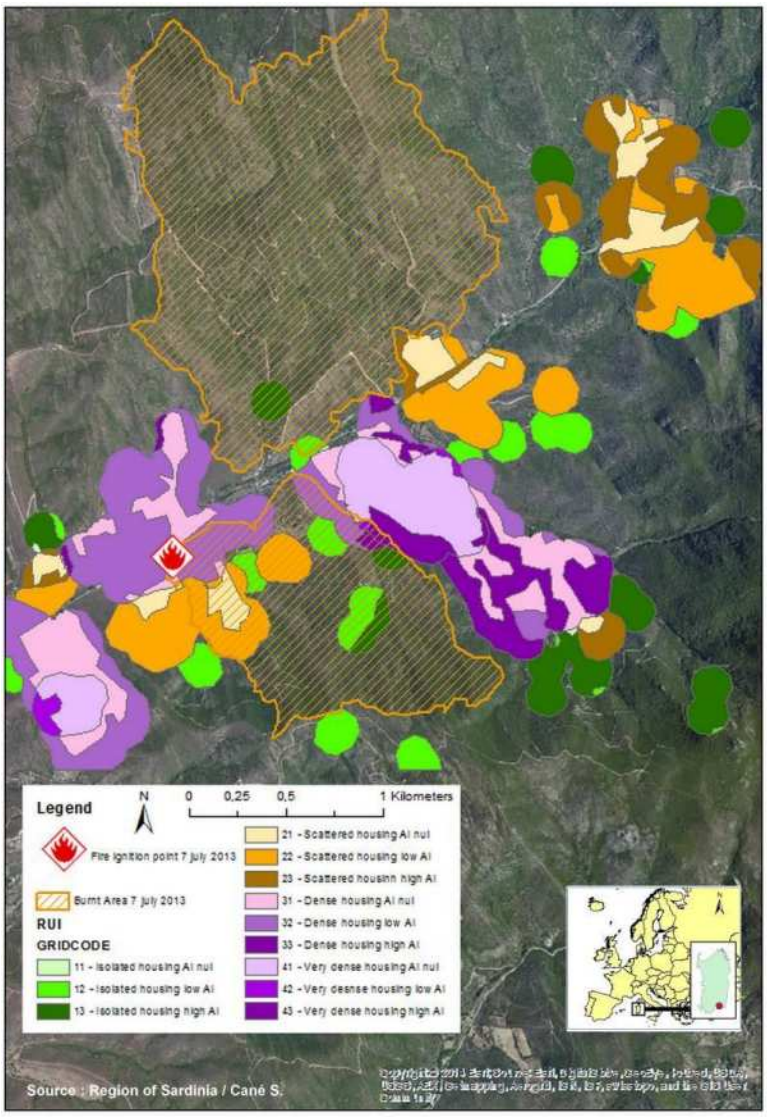

Figure 13. Mimose village -RUI map and burnt area

Bouches-du-Rhône, France

Irstea did a study for the regional ministry of the environment office. The aim was to get an overview of the RUI in the Bouches-du-Rhône department including the metropolitan area of Aix Marseille. The RUI of all the area was performed with two sets of data with a lapse of ten years. The results show an increase of 11% of the WUI area. The data were used later in the FUME program and related to fire historic data. The result shows a high number of ignition points located within the RUI zone with a higher density. The results are useful for stakeholders to make prevention action in this areas
In the study area of the Bouches-du-Rhône the evolution of the RUI between 1999 and 2009 shows changes in the composition and areas of RUI. The first results concerning housing configuration show a global intensification of urbanization in the area with several trends. The densification of the already built RUI zones evolve towards higher density classes. The densification concerns also isolated housing with an increase despite planning policy recommendation over soil sealing of the territory.
The main cause of this fact is an increase of the urban territory on the outskirts of the metropolitan area of Aix-Marseille. The attractiveness of southern France for its climate and lifestyle is part of the increase of built areas even in the remote towns with cheaper building prices.

According to figures it is possible to give some conclusion. The area of the RUI is increasing globally by 10%. The main increase in RUI types occurs principally in dense areas.

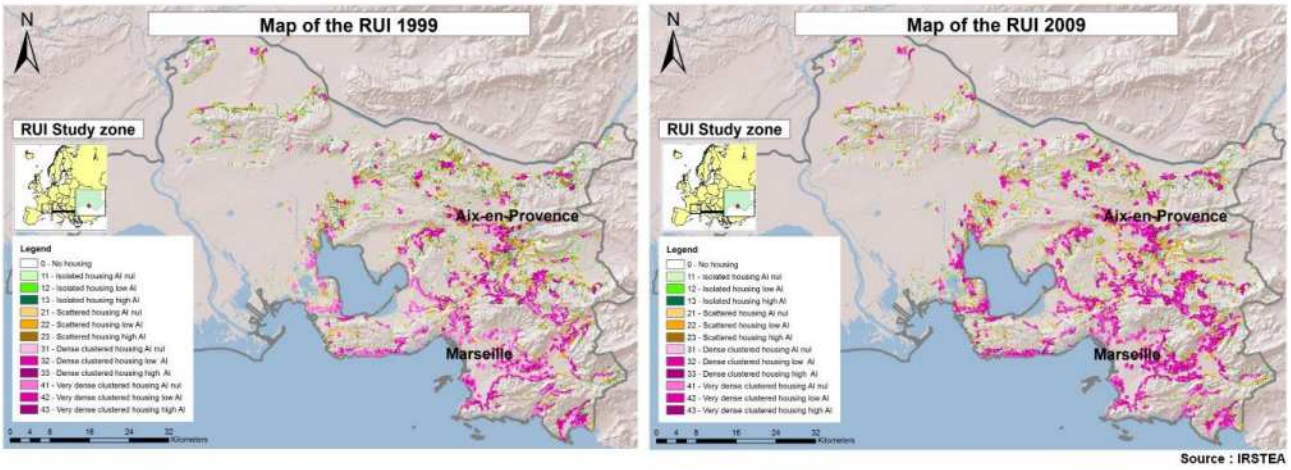

Figure 14. Bouches-du-Rhône, France :RUI evolution 1999-2009

Conclusion

The several outputs produced by the tool were compared and a genuine consistency between the obtained maps was noticed. The direct knowledge and some surveys in the territory are useful to compare the outputs with the real situation. A clear agreement between the software results and the RUI distribution on the territory was checked.

The two approaches, global and local, are both useful to know, describe and map the territory on different scales and definition. The general map that the global tool produces can be used to have a general view of the territorial characteristics on the regional scale and to focus the areas where the use of the local tool would complete the analysis.

In a general interpretation of the local tool application, the IRSTEA and TRAGSATEC methodologies could be considered as complementary. The first method developed by Irstea analyses the residential buildings and the presence/continuity of vegetation; the Tragsatec one also works on the dwellings but it considers the environment (forested, urban, agricultural) in which they are located. Running the local tool with both methods, more information can be collected and a more complete description of single RUI contexts can be obtained.

The use of the tool could be very advantageous for fire risk analysis on RUI scale, and for local quantification of fuels charge and continuity. The information, associated with the direct knowledge of the general context is very important for the local fire risk assessment.

The growing of RUI zone in all the Mediterranean study sites is a challenge for community leaders. This zone is at high risk due to numerous fire ignition density in a zone of human density and high valuable goods. The RUI expansion is a problem for prevention, organisation and fire-fighting. It increases the costs of protection as in these areas great losses are observed when a fire occurs. (human lives, houses).

RUI mapping can participate to prevent devastating loss for homeowners through assessment of information, to protect homes and lives in a better way in the interface where "lives community at risk".

Abstract
In this study, we describe how WRF-SFIRE is coupled with WRF-Chem to construct an integrated forecast system for wildfire and smoke prediction. The integrated forecast system has the advantage of not requiring a separate plume-rise model and assumptions about the size and heat release from the fire in order to determine fire emissions into the atmosphere. With WRF-SFIRE, wildfire spread, plume and plume-top heights are predicted directly, at every WRF time-step, providing comprehensive meteorology and fire emissions to the chemical transport model WRF-Chem. Evaluation of the system was based on comparisons between available observations to the simulations of the 2007 Santa Ana fires. The study found overall good agreement between forecasted and observed fire spread and smoke transport for the Witch-Guejito fire. Also the simulated PM2.5 (fine particulate matter) peak concentrations matched the observations. However, the NO and ozone levels were underestimated in the simulations and the peak concentrations were mistimed. Determining the terminal or plume-top height is one of the most important aspects of simulating wildfire plume transport, and the study found overall good agreement between simulated and observed plume-top heights.

Keywords*: fire modeling, smoldering, smouldering, smoke, air quality, emissions, dispersion, plume rise*

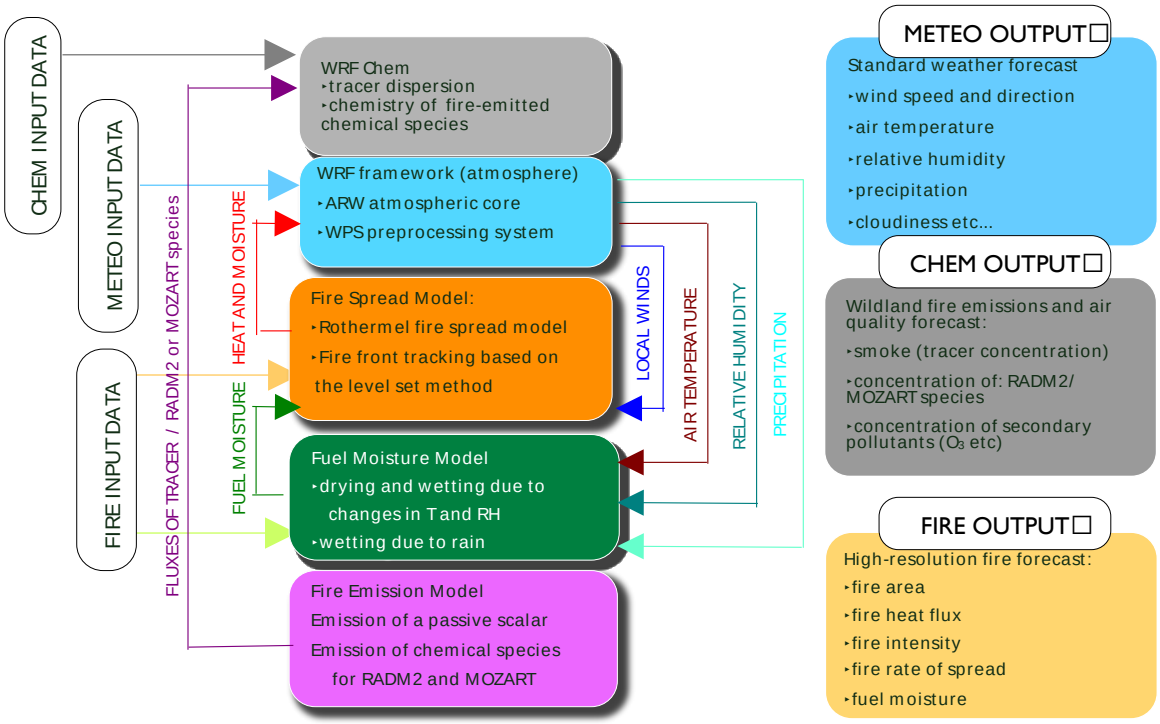
Introduction

A wide suite of tools exists that can be used to help assess smoke dispersion. They range from simple Gaussian smoke models that aim to assess the area affected by smoke based on fuel type, fire area and wind conditions, to complex multi-model systems predicting the emissions, dispersion and air quality effects associated with wildland fires. The latter ones generally use a set of specialized sub-models, designed to perform specific tasks associated with the fire emission forecasting. The multi-model systems typically consist of a fuel consumption model, providing an estimate of the amount of burnt fuel, an emission model, computing fluxes of chemical species, a plume rise model, assessing the injection height, and a chemical and transport model, computing how the species react and disperse in the atmosphere. The fire emissions and plume dispersion may be linked to meteorological conditions, by feeding these models with weather data provided by a separate numerical weather prediction model. There are two major limitations of this approach. First, this modular approach generally does not capture the two-way interactions between the system components. For instance, even if fire spread and fuel consumption are computed based on the simulated weather forecast, the fire's convection is not coupled to, and represented in, the weather model. The weather prediction used for fire progression will not therefore include local, fire-affected weather conditions. As a consequence, the inaccuracies in the prediction of the local weather conditions may adversely affect estimates of the plume height and dispersion, both which depend heavily on the weather input.

The second drawback is the limited fidelity of such a system in terms of realistic representation of the fire progression, fire emissions, plume rise, and plume dispersion. For example, a typical plume-rise model is based on classical plume theory, and assumes a single idealized Gaussian-shaped plume (in most cases, rising vertically; i.e., not bent-over) placed over a point-source fire. In reality, both the surface fire emissions and fire plume behaviour are much more complex. The majority of the flaming emissions take place at the fire perimeter, while the smoldering may be a source of emissions within it. Regions of high fire activity can induce more than one strong updraft core, ingesting fire emissions at much higher rates than is estimated by the typical plume rise model, while strong winds may limit the plume rise to much lower elevations than those predicted by an idealized plume rise model.
In this paper we present a new integrated approach to the problem of the simulation of the fire emissions. We show an integrated modelling framework that predicts fire progression, taking into account the fire-weather and fuel-weather feedbacks, and explicitly resolves fire-induced convective plumes, as well as simulates the chemical reactions, transport, and dispersion of the fire-emitted species in the atmosphere.

Model description

The core of the system is the WRF-SFIRE model (Mandel *et al*., 2011), which is a two-way coupled fire atmosphere model based on Weather Research and Forecasting model (WRF – Skamarock *et al*., 2005) and Rothermel (1972) fire spread model implemented by a level set method. WRF-SFIRE has evolved from the CAWFE code (Clark *et al*., 1996, 2004), which was built on the Clark-Hall code. The switch to WRF allowed faster than real time parallel execution on fine meshes and a natural coupling with WRF-Chem. WRF-SFIRE predicts fire spread based on local meteorological conditions, taking into account the feedback between the fire and atmosphere.
To capture the effects of local weather on fuel characteristics, WRF-SFIRE is also coupled with a fuel moisture model, which assesses the fuel moisture based on local meteorology (air humidity, temperature, and precipitation). The fire-emitted heat (computed by the fire model) is fed into the atmospheric component of the model, so WRF-SFIRE dynamically simulates and resolves the fire convection and plume rise. The mass of the burnt fuel in the WRF-SFIRE simulation is used to estimate the fire emissions associated with flaming and smoldering in every time step. The linked WRF-Chem (Grell *et al*., 2005) predicts the transport, dispersion, and chemical conversion in the atmosphere of the fire-emitted chemical species as the plume evolves. The impact of fire emitted heat on the plume characteristics accounts for different plume injection heights. Emissions from regions of high intensity fires are carried higher by stronger updrafts and greater plume rise, than from lower intensity fires generating weaker updrafts.



9

Figure 1. Diagram of the integrated fire emission system based on WRF-SFIRE coupled with moisture model and WRF-Chem

In this model framework, the model resolves the fire plumes instead of parameterizing them, and instantaneous fire activity at any given place is linked with the fire-driven emissions, fluxes, buoyancy, and local winds. Assumptions about the vertical distribution of the fire emission as part of a sub-grid scale parameterization based on classical plume theory are therefore avoided, as the vertical dispersion of the fire emissions are simulated by the model explicitly. The diagram showing the WRF-SFIRE model components is presented in Figure 1.

The fire emissions are estimated based on the combustion rates computed for each fire-grid point as the mass of fuel consumed within one WRF time step. Once the fuel consumption is known, emission fluxes are computed as the products of the fuel-combustion rates and the fuel-specific emission factors. Currently the global fire emission factors from FINN (Fire INventory from NCAR, Wiedinmeyer *et al*., 2011) are used, however; the model also accepts user-defined emission factors provided in one of the model configuration files. The fire emissions are represented as a sum of the fluxes of the chemical species compatible with two chemical mechanisms supported by WRF-Chem – MOZART (Emmons *et al*. 2010), and RADM2 (Stockwell *et al*. 1990) as presented in Figure 2. The emission fluxes are then ingested into the first model layer of WRF-Chem, which handles dispersion and chemical transformation of the fire emissions.

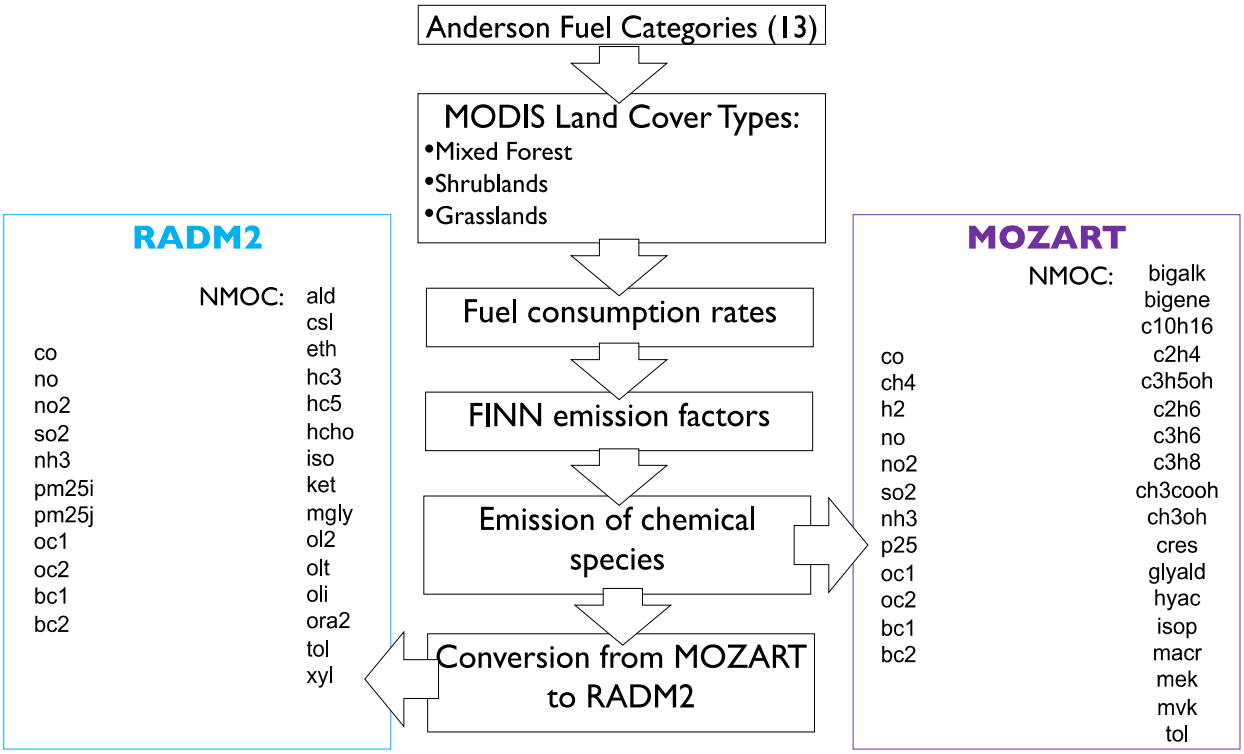


Figure 2. Computation of fire emissions in the WRF-based integrated system for fire and air quality simulations.

Model setup

We tested the system on the 2007 Witch and Guejito Santa Ana fires. In order to model evolution of the Santa Ana event, together with the local circulation dictated by the complex topography of southern California, WRF was configured with four nested domains: D01, D02, D03, and D04, of horizontal-grid sizes 32km, 8km, 2km, and 500m, respectively, as shown in Figure 3. The model's vertically-stretch grid extended up to 15.4 km, with a surface layer roughly 20 m thick and the top-most vertical layer roughly 2000 m thick. The surface fire mesh located in domain D04 had a refinement ratio of 25, making the horizontal fire-grid cell size 20 m. Output from the fire simulation was saved every 10 minutes. The fire model, SFIRE, used 30m-resolution elevation and fuel data, while the atmospheric model, WRF, used approximately 1.5km-resolution MODIS land-use representation. Further details of this setup can be found in Kochanski *et al*. (2013).

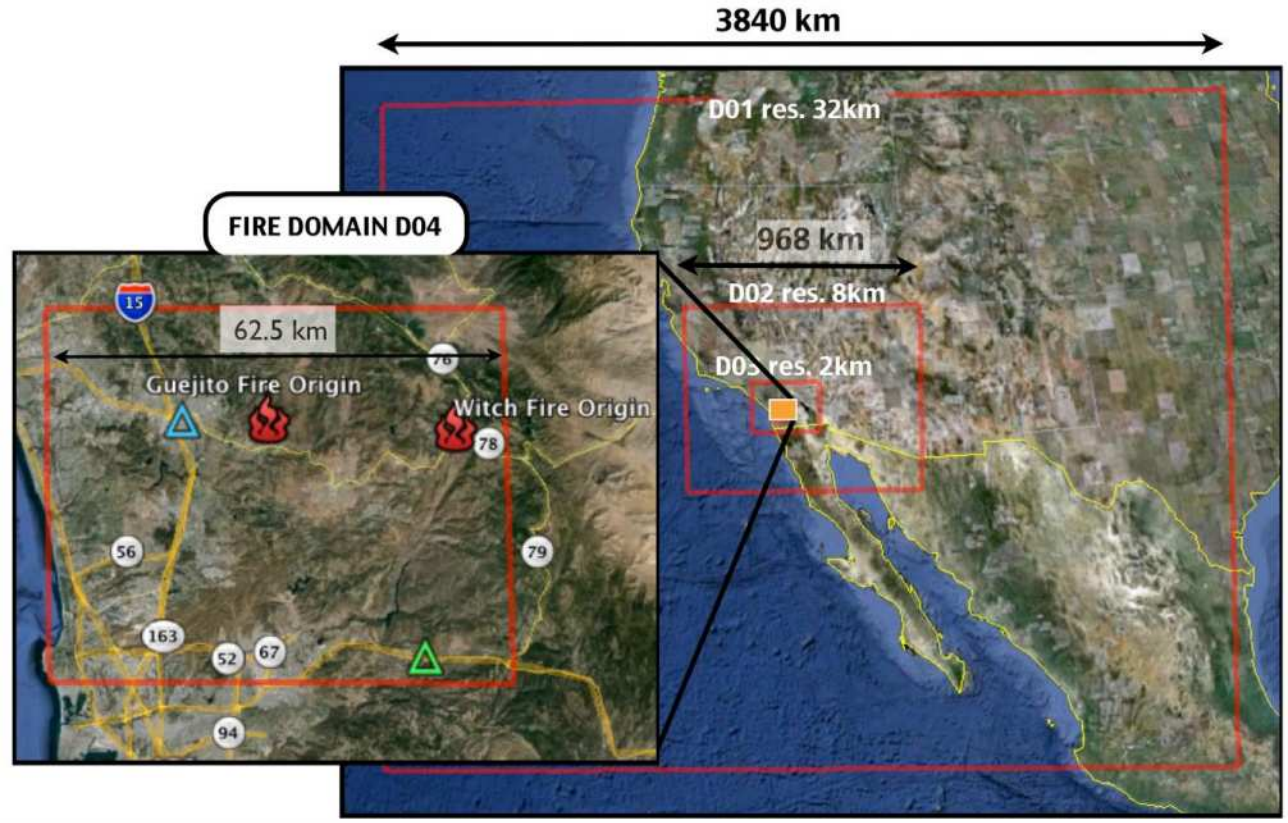

Figure 3. The multi-scale WRF setup in this study, including locations of the Witch and Guejito fire origins and the air quality stations used for model validation (Escondido - blue triangle; Alpine - green triangle). Horizontal domain resolutions vary from 32km (D01) to 500m (D04).

Results and discussion

The model's ability to accurately resolve the plume height was evaluated using available satellite data. There was no MISR (Multi-angle Imaging SpectroRadiometer) data collected for this particular fire, but there were two other nearby fires actively burning at approximately the same time (see Table 1).

Table 1. MISR plume retrieval data for wildfires in the vicinity of Witch-Guejito fire on date 200710-21 and time 18:39:52 UTC. SDev = Standard Derivation

Longitude	Latitude	Plume Perimeter Length	Plume Area [km²]	Median Plume Height [m AGL]	Top Plume Height [m AGL]	SDev
-117.441	33.244	70	259	943	1260	269
-116.562	32.623	269	2168	684	1017	314

The maximum simulated plume top height for the Witch and Guejito fires computed from the PM2.5 field using 1 μg/m^3 threshold was 1574m. This is slightly higher than suggested by the MISR data for the two nearby fires, but it has to be noted that they were also smaller than the Witch and Guejito fires. The two-way coupling between the WRF domains enables pollution transport across the domains, so the smoke emitted from the fire simulated within the inner most domain is also present in the outer domain D03, which may resolve larger-scale smoke transport. An example of the smoke dispersion simulated in the D03 and the visible satellite picture are presented Figure 4.

Figure 4. Smoke dispersion within domain D03 (2km resolution) simulated by WRFSC (left panel) and MODIS satellite image (right panel). The red color fill in left panel represents the fire area projected from the nested fire domain D04 (500m resolution). Red contours in right panel represent remotely detected hot spots.

The transport and dispersion of the fire-emitted pollutants as well as the chemical processes simulated by the model were tested based on the surface measurements of the PM25 and NO. An example of the time series of the PM2.5 and NO concentrations simulated by the model and observed by Escondido air quality station (green triangle in Figure 3) are presented in Figures 5 and 6.

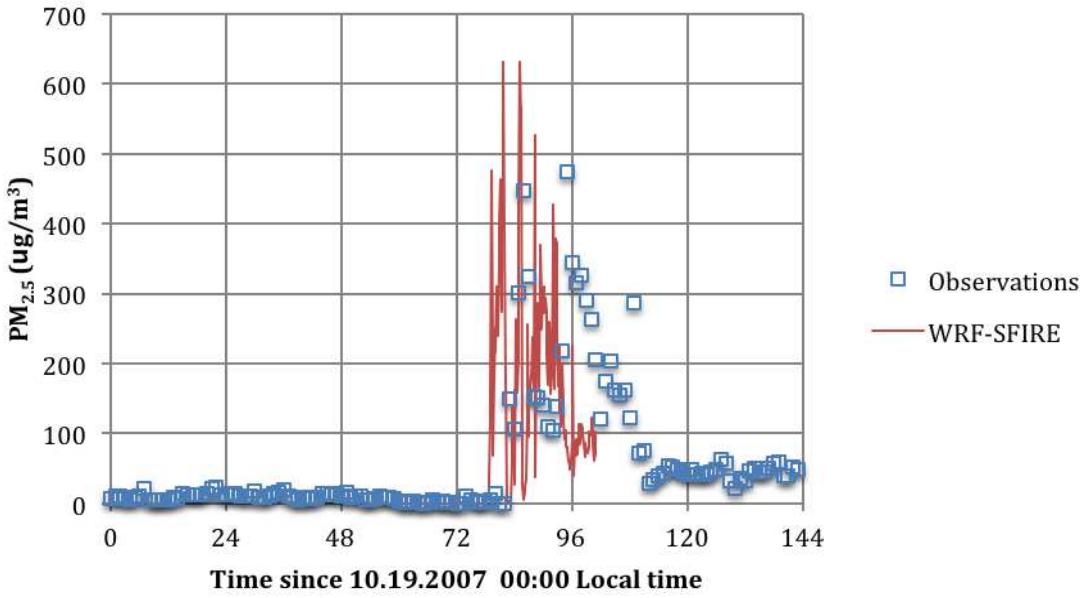

Figure 5. Time series of the simulated (red line) and observed (blue squares) PM25 concentrations at Escondido air quality station.

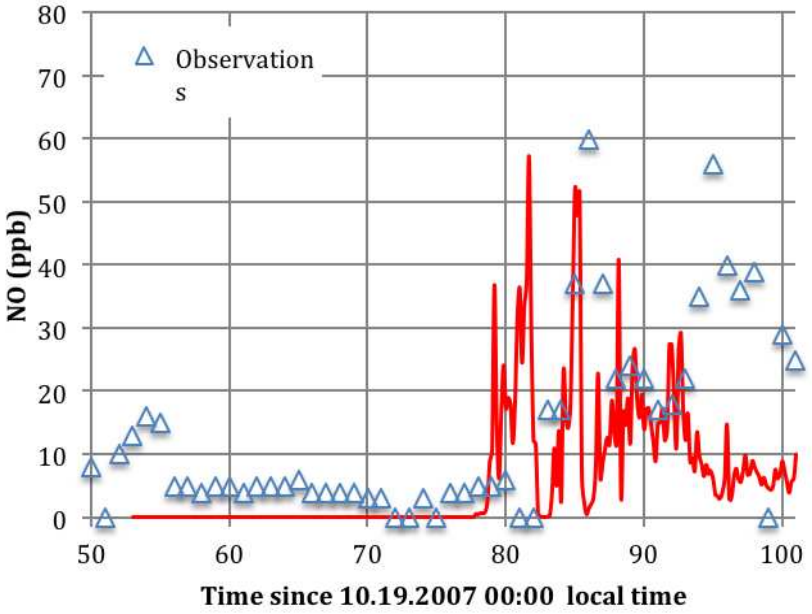

Figure 6. Time series of simulated (red line) and observed (blue triangles) NO concentration at Escondido air quality station.

In terms of the PM2.5 the modelled instantaneous values were slightly higher than the observed ones. The model estimated peaks at 632 μg/m^3 while the observations show maximum hourly values at 475 μg/m^3. It has to be noted that the WRF-predicted values peaked a couple of hours earlier than observed ones. The time shift between observed and simulated peaks can possibly be attributed to an overestimation in the north-west fire progression toward Escondido. Kochanski *et al*. (2013a) determined that the simulated fire progressed approximately 10km further in the north-west direction than the actual fire.

In terms of the NO concentrations, the model slightly underestimated the concentration, predicting peak values of 57.3 ppb, while the observed NO peaked at 60 ppb. Similarly like in the case of PM2.5, the timing of the simulated NO peaks appear earlier than in observations.

In a complex modelling system like WRF-SFIRE coupled with WRF-Chem, it is very difficult to determine directly reasons for the discrepancies between the simulated and observed pollutants levels. One reason may be that the three MODIS Land Cover Types used for emission computations (i.e., mixed forest, shrublands, and grasslands) are not detailed enough to represent the chemical smoke composition from fires spreading across 13 different fuel-bed categories (Anderson 1982). Another reason may be that global NO emission factors for grass and shrubs may be slightly lower than the actual NO emission factors for the fuel types in the Witch-Guejito region of Southern California. Finally the simulated local meteorology and smoke dispersion, as well as the fire progression are not perfect. Nonetheless, these differences between PM2.5 and NO simulated and observed are relatively low, and show promise for integrated fire-emissions forecasts.

Summary

In this paper, we presented an integrated system for simulating fire progression and fire impacts on air quality. The system utilizes the WRF-SFIRE as a component resolving the fire spread forecast and plume rise, and the WRF-Chem handling the chemical transport of fire-emitted pollutants. This pilot study is designed to demonstrate the potential of WRF-Sire and WRF-Chem as an integrated system for use by researchers and resource managers. What the study does establish is the increased level of detail provided by the system, such as locations of high reaction intensity, smoke emissions, and plume

injection heights that can provide a more comprehensive understanding of the wildfire environment, wildfire behaviour, and downwind ramifications of wildland fire emissions on air quality. Future quantitative research is warranted to prove the validity WRFSC, and evaluation of the model by comparison to new and different data sets is necessary. Observations that provide information for all components of the system - local micrometeorology, fire spread, fire emissions, plume rise, and dispersion and chemistry - are needed. Coordinated field measurements of fire spread data, fire heat release, and in-situ meteorological conditions are required to evaluate the fire spread component of the system. Radiosonde data are needed to provide information on the vertical structure of wind, moisture and temperature. Airborne measurements in the smoke plume of the updraft velocities, temperature, and chemical composition, combined with estimates of local emission factors, are needed to analyse fire-plume dynamics, dispersion, and chemistry. A comprehensive dataset providing information on all these aspects is essential to fully understand how the integrated system performs and what components need to be improved.

Abstract
The common location of camping parks in forested or wooded areas, the normal use of combustible material by the campers and the frequent use of campfires to cook turn camping parks into areas with a high propensity for the occurrence of fires. Moreover, fires occurring close to parks induce to evacuations that disturb their normal activities. Despite the occurrence of several of such events, the associated risk is not yet well studied.
Project FireCamp is being developed in Portugal to analyse the propensity of fires in camping parks. This project has as main objectives: (1) analysis of past occurrences; (2) analysis of the combustibility of typical materials used in camping parks such as tents, sleeping bags or camping mattresses; (3) characterization of the camping park fuel cover and its surrounding by image analysis taken by UAV; (4) modelling of fire spread in camping parks; and (5) security measures for fire prevention and mitigation. A pilot study is being carried out in the Camping Park of Coja, in Arganil - Coimbra, which in September of 2012 was threatened by a forest fire that arrived to the perimeter of the camping park. A survey of this occurrence was done.
Several laboratory tests have been carried out in order to analyse the properties of the camping materials. Real tents with and without typical material inside (e.g., sleeping beds) were burnt in controlled environment in order to determine the mass loss decay, the increase of temperature and the convective winds produced. In parallel, each type of typical camping materials were analysed to determine the calorific power value.
Considering that external fires frequently threat camping parks, the survey of the neighbourhood of camping parks is also of great interest. In FireCamp Project, the aerial photographic survey of the camping park of Coja was carried out in order to produce a fuel map of this area. Based on this fuel map, a stochastic model to predict the fire spread in the covered area was set up.
The results obtained in the pilot study of the project applied to the Camping Park of Coja are also presented.

Introduction

The occurrence of fires in Camping Parks (CP) are relatively frequent and in several cases they drive to wounded people or even to dead fatalities. The most serious fire incident occurred in camping parks took place in the CP Los Alfaques, in Terragona-Spain in 1978, where cascading explosions of fuel storages led to 217 deaths and more than 300 wounded people. Several other fire incidents have been reported by, for example, Fraser *et al*. (2003) or Klein *et al*. (2005).

Fires affecting camping parks may have origin inside the park or may come from the outside since parks are typically located in forested areas. The main ignition sources of fires starting inside the park are: electric equipment, use of fire for cooking or other practices, or neglect use of some common potentially igniter camping accessories like gas lighting, candles and others. Fires coming from outside the camping area may request the evacuation of the CP, endangering people and goods.

Fires in camping parks also assume great relevance given the many common ignitable camping accessories used such as tents, caravans, sleeping beds, mattresses, etc, which can sustain the fire and, when supported by other forest fuels, increase the fire spread through the camping park by conductivity and radiation mechanisms or by spotting. Besides all these risks, the knowledge of fire ignition, spreading and suppression in camping parks is still poor and requires a methodical analysis.

In Portugal there is a set of regulations about this matter like the regimes applicable to the installation and operation of public and private camping parks to simplify and standardize the respective licensing procedures, or the measures to prevent and control any actions that may cause damage to natural resources and facilities including (naturally) fire hazards:

- outside the CP and during the highest fire hazard season it is prohibited to burn anything within a certain distance of any woodland or brushland during the most part of the day; the law is intended to prevent forest fires by allowing outdoor burning only when the weather conditions are in general less favourable to spread an eventual wildfire;
- there are peripheral circulation paths with a reasonable width along the CP not only to prevent the spread of any fire to its interior but also to facilitate the passage of emergency and fire fighting vehicles;
- inside the CP only campfires and charcoal BBQs are allowed, and in specified fixed places; even so it is prohibited leaving a fire without completely extinguishing it, or failing to maintain it under control.

Albeit in a more or less insipid way and yet revealing the positive trend of the authorities in this matter, among the legislation set out one can list: the impacts of the legislation on CP in specific emergency plans of some Portuguese municipalities; the framework of CP in broader plans for local and regional spatial planning and management; and the existence of specific emergency plans for temporary CP.

The work presented in this paper is integrated in the FireCamp Project that is an internal project of the Associated Laboratory for Energy, Transports and Aeronautics (LAETA). The main objective of FireCamp is to understand and model the fire spread in camping parks as well as present alternatives to reduce the fire risk in CP. A pilot case study to apply the methodologies established in FireCamp was developed in the Camping Park of Coja. Several laboratorial experiments were carried out in order to determine the most important characteristics for modelling the fire spread. Burning tests with real tents and other camping accessories were performed as well. A survey of the area where the CP of Coja is located using Unmanned Aerial Vehicles (UAV) was carried out. A stochastic model to predict the fire spread in CP was produced. The methodologies used and the main results of the work developed are described in the following chapters. Some simulations of the fire spread in the CP of Coja are presented.

Methodology

In order to develop a tool for simulate the fire spread in a camping park, two set of inputs related to the combustible materials are necessary. The first set of inputs consists of the properties of typical camping accessories that can influence the fire spread. Several laboratorial tests were carried out with several different materials under different conditions to obtain these data. The second set of results is related to the characterization of the fuel cover of the area where the CP is located. As it was previously

mentioned, the survey methodology was applied to the Camping Park of Coja that was the pilot case of the project. The methodologies used to achieve the required inputs to modelling are described below.

Analysis of the combustibility of typical accessories used in camping parks

There are many combustible accessories used in camping activities and, for a question of simplicity, tests were restricted to the accessories that were considered to be more relevant, namely: tents, sleeping beds and camping mattresses. On the other side, accessories have different shapes and sizes, and these accessories may be composed by several different materials depending on the brand manufacturer, quality, etc. For example, the walls of some tents only have one layer of fabric while other tents have an additional interior layer of cotton. Therefore, a limited but representative number of the existing types of materials and accessories were analysed. Table 1 and Table 2 resume the accessories and materials tested.

Table 1. Resume of the materials analysed.

Code Sample	R1	E1	B1	W1	I1	P1	SB1	CP1
Picture								
Description	Tent roof	Tent entrance door	Tent base	Tent wall	Tent interior	Tent entrance mosquito protective net	Sleeping bag	Camping mattress
Material	Polyester or polyamide coated with a PU or silicone	Rip stop nylon	Woven PE Sheeting "Poly Tarp"	coated polyester and vinyl	cotton with polyester	Oxford cloth and mesh	100% polyester	PE foam

Since the amount of materials to be tested was limited, it was decided that focus should be given on the determination of the Higher Calorific Value (HCV) of sample materials mainly used in camping tents. These tests were performed in the calorimetric bomb according to standard EN ISO 1716. The bomb calorimeter is the most common device for measuring the heat of combustion or calorific value of a material. A small test specimen with a specified weight is combusted completely during constant volume and oxygen atmosphere inside a high-pressure calorimetric bomb. The calorimeter measures the temperature rise of the surrounding water and calculates the gross heat of combustion. Before testing, samples were conditioned at a temperature of 23 ± 2 ºC and relative humidity of 50 ± 5 %.

Besides the analysis of HCV, other tests of burning tents were also performed in order to understand the mechanism and the main factors affecting the burning. Table 3 resumes the burning tests carried out varying the initial conditions.

Table 2. Resume of the accessories tested.

Ref.	Weight (kg)			Fabric composition (m^2)	Number of layers of fabric	Dimensions (cm)	Photo

140127_TC05	Igl03	1 sleeping bag 1 camping mattress	1.1 m.s-1	St

* Fb – Ignition by firebrands falling over the tent.
**St – Propagation of the fire to the tent by a linear fire front spreading on a straw fuel bed.

Tent ignition was achieved using a firebrand generator as can be seen in Figure 1. The firebrands were provided from the burning of cylindrical pellets with less than 10mm high and with a diameter lower than 4mm. In some cases, the firebrands were directly projected to the tent (Fb). In other experimental tests, a linear fire front spreading on a straw fuel bed propagates the fire to the tent. In one particularly case, the firebrands were simultaneously projected to the tent and to the straw fuel bed adjacent to the tent (Fb+St), resulting in several ignition points in both tent and straw fuel bed. The fuel load of the straw fuel bed was always 0.6 $kg.m^{-2}$.

Figure 1. Experimental apparatus of the burning tests.

The total mass decay (tent, filling and fuel bed) and the convective velocity were the parameters considered for control. The burning tests were carried out in the Forest Fire Research Laboratory (LEIF) using the platform of combustion that is a combustion table fitted on a weight balance that automatically registers for every second the total weight during the experiment. Up flow velocity was automatically measured using Pitot tubes installed on the top of the tent. The experimental installation and equipments can be seen in Figure 1.

Characterization of the camping park fuel cover and its surrounding by image analysis taken by UAV

The determination of the risk of fire in a CP area requires the characterization of factors such as vegetation type, fuel load, distribution of occupied spaces, neighbour water sources and available access routes. In order to facilitate the characterization procedure, either by doing it remotely or even automatically, a high-resolution digital mosaic may be obtained from aerial images acquired by UAVs flying over the camping park area.

With this purpose, some flight tests were made in June 2013 over the CP of Coja, near of Coimbra – Portugal, using the UX-401 quadcopter from UAVision. The quadcopter was equipped with a GoPro HD Hero camera, set for 5MP still image acquisition every 2 seconds. In each of these flights a set of pre-determined waypoints was defined as reference for the quadcopter autonomous navigation. One of these flights is represented in the left image of Figure 2. The right image shows one of the photos taken during the flight.

Figure 2. Left: Trajectory described by the quadcopter while on autonomous navigation over the area of the CP of Coja (seen on Google Earth). Right: One of the pictures taken during the flight with a GoPro camera.

In order to be used as an input variable in fire spread modelling systems, the fuel cover of the camping site and surrounding must be spatially characterized. The processed followed was based on photointerpretation of the produced high-resolution digital mosaic. The photo mosaic was loaded into ArcGIS and the different fuels were identified and vectorized. The fuel models used to characterize the vegetation were the ones produced by M. Cruz (2005) and represent the typical vegetation found in Portugal. A fuel model is by definition a complete set of fuel inputs needed for a mathematical fire spread model (e.g., Rothermel, 1972). It represents a homogeneous vegetation formation in which fire behaviour is expected to be constant and predictable. For each continuous vegetation group identified in the photos a polygon was designed and the corresponding fuel model was assigned in the attributes table. The same was done to non-fuels such as roads, urban areas or water bodies. In the end of the process a continuous fuel map of the entire region was produced.

2.3. Modelling of fire spread in camping parks

Based on the laboratorial experiments results and on the characterization of the camping park fuel cover and its surrounding by image analysis taken by UAV a simulation of a fire front propagation was made. Given the non-deterministic nature of some available data, the fire propagation model was also developed to investigate the quantification of the complex fire propagation uncertainty using stochastic equations and a parametric study (number of variables, stochastic dimension of space) to determine the various parametric influences on the numerical solution of the asymptotic state.
Faster than real time stochastic fire spread predictions were obtained using a Non-Intrusive Spectral Projection (NISP) method in which the solution is expanded in a series using Polynomial Chaos. The unknown coefficients of the expansion terms were calculated from deterministic solutions using a conventional fire growth model. In the present case, the fireLib functions were used for the calculation of the rate of spread together with raster surface fire growth algorithms. The fire growth model of the raster type was ported to the Graphical Processor Units (GPUs) architecture using the Compute Unified Device Architecture (CUDA) programming language.
For the present case three input parameters were considered uncertain, namely the wind speed, the wind direction and the fuel moisture. These three variables were characterized by a Gaussian Distribution with a coefficient of variation of 20%. The stochastic simulations with input parametric uncertainty as random variables were simulated under the complex realistic terrain of the camping park of Coja.

3. Results and discussion

The methodologies previously described were applied in order to obtain the results detailed and discussed in this section. The division into different themes follows the same approach of the previous chapter.

3.1. Analysis of the combustibility of typical materials used in camping parks

The tests performed with the typical camping materials previously described resulted in the values of HCV shown inTable 4.

Table 4. Values of HCV for the different materials tested.

Code Sample	R1	E1	B1	W1	I1	P1	SB1	CP1
HCV (MJ/Kg)	23.13	29.27	45.51	22.58*	22.09	22.86	22.45	41.45

*this sample requires specific accessories for measurements as it contains halogenated components

According to the Portuguese legislation, the tested materials fall within the use-type IX "Leisure and Sports Venues" whose characterization is described in paragraph 1i) of Article 8 of Decree-Law no. 220/2008. This decree-law is regulated by Decree no. 1532/2008 of 29 December, which in point a) of Article 282 stipulates that "in camping parks, coverings used in camping tents, caravans or motorhomes are allowed only when they are constructed with materials with fire reaction classification of at least grade C-S2-d0". This kind of classification is obtained by performing SBI (Single Burning Item test) or the small flame test. However, for SBI tests a very large amount of material is requested by test (1.5x1.5m^2) restraining this to be used mainly for certification of construction and building materials.
Classifications A-B-C-D are dependent of materials fire reaction properties. According to standard NP EN 13501-1, these classes can be related with HCV according to Table 5. In this table, class C does not have a correspondence with HCV.

Table 5. Relation between material classes and HCV according to NP EN 13501-1.

Class	Classification Criteria*
A1	HCV ≤ 1.4MJ/Kg HCV ≤ 3.0MJ/Kg
A2	HCV ≤ 3.0MJ/Kg HCV ≤ 4.0MJ/Kg

*depending on the application

The analysed materials have high calorific values (about 7 to 13 times) above the criteria stipulated for A1 or A2 classes. Based on these high values, it is predicted that they cannot be categorized as class C, suitable for use-type IX "Leisure and Sports Venues" in Portuguese legislation.
The parameters initially considered for control show some problems of measurement due to the convective flow effects, as can be seen in Figure 3. When a tent starts burning, the temperature inside the tent increases creating an uplift which drives to a fake reduction of weight. Occasionally, during the burning some holes in the top of the tent are created and thus the hot air inside the tent can be dissipated. Consequently, the total weight increases suddenly and the up flow velocity abruptly increases to higher values. As the hole enlarges, the exhaust air velocity decreases, even if the tent is burning more intensively. Therefore, these measurements were considered invalid and a qualitative evaluation was made as it is presented in Table 6.

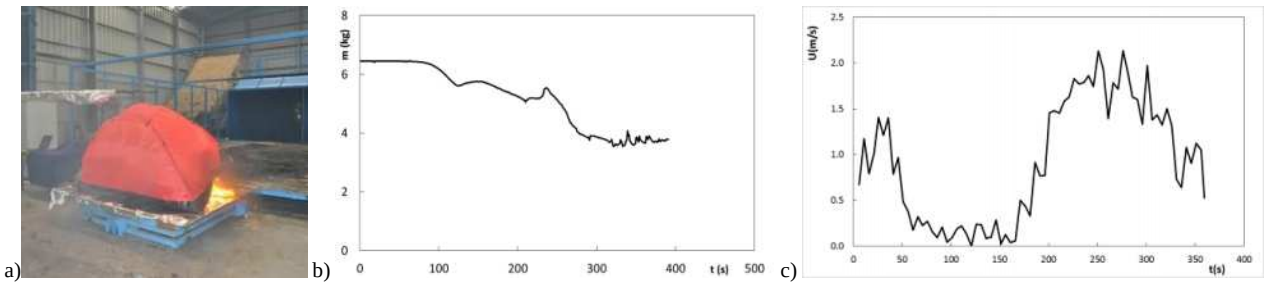

Figure 3. (a) Evidence of the up lift effect caused by the convective flow (140127_TC04); (b) mass loss decay (110516_TC01); (c) up flow variation (140127_TC04).

It was observed the shape of the tent is an important parameter to have ignition. The Canadian tent burned completely because the firebrands felled in the wrinkles accumulating heat. In igloos tents with the fabric well taut, the firebrands did not have that heat accumulation and firebrands just made a hole in the fabric not leading to a sustainable combustion.

The existence of flammable materials inside the tent, a common situation in camping parks, leads to a complete burning of the tent, even if the tent has a specific fabric with favourable combustion behaviour.

Table 6. Qualitative results of the burning tests.

Reference	Characteristics	Results
110516_TC01	Igloo with 2 layers and filling inside; ignition by firebrands and fire line	Complete burn. Ignition in parallel by the straw and by the firebrands. Some firebrands fell on the tent making some holes with no sustainable combustion. Some firebrands passed the fabric of the tent and fell in the blanket and in the duvets that started burning intensively.
130125_TC02	Canadian with 1 layer and no filling inside; ignition by firebrands	Complete burn. Some firebrands fell in the wrinkles of the fabric igniting the tent.
130616_TC03	Igloo with 2 layers and no filling inside; ignition by firebrands	Not burned. Some firebrands fell on the tent making some holes with no sustainable combustion. Some firebrands passed to the floor creating holes which rapidly self-extinguished.
140127_TC04	Igloo with 1 layer and filling inside; ignition by fire line.	Complete burn. The sleeping bed and the camping mattress started burning very intensively, however, when the fire reached these accessories the tent was already burning sustainably.
140127_TC05	Igloo with 1 layer and filling inside; ignition by fire line; induced wind of 1.1m.s^{-1}.	Partially burned. The tent started burning very intensively and the filling was completely burned. At a certain time the tent was inflated by the wind and turned over stopping the experience.

In the presence of wind, if a tent starts burning it can be inflated and dragged by the wind and, consequently, behaving itself as a firebrand spreading the fire to other tents or wounding people. This is a very dangerous situation that shall be taken into account.

3.2. Characterization of the camping park fuel cover and its surrounding by image analysis taken by UAV

The images acquired during the flights in Coja allowed to automatically construct a high-resolution mosaic of the camping site (Coito, 2013), (Costa, 2013). This mosaic is represented in the left image of Figure 4, as an over layer in Google Earth, while the right image represents a zoom of the area indicated by the red rectangle in the left image.

Figure 4. Left: High-resolution mosaic, constructed from aerial images acquired by a quadcopter over the camping site of Côja, overlaying Google Earth. Right: Zoom of the area indicated in red in the image on the left.

Observing the zoom image, one confirms the higher resolution of the resulting mosaic when compared with the available aerial images provided by Google Earth, allowing a clearer identification of the area. Another advantage of the UAV based imagery is that it may be acquired when conveniently, allowing, for example, the characterization of the camping site in different seasons (e.g., summer and winter) corresponding to a quite different distribution of occupied spaces as well as vegetation type and fuel load.

During the photointerpretation phase four fuels were identified: herbaceous (HER-01), low shrubs (MAT-01), pine stand with understory (PPIN-04), and deciduous broadleaves (FOLC-01). The physical parameters of these fuels can be found in Table 7.

Table 7 –Fuel models parameters (from Cruz, 2005)

	Fuel load (kg.m^{-2})				S/V ratio (cm^2.cm^{-3})		Depth (m)	Heat content (kJ.kg^{-1})	Moisture of extinction (%)
	Dead fuels			Live woody					
Model	1 hr	10 hr	100 hr	(Ø<6mm)	1 hr	Live woody			
HER-01	0.3	0	0	0	80	-	0.35	18000	30
MAT-01	0.2	0	0	0.7	60	60	0.4	22500	40
PPIN-04	0.7	0.3	0.2	0.6	60	60	0.7	22000	50
FOLC-01	0.3	0.3	0.2	0	79	-	0.06	18500	21

The area covered by the quadcopter was limited to the Coja camping site but in order to simulate the approach of a wildfire, the surroundings were mapped as well. To do so, Google Earth imagery were used. The final fuel map for the area is shown in Figure 5. The red polygon shows the area covered by the photo mosaic. The surroundings were mapped based on Google Earth.

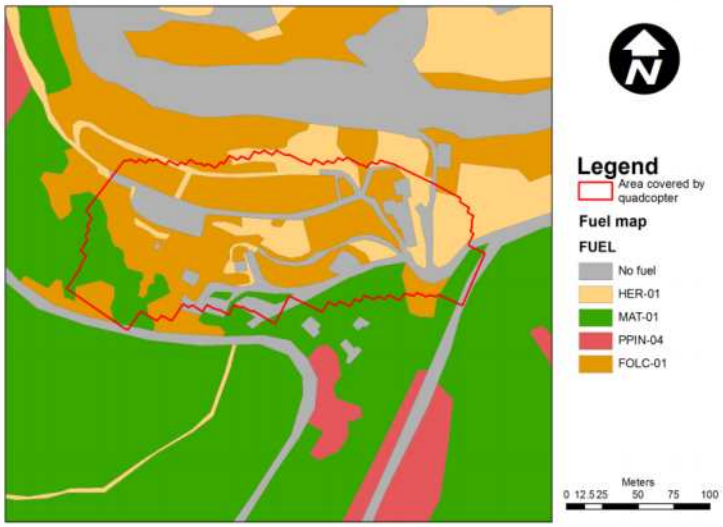

Figure 5. Fuel map of the Coja Camping Site

The fuel map was produced at a resolution of 1 m. The detail obtained with the photographs of the quadcopter is undoubtedly better than the one on Google Earth, thus, the precision of the fuel map inside the camping site is greater than outside. Besides the use of the quadcopter, a fixed-wing UAV (a Twinstar II) is planned to be used for imaging the surroundings of the camping park area. Preliminary imaging will be conducted with a remotely controlled flight of the vehicle and then autonomous flight tests will be performed for the same task. While the quadcopter dealt with the imaging of the camping park and its immediate surroundings, the fixed-wing UAV will focus on taking images of the outer surrounding area.

3.3. Modelling of fire spread in camping parks

Stochastic simulations allow predicting the effect of parametric input uncertainty through the model and, consequently, on the simulation results such as: burned area; fire front velocity and fire front propagation direction. Figure 6 shows the forecast of the fire front (stochastic mean) and its error bar area, based on a 95% confidence interval, at 4 hours of fire propagation.

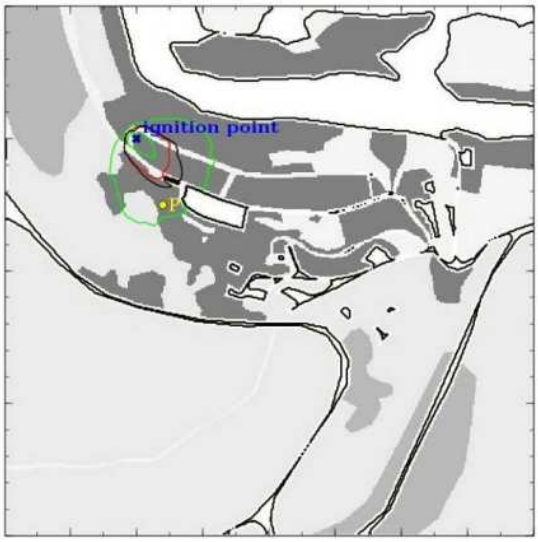

Figure 6. Forecast of the fire front in the CP of Coja after4 hours of ignition: deterministic mean (black); stochastic mean (red); error area with 95% CI (between green lines).

The statistical output of the predicted fields allows to know the probability of fire occurrence at a selected point (any location, as a function of time) and to decide accordingly about actions to have in real wildfires. This becomes particularly interesting when specific locations are of utmost importance and require priority protection. Figure 7 presents the temporal normalized Probability Density Function (PDF) at a selected point (see Figure 6, yellow point) that quantify the uncertainty on the fire spread.

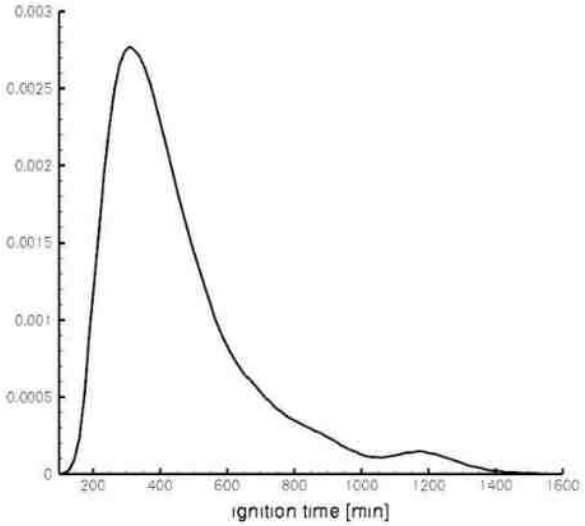

Figure 7. Normalized Probability Density Function (PDF) of ignition time at P location (see Figure 6, yellow point P)

The novel algorithm targeted for GPU architectures achieved a speedup of 176x against serial Central Processing Unit (CPU) execution. The GPU have allowed to obtained two orders of magnitude faster

stochastic fire spread predictions than the real time fire propagation. These results may prove useful toward firefighting methodologies.
The proposed methodology can be used for any camping park scenario. The output provides the time evolution of the ensemble mean fire front location and burned area error bars for a certain confidence interval and the PDF at each point as a function of time. In addition, the hierarchy of input parametric uncertainties based on the stochastic coefficients in the fire spread simulation was quantified. These estimators may add relevant information because wildland fire growth is an intrinsic stochastic process.
Figure 8 shows the stochastic mean (first bar) and the first (second to fourth bars) and second order (last six bars) stochastic coefficients at point P (see Figure 6), where v1, v2 and v3 represent wind speed, wind direction and fuel moisture, respectively. For instance, v1.v2 is the second order cross stochastic coefficient between wind speed and wind direction parameters. The stochastic coefficients characterize the respective parameter variability weight into the final solution. These results permit a sensitivity analysis about the influence of each parameter variability on the fire propagation.

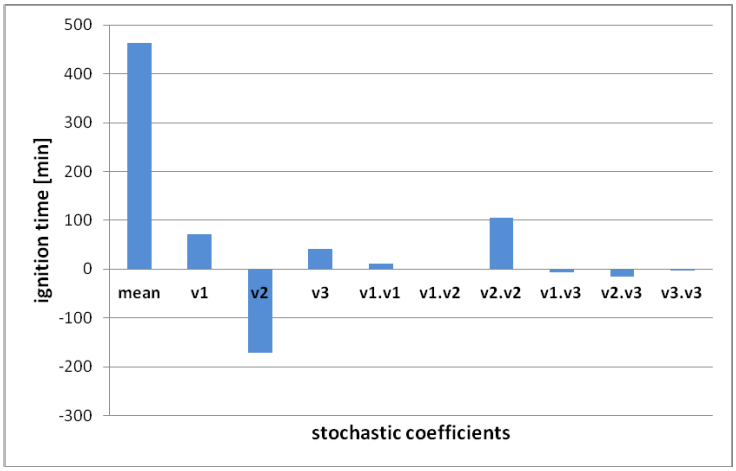

Figure 8. Stochastic coefficients at point P, being the uncertain input parameters: v1 – wind speed; v2 – wind direction; and v3 – fuel moisture.

Conclusion

Several conclusions can be vased on the work performed previously described.
The burning tests of tents resulted in some interesting conclusions. The ignition of the tent by a fire front is very effective, showing the importance of having the area adjacent to the tent free of fuels like straw, needles, garbage, etc. The ignition of tents by firebrands is very alike, and tents not well stretched have a greater probability to ignite as the firebrands accumulate in the wrinkles. The material inside the tent has a great relevance on the probability of the tent burning. Tents should be made of non-flammable fabrics (class C), being observed that when the fabric was taut, firebrands only caused some holes in the tent not leading to a sustained combustion. However, when firebrands crossed the fabric, falling in the other fuel accessories (for example, sleeping beds), they ignited and the tents were completely burned, even if the fabric material was of class C. Since the common situation is tents with accessories inside, it is extremely important to reflect about the need of the actual existing mandatory rules demanding the use of fabric class C in tents or if other camping materials, namely accessories, should have the same compulsory.
This set of tests also highlighted the fact that on windy days a burning tent may become very dangerous. The holes in the tent created by the fire allow the entrance of air, causing the inflation of the tent that is easily pulled from the ground. In this situation, the tent may be dragged over the CP

causing spot fires or even wounding people. As the material of tents is synthetic, the flaming drops released by this kind of materials may cause deep burns.
Regarding to the characterization of the camping park fuel cover and its surrounding, it is clear the advantage of using imagery acquired by an UAV as opposed to Google Earth images. UAV-based imagery results in a high resolution mosaic from which a more detailed fuel map may be obtained. Moreover, with UAVs it is possible to determine when the images are acquired, and thus have fuel maps for different times of the year, corresponding to different camping park occupancies or vegetation degrees of curing.
An accurate and reliable characterization of input variables is necessary because they strongly affect forest fire simulations. Despite the successfully effort in characterizing some fire spread dependencies, such as the fuel cover well featured during this work, there are some parameters that are not easily defined because their values are not constant neither in time nor in space. The non-deterministic behaviour of such parameters leads to stochastic simulations of fire propagation with methods that consider the input variability in the model used. The results obtained provide, admitting a certain confidence interval, error bars of the ignition time in space, as well as sensitivity analysis studies about the influence of each input parameter variability into the final solution. Moreover, the results obtained were faster than real time fire propagation which is mandatory when model predictions are applied to real-time fires.

Abstract
In order to assess the fire risk in Wildland-Urban Interfaces (WUIs) of SE France according to the environment of the housing, several descriptive parameters (ornamental species, types of vegetation adjoining the environment of the housing, types of fence, structure of the hedges and implementation of the regulation on brush-clearing) assumed to either increase or decrease the fire propagation, thus the fire risk, were surveyed according to the types of WUI (isolated, scattered, dense and very dense clustered), in two different locations (coastal and inland) of the study area (département Bouches du Rhône). The flammability of the most frequent ornamental species was assessed at the levels of live and dead surface fuels.
Results showed that the two areas differed according to the main WUI type, the main ornamental species, the main type of fence, the main type of vegetation adjoining the environment of the housing. There was also a variation of these parameters between the different types of WUI, especially according to the ornamental species. The fire risk, assessed through the parameters surveyed and through the flammability of the main ornamental species, increased from the very dense and dense clustered WUIs to the isolated and scattered WUIs and from the coastal area to the inland area.
The improvement of the knowledge on WUI environment at the small scale will allow an increase in the efficiency of the wildfire prevention targeting the areas most at risk.

***Keywords**: Wildland-Urban Interfaces, wildland fire, fire risk, flammability of ornamental vegetation*

Introduction

In the South of France, urbanization, along with the phenomenon of forest extension is generating new spatial configurations called wildland urban interfaces (WUI). In the context of high urban pressure and the accumulation of wildland biomass, WUIs represent serious issues in terms of fire risk management (Davis 1990; Vélez 1997; Cohen 2000). The WUI is becoming a priority region for fire prevention and suppression (Stephens, 2005) and assessing the risk of forest fire in WUI is essential for wildfire prevention and land management. Indeed, wildfires in these areas are a serious threat to communities in many countries worldwide as they can be extremely destructive, killing people and destroying homes and other structures (Mell *et al*. 2010; Haynes *et al*. 2010), thus having ecological, social, and economic consequences. Research using modelling, experiments, and WUI case studies indicates that home ignitability during wildland fires depends on the characteristics of the home and its immediate surroundings, area called the "home ignition zone" (Cohen 2000). A home's ignition potential during extreme wildfires is determined by the characteristics of its exterior materials and design and their response to burning objects, within one hundred feet (30-40 metres), and firebrands (burning embers). Actual case examinations found that most destroyed homes ignite from smaller flames and directly from firebrands and unconsumed vegetation surrounding most destroyed homes (Cohen 2008). Thus, addressing conditions within the home ignition zone can significantly reduce the home ignition potential.
In the present paper, and according to previous works (Stewart *et al*. 2007; Lampin-Maillet *et al*. 2009, 2011), we use the term WUI to refer to the conjunction of housing as well as vegetation characteristics and human presence can be measured by the density of houses and other infrastructures (Lampin *et al*. 2006a, 2006b; Caballero 2004; Camia *et al*. 2003). A WUI typology has been built regarding the spatial

organization of residential houses (Lampin-Maillet *et al.* 2010) and four types of WUI were identified accordingly: (i) isolated (I), (ii) scattered (S) and clustered dwellings divided into (iii) dense clustered (D) and (iv) very dense clustered (VD). The authors of this work hypothesized that the fire behaviour in WUIs was influenced by the pattern of urban areas within a natural landscape and taking into account three variables of fire risk (ignition density, wildfire density and burned area ratio), they showed that isolated and scattered WUI were the most at risk. Hence, it was interesting to explain these results working at a smaller scale, regarding the environment around the housing. At this scale, a first approach assessing the flammability of some ornamental species in SE France was made by Ganteaume *et al*. (2013a, 2013b).

In the present work, we wanted to assess the fire risk at this small scale, taking into account the area surrounding the housing (Cohen's home ignition zone) which corresponds to the ornamental garden commonly found in WUI of SE France. Within this zone, we recorded several indicators which can enhance (vector of the fire propagation) or mitigate the fire risk such as the main ornamental species whose flammability was assessed in laboratory conditions, the structure of the ornamental hedges, the fence type, the vegetation adjoining the environment of the housing and the implementation of the regulation on brush-clearing. The aims of this work were, first, to describe the environment of the housing in each type of WUI in different locations of the study area, and then to assess the fire risk in these WUIs determining which type was the most at risk according to the environment of the housing.

Methods

Study area

The study area is located in the département Bouches du Rhône (Northwestern coordinates: 43.655°N, 5.495°E; Southeastern coordinates: 43.832°N, 5.672°E; total area: 508 700 ha), one of 15 administrative districts composing Southeastern France (Fig 1) which is among the areas most affected by wildfires (54 fires/year and 1247.3 hectares burned per year in the 2000-2010 period according to the regional forest fire database Prométhée). The main natural fuel types of the study area, located mostly on limestone-derived soils, are *Pinus halepensis* forests (Quézel 2000) and mixed pine-oak (*Quercus ilex* and *Q. pubescens*) forests, often the pre-forest vegetation type before oak forests (Quézel and Barbéro 1992). Shrublands, called "garrigue" on limestone-derived soils, are another dominant fuel that corresponds to the predominant successional stage after woodland degradation (Barbéro *et al*., 1998). Wildfires occur frequently in the whole area and overall, the study area is a mosaic of all the previously mentioned types of vegetation and agricultural areas. Because of the difference in climatic conditions between the coastal fringe and the inland part, the study area was divided into two sub-areas (coastal and inland) for sampling, as the variables recorded in the WUI (especially the ornamental vegetation) may differ depending on their location. Thus, 117 housings were surveyed in four coastal locations and 110 housings in five inland locations.

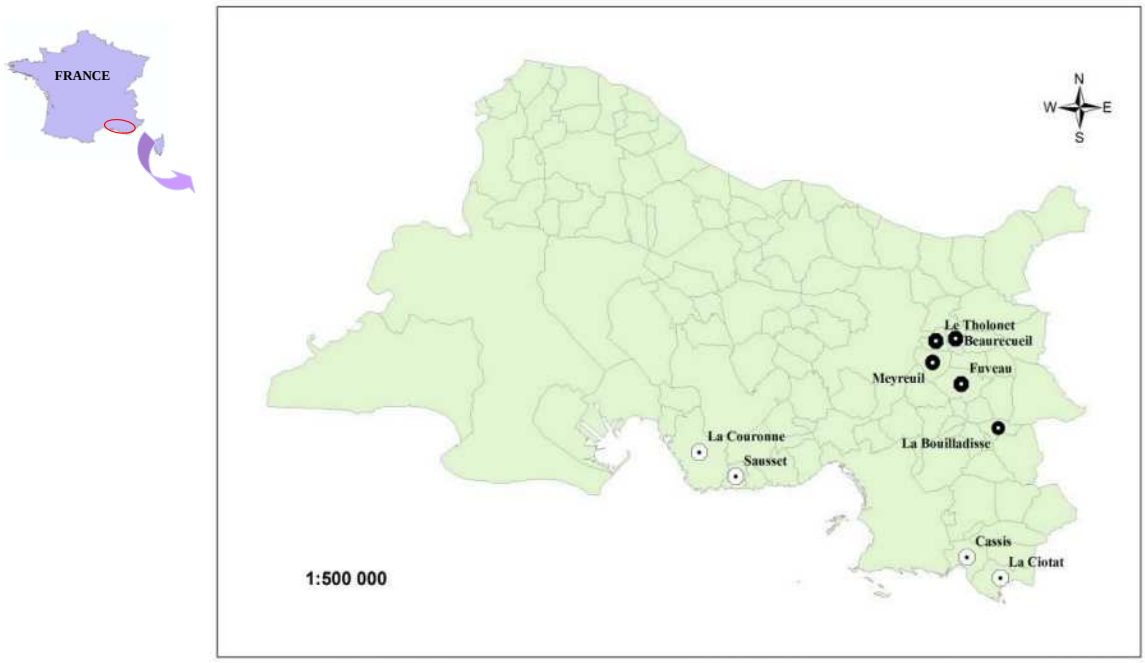

Figure 1. Map of the study area (Département des Bouches du Rhône) in Southeastern France showing where the hedges were surveyed (BD Carto). White spots: coastal area, black spots: inland area

Parameters surveyed for the characterization of the area surrounding the housing

The surveys were also carried out according to the four types of WUI defined by Lampin-Maillet *et al*. (2010): isolated, scattered, dense and very dense clustered. The ornamental species present in each hedge, the structure of the hedge (continuous, discontinuous), the fence type (wall, low wall, low wall and wire, wire, none) surrounding the housing, the vegetation adjoining the ignition zone area (forest, shrubland, crops, another ornamental garden) and if the regulation on brush-clearing was implemented or not, were recorded in each survey. Multiple correspondence analysis (MCA) was carried out in order to highlight the relationships between the parameters recorded in the field and the different types of WUI. This multivariate analysis was performed with R software (R 2.11-1, ADE-4 1.5-1 package).

2.3. Assessing the fire risk according to the flammability of the ornamental species

The flammability of the most frequent ornamental species was assessed during burning experiments of both live and dead fuel samples which were performed at the Irstea Aix-en-Provence facility. Litters (dead fuels), which are the targeted fuel bed in case of spot fires, were burned on a fire bench (experimental conditions described in Ganteaume *et al*. 2013a) and the ignitability, sustainability and combustibility variables were recorded during these experiments. Following the definitions of Anderson (1970), these variables were: (i) the ignition frequency (IF in %) which was computed as the number of successful ignitions relative to the number of trials for a same species; (ii) the time-to-ignition (TTI in s) which corresponded to the time necessary for the appearance of a flame after the firebrand had been placed on the sample; (iii) the flaming duration (FD in s) and (iv) the number of opposite directions of the sample reached by flames (0 to 4) assessing the initial flame propagation.
Live leaves, which are the targeted fuels during the fire propagation from plant to plant, were burned on an epiradiator (experimental conditions described in Ganteaume *et al*. 2013b) and their ignitability and sustainability variables were recorded.
Hierarchical cluster analysis was performed on the flammability variables recorded during the burning experiments of live and dead fuel samples to rank the most frequent species from the least flammable to the most flammable. This analysis was performed with R software (R 2.11-1, ADE-4 1.5-1 package).

2.4. Assessing the variation of the fire risk in the study area

The fire risk was assessed according to the descriptive parameters recorded in the environment of the housing. Multiple correspondence analysis allowed the determination of the types of WUI and the area that were the most at risk and the characterization of the different level of fire risk.

Results and discussion

3.1. Results of the surveys in the study area

Regarding the 227 housings surveyed in the study area, the main types of WUI identified were "very dense clustered" (37%) and "scattered" (31.3%) and a total of 20 ornamental species were recorded. The cypress (all species taken into account) was the most common plant regardless of the WUI type (up to 45% of the ornamental vegetation in the "isolated" WUI type), especially *Cupressus arizonica* (except in the "dense clustered" type). The other most frequent species were *Prunus laurocerasus* and *Thuya plicata* (in scattered WUI), *Eleagnus ebbingei* and *Viburnum tinus* (in dense clustered WUI) as well as *Nerium oleander* and *Pittosporum tobira* (in very dense clustered WUI). The distribution of the ornamental species varied according to the WUI types (Figure 2). Species characterizing the "dense" and "very dense" clustered types clearly differed and differed also from those characterizing the "isolated" and "scattered" types; these two last types did not form two separated clusters of species.

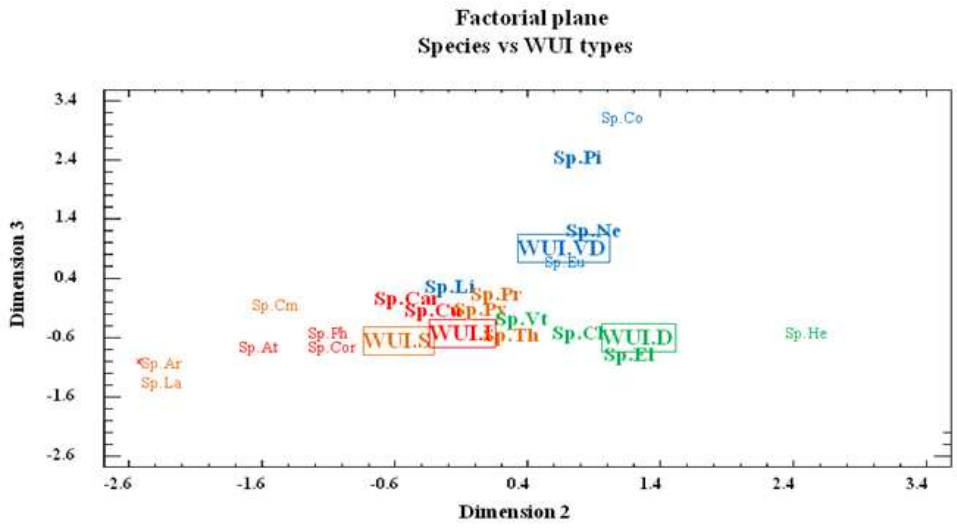

Figure 2. Factorial plane of the MCA showing the characterization of the different WUI types (I: isolated, S: scattered, D: dense clustered, VD: very dense clustered) by the ornamental species (in bold: most frequent species; Ar: Arundo donax, La: Laurus nobilis, At: Atriplex maritimus, Cor: Coronilla sp., Ph: Phyllostachys sp., Cu: Cupressus sempervirens, Cm: Cupressus macrocarpa, Car: Cupressus arizonica, Li: Ligustrum japonicum, Pr: Prunus laurocerasus, Py: Pyracantha coccinea, Vt: Viburnum tinus, Cl: Cupressus leylandii, Th: Thuja occidentalis, El: Eleagnus ebbingei, Eu: Euonymus japonicus, Ne: Nerium oleander, Pi: Pittosporum tobira, Co: Cotoneaster sp., He: Hedera helix).

Among the descriptive parameters recorded in the environment of the housing, we found that the hedges composed of ornamental vegetation were mostly continuous (87%) and the main types of fence were "low wall + wire" (39%, mostly in dense and very dense WUI types) and "wire" (35%, mostly in scattered and isolated WUI types). On the contrary, the "wall" was the less frequent type of fence (16%). The main vegetation types adjoining the buffer around the housing were another ornamental garden (43% especially in dense and very dense WUI types) and forest (31%, especially in scattered

and isolated WUI types). In total, 49% of the houses surveyed were directly adjoining wildland vegetation and the mandatory brush-clearing was implemented at 96%.

3.2. Results of the spatial variation within the study area

The very dense clustered WUI was the most frequent type in the coastal area (47%) whereas the scattered WUI was the most frequent type in the inland area (36%).
The main ornamental species also differed spatially. *Prunus laurocerasus* and *Pyracantha* (in mostly in scattered and very dense types), *Eleagnus ebbingei* and *Cupressus leylandi* (mostly in dense type) as well as *C. sempervirens* and *C. arizonica* (mostly in isolated type) were the most frequent species in the inland area whereas *Nerium oleander* (mostly in scattered, dense and very dense types), *Pittosporum tobira* (mostlin very dense and isolated types), *Thuya plicata* (mostly in dense type) and the cypress (all species regardless of the WUI type) were the most frequent in the coastal area.
There was no spatial difference in the type of hedge (mostly continuous) and the main types of fence were "low wall + wire" in the coastal area (49%) and "wire" in the inland area (53%).
The main vegetation types adjoining the environment of the housing were another ornamental garden (58% especially in dense and very dense types) in the coastal area and forest (42%, especially in scattered and dense types) inland. In total, 30% of the houses surveyed were directly adjoining wildland vegetation in the coastal area against 70% in the inland area and the mandatory brush-clearing was implemented at more than 90% in both areas.

3.3. Flammability experiments

Among the 20 species recorded during the surveys, which were hypothesized to be representative of the species planted in the whole study area, eight species were chosen for the study of their flammability, either because of their frequency in the study area, e.g. *Prunus laurocerasus* (Pr), *Pyracantha coccinea* (Py), *Cupressus sempervirens* (Cu) assumed to have the same flammability characteristics as the other species of *Cupressus* and as *Thuya plicata* (because of the same foliar structure), *Nerium oleander* (Ne), *Eleagnus ebbingei* (El), *Ligustrum japonicum* (Li) and *Pittosporum tobira* (Pi), or because of their uniqueness, e.g. *Phyllostachys sp.* (Ph), the only monocotyledon recorded, which may have particular flammability characteristics.
Results of the flammability experiments are presented in table 1. At the litter level, *Cupressus sempervirens* and *Pyracantha coccinea* litters ignited very frequently (IF $\geq$ 90%) in contrast of *Pittosporum tobira* litters (20%). Litters sampled in the hedges of *Ligustrum japonicum* and *Nerium oleander* were the quickest to ignite (47 and 49 s) in contrast of these of *Prunus laurocerasus* and *Pyracantha coccinea* (153 s and 188 s). The longest flaming duration were recorded in *Eleagnus ebbingei*, *Cupressus sempervirens* and *Pyracantha coccinea* litters (between145 and 148 s) and the shortest in *Pittosporum tobira* litter (55 s). Initial flame propagation was the best in *Ligustrum japonicum* litter (on average 3.7 sides of the sample were reached by the flames) in contrast of *Cupressus sempervirens* litter (on average, 2.4 sides of the sample were reached by the flames). At the live leaf level, *Cupressus sempervirens*, *Eleagnus ebbingei*, *Phyllostachys sp.* and *Pyracantha coccinea* litters ignited very frequently (IF $\geq$ 90%) in contrast of *Ligustrum japonicum* and *Pittosporum tobira* litters (42 and 46%). Litters sampled in the hedges of *Phyllostachys sp.* were the quickest to ignite (11 s) in contrast of these of *Cupressus sempervirens* and *Pittosporum tobira* (36 s and 30 s). *Eleagnus ebbingei* litters burned the longest (12 s) in contrast of these of *Prunus laurocerasus* (5 s).

Table 1. Flammability variables of the litter and live leaf recorded on each species studied (mean and standard deviation; IF: ignition frequency, TTI: time-to-ignition, FD: flaming duration, Ph: Phyllostachys sp., Cu: Cupressus sempervirens, Ne: Nerium oleander, Li: Ligustrum japonicum, El: Eleagnus ebbingei, Pi: Pittosporum tobira, Pr: Prunus laurocerasus and Py: Pyracantha coccinea)

The combination of the flammability variables recorded on live fuel and dead fuel (litter) using hierarchical cluster analysis highlighted three groups of species with different flammability (Figure 3): the most flammable species (*Phyllostachys sp. , Eleagnus ebbingei , Ligustrum japonicum* and *Nerium oleander*), the least flammable species (*Pittosporum tobira*) and the group of species having intermediate flammability (*Cupressus sempervirens, Prunus laurocerasus* and *Pyracantha coccinea*). According to the type of fuel (live or dead), some species showed the same type of flammability like *Pittosporum* (always poorly flammable), *Cupressus* and *Pyracantha* (always moderately flammable) or *Eleagnus* (always highly/extremely flammable) in contrast of other species (*Phyllostachys sp., Prunus laurocerasus , Ligustrum japonicum* and *Nerium oleander)* which were less flammable at the live leaf than at the litter level.

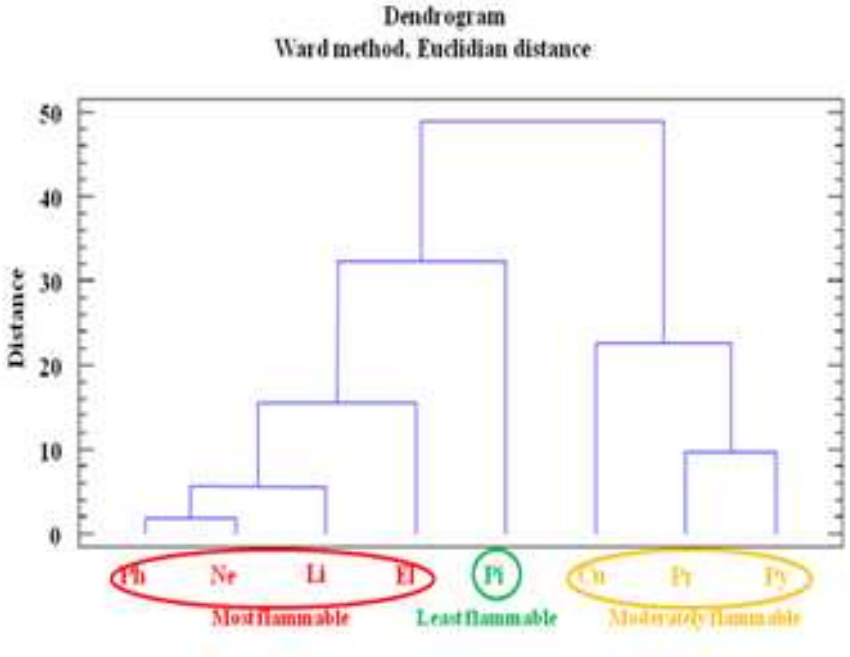

Figure 3 : Dendrogram of hierarchical cluster analysis based on the flammability variables recorded on live leaves (time-to-ignition, flaming duration, ignition frequency) and litters (time-to-ignition, flaming duration, ignition frequency, initial propagation) sampled in the different species studied (Ph: Phyllostachys sp., Cu: Cupressus sempervirens, Ne: Nerium oleander, Li: Ligustrum japonicum, El: Eleagnus ebbingei, Pi: Pittosporum tobira, Pr: Prunus laurocerasus and Py: Pyracantha coccinea)

3.4. Assessment of the fire risk

The fire risk was assessed taking into account the flammability of the main ornamental species, the type of vegetation adjoining environment of the housing, the type of fence, the structure of the hedges and the implementation of the regulation on brush-clearing.

Among these descriptive parameters, some can mitigate the fire propagation toward the housing, thus mitigate the fire risk, such as crops and another garden as vegetation types adjoining the environment of the housing, discontinuous hedges or high wall surrounding the housing. Poorly flammable species (like *Pittosporum*) as well as the implementation of the regulation on brush-clearing around the housing also contribute to mitigate the fire risk. On the contrary, other parameters can enhance the fire risk, such as shrubland and forest adjoining the environment of the housing, the absence of fence or fence made of wire that cannot mitigate the radiant heat or the firebrands emitted by the flaming vegetation. Continuous hedges, particularly composed of very flammable species as well as the non-implementation of the regulation on brush-clearing can also enhance fire propagation toward the housing.

The multivariate analysis showed that the fire risk increases from the dense and very dense clustered WUIs to the isolated and scattered WUIs on axis 1 with a gradient of fire risk from low fire risk (other garden, high wall, discontinuous hedges) to high fire risk (shrublands which means a vegetation burned at least one time, no fence or wire-made, continuous hedges). The presence of, at least, seven species characterized by intermediate or high flammability and no poorly flammable species in the isolated and scattered WUI types also indicates higher fire risk in these areas whereas the presence of at least one poorly flammable species and five species characterized by intermediate or high flammability in the dense and very dense clustered WUI types contribute to decrease the fire risk. The same trend as on axis 1 was also highlighted from the coastal area to the inland area on axis 2. Implementation of the regulation on brush-clearing was not a significant parameter in the analysis (Figure 4).

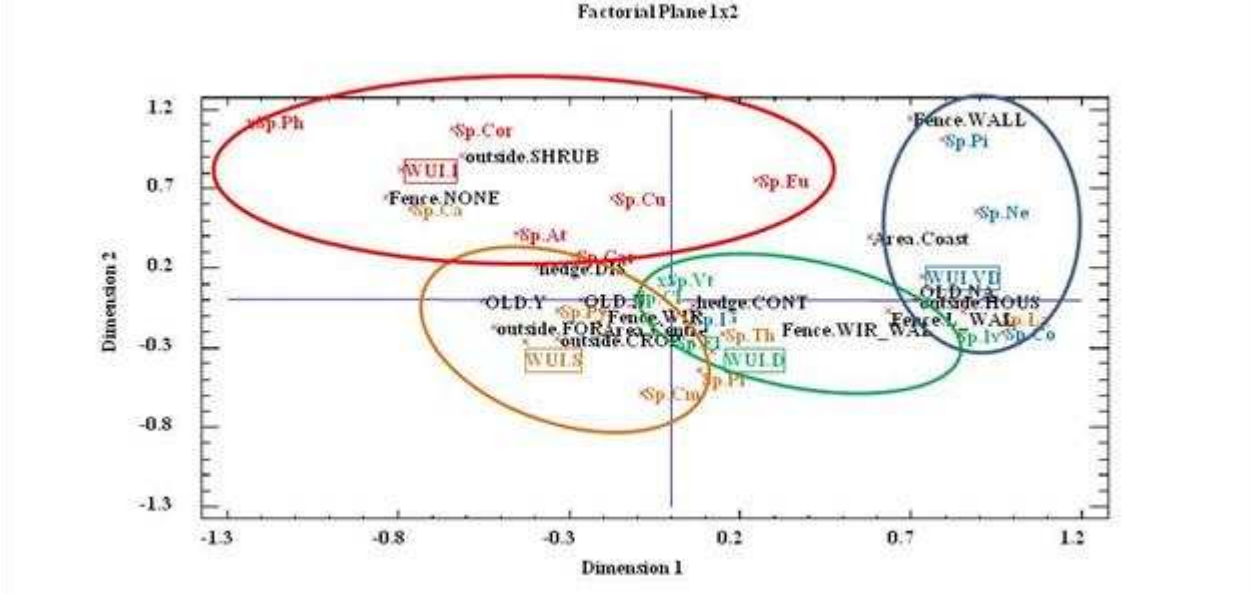

Figure 4. Factorial plane of the MCA showing the variation of the fire risk (red: high, orange: medium, green: low, blue: very low) between the different WUI types (I: isolated, S: scattered, D: dense clustered, VD: very dense clustered) and the location in the study area (coastal vs inland) according to the parameters recorded in the area surrounding the housing. (Sp: Ar: Arundo donax, La: Laurus nobilis, At: Atriplex maritimus, Cor: Coronilla sp., Ph: Phyllostachys sp., Cu: Cupressus sempervirens, Cm: Cupressus macrocarpa, Car: Cupressus arizonica, Li: Ligustrum japonicum, Pr: Prunus laurocerasus, Py: Pyracantha coccinea, Vt: Viburnum tinus, Cl: Cupressus leylandii, Th: Thuja occidentalis, El: Eleagnus ebbingei, Eu: Euonymus japonicus, Ne: Nerium oleander, Pi: Pittosporum tobira, Co: Cotoneaster sp., He: Hedera helix;Outside: HOUS: house, FOR: forest, SHRUB: shrubland; Type of fence: WAL: high wall, L_WAL: low wall, WIR_WAL: wall and wire, WIR: wire; type of hedge: CONT: continuous, DIS: discontinuous; implementation of mandatory brush-clearing: OLD_Y: yes, OLD_N: No, OLD_NA: no data)

Conclusion

The improvement of the knowledge on WUI environment at small scale will allow an increasing efficiency of the wildfire prevention targeting the areas most at risk. Assuming that the parameters recorded in the environment of the housing correspond to important aspects of fire risk, we showed that isolated and scattered WUI, especially in the inland area, are in fact at high risk of wildfire. This result agrees with the work of Lampin-Maillet *et al*. (2010) who also highlighted a higher fire risk in isolated and scattered WUI types than in the clustered types taking into account different fire metrics.

Abstract
Areas where urban and wildland intermingle, known as wildland-urban interface (WUI), are increasing worldwide over the last decades (Theobald and Romme 2007; Montiel and Herrero 2010). These WUI areas are of particular concern in forest fire risk management because the presence of housing developments in contact with forestlands increases the likelihood of a fire starting as a consequence of human activities. In Spain, for example, there is increasing evidence that the wildland-urban interface constitutes a highly risk prone area (Herrero *et al*. 2012; Chas-Amil *et al*. 2013). Given the recognised role of land cover distribution in fire risk (Bajocco and Ricotta 2008; Oliveira *et al*. 2013), this paper evaluates recent fire activity across different land cover categories, and the causes and motivations, comparing WUI and non-WUI areas. Fire data were collected in Galicia, Spain, where fires are mostly due to deliberately-caused ignitions. We show that arsonist are more likely to ignited a fire in WUI areas than in non-WUI; and the same seems to be true for fires ignited by agricultural activities. Moreover, land cover types only have a significant impact on the patterns of fire occurrence in WUI areas.

Keywords*: fire hazard, land-use cover, wildland-urban interface, intentional-caused fires, Galicia, Spain.*

Introduction

Fire is a natural process in many ecosystems, with an important role in shaping species adaptations and landscapes (Bond and Keeley 2005). However, human activities have altered fire regimes in areas such as southern Europe, increasing fire frequency, especially of large fires (Moreno *et al*.1998). In Spain, for instance, more than 90% of wildfires are caused by human activities, according to official statistics (MAGRAMA, 2010). Therefore, areas where wildland and human developments intermingles, known as wildland-urban interface (WUI), are especially vulnerable to the risk of fire ignitions (Chas-Amil *et al* 2013; Lampin-Maillet et. al. 2010; Syphard *et al*. 2007). In addition, the presence of population living close to forestlands increases the likelihood of severe consequences in properties and land-use activities and may also pose serious threats to lives.
The fire risk (or ignition risk) is the chance of a fire starting as determined by the incidence of causative agents (FAO 1986; NWCG 2006). A good understanding of the patterns and causes of fire ignition is essential for effective fire prevention (Finney 2005). Land use and land cover (LULC) have been recognized as a major determining factor of fire risk (Bajocco and Ricotta 2008; Moreira *et al*. 2009; Carmo *et al*. 2011; Xystrakis and Koutsias, 2013) and, in contrast with other factors such as weather and topography, it can be subject to active policy management, which makes the analysis of fire risks associated with LULC types especially interesting for fire prevention policies. In addition, it can provide useful information for local residents, as these are often not aware of the fire risk associated with their behaviour. The type of LULC determines fuel load and characteristics (e.g. flammability and moisture content; Saura-Mas *et al*. 2010; Ganteaume *et al*. 2009) and is associated with human activities with contrasting levels of fire risk (e.g. use of fire as a management tool for agricultural waste disposal in farmlands or for pasture renewal in rangelands; Vélez 2002; Ganteaume *et al*. 2013).

Moreover, socio-economic factors may lead to land-use conflicts that can trigger intentionally-caused fires (e.g. urbanization pressure or unemployment; Prestemon *et al*. 2012; Romero-Calcerrada *et al*. 2010).
In this paper, we analyse the level of fire risk at different land covers and the causes and motivations of fires, comparing WUI and non-WUI areas. We analyze whether different land cover types are equally fire-prone, i.e. fires occur in direct proportion to the availability of those land cover types in the landscape, or otherwise some land cover types burn more or less frequently than expected given their abundance. We contribute to the previous literature on fire ignition selectivity towards different land cover types by comparing WUI and non-WUI areas, in order to determine whether the contrasting socio-economic contexts in these types of areas have a significant impact on the patterns of fire occurrence and its causes.

Materials and methods

Study area

The study was carried out in Galicia (NW of Iberian Peninsula). Its ancient mountains, with an average altitude of 508 meters, characterize the territory. Climate is rather humid and because of Galicia's meridional latitude, it can be quite warm in some areas. Galicia is the most important forestry region in Spain (Manuel and Gil 2002), with c. 70% of the land being forested. More than half of the forested area is covered by tree plantations of *Pinus pinaster* and *Eucalyptus globulus*, in pure and mixed stands. Depopulation and farming abandonment has led to an increase of forested land, as in many other rural areas in Europe, particularly the expansion of eucalypt plantations, resulting in important changes in the regional landscape, mainly in rural lowland areas (Marey-Pérez *et al*., 2006; Cramer and Hobbs, 2007). Native forests dominated by *Quercus robur*, which occupied large areas in the past, have now been reduced to small, isolated patches (Ramil-Rego *et al*., 1998; Teixido *et al*., 2010). Based on Chas-Amil *et al*. (2013), the interface between urban and forested areas (WUI) totals 2,442 km^2 in Galicia, which represents 8.3% of the region, with many WUI areas located along the Atlantic coast and in the southwest of Galicia. A significant proportion (79%) of the WUI areas are classified as non-forested areas, while the forested land in WUI is mainly characterized by a high level of fragmentation. On the other hand, forestlands dominate non-WUI areas, covering nearly three-quarters of these areas. Compact forestlands with little fragmentation cover more than half of the territory outside the interface (56%), while highly fragmented forestland covers 14%.
With an annual average of more than 4,000 forest fires and 30,000 ha burned between 2006 and 2009, Galicia is the region of Spain with the highest frequency of fires; more than 30% of forest fires in Spain each year are located in this region, even though it represents only 6% of the Spanish territory. In addition, most fires are human-caused (99%), mainly associated with intentional behaviour (80%) (Chas-Amil *et al*. 2010).

Fire and land cover data and analyses

We defined wildland-urban interface (WUI) as the intersection of the forest area and/or forest influence areas (up to 400 m from forestland) with the buffer of 50 m around buildings, where bush clearing is compulsory by law (Law 3/2007 of April 9, 2007, addressing the issues of wildfire prevention and suppression, as modified by Law 7/2012 of June 28, 2012). The identification and mapping of WUI en Galicia was obtained from Chas-Amil *et al*. (2013).
A database of the daily forest fire ignition points for the period from January 1, 2006 to December 31, 2011 was employed for this study. These fire ignition data were obtained from the Rural Affairs Department of the Regional Government (Xunta de Galicia), and the Spanish Ministry of Agriculture, Food and Environment (MAGRAMA). Forest fire reports list general information on burned areas, date and estimated time of ignition, the geographic coordinates of the ignition point, causes and motivations, and the fire-fighting measures applied. A fire is included in the official database only if

it fully or partially affects forest and other woodland areas. The coordinates of the ignition points for all fires in the database were evaluated and corrected if errors were detected. We refined the coordinates by using maps of administrative boundaries (parishes, municipalities, population entities) at a scale of 1:25000, a raster topographic map 1:25000, and Landsat TM images. All computations were performed with ArcGIS® 9.3.1 by ESRI and Geomedia Professional 6.0 by Intergraph.
We then combined the WUI layer and the geographic coordinates of the ignition points to randomly select a total of 600 wildfires (100 per year), 300 in WUI areas and 300 in non-WUI areas, together with all their characteristics included in the wildfire database. Fire causes were grouped in 4 classes: deliberate, negligence, unknown, others (natural causes and accidents that are not considered negligence). For deliberated fires, the motivation behind the fires is also included in fire reports, and was grouped in the following categories: farmers (fires caused by farmers for clearing shrubland areas), rangers (burning of shrublands for pasture renewal), arsonists, vandals, chasing wildlife away (e.g. wolfs or wild boars), others or unknown motivations. Note that causes are, in most cases, presumed by the technical staff in the field, and only in c. 10% are confirmed caused.
The land cover type of all these locations was identified, using information from the Fourth National Forest Inventory (IFN4), which was developed in Galicia in 2008-2009. The IFN4 has been based on the cartography of the Forest Map of Spain at 1:25.000 (MFE25) carried out on aerial orthophotos of the PNOA of the National Geographic Institute that are divided in homogeneous polygons of 0.5 to 2 ha in size (depending on the cover type) and are classified according to a hierarchic classification with a total of 63. We re-grouped these categories according to our research interest into the following categories: broadleaved forests (broadleaved natural forest, as differing from tree plantations, dominated by native broadleaved trees, mostly *Quercus robur* and *Quercus pyrenaica*; plantations of broadleaved trees such as *Castanea sativa* or *Betula pendula* has been included also in this category), tree plantations (pure or mixed stands dominated by *Eucalyptus globulus*, *Pinus pinaster*, *Pinus radiata* and *Pinus sylvestris*), shrublands (dominated by shrubs, with no tree cover), farmland (used for crops and pastures for livestock), and artificial (areas devoted to urban or industrial developments and infrastructures).
In order to determine fire selectivity for different land cover, the frequency of different land covers between ignition points and a random null model, was investigated using Maximum Likelihood Ratio tests (G test, Sokal and Rohlf 1995). For this, we selected a total of 200 random points (100 in WUI and 100 in non-WUI areas) and determined their cover type. Significant differences indicate that fires would not occur randomly in the landscape, with different proportion of ignition points and available land-cover types. We also estimated the selection ratio (w_i) for a given cover class, an index estimated as $w_i = U_i/A_i$, where U_i is the proportion of the ignition points belonging to cover class i and A_i is the proportion of available area belonging to that cover class i (Manly *et al*. 1993). A cover type with a percentage of ignition points proportionate to its availability has a value $w_i = 1$, a class with a percentage of ignition points exceeding that expected by chance (i.e. selected positively by fire, thus more fire-prone than expected by random) had a value $w_i > 1$, whereas a cover type with a less than expected proportion ignition points (i.e. avoided by a fire, less fire-prone than expected by random), has a value $w_i < 1$ (e.g. Moreira *et al*. 2001; Nunes *et al*. 2005).

3. Results

3.1. Wildfire causes

Most wildfires in Galicia were considered deliberate for the period 2006-2011. Differences between WUI and non-WUI in regard to causes of wildfires were marginally significant ($G=13.5$, 3 d.f., $p<0.05$), with a higher number of fires due to negligence in WUI areas (1.9 times more than in non-WUI areas) (Figure 1).

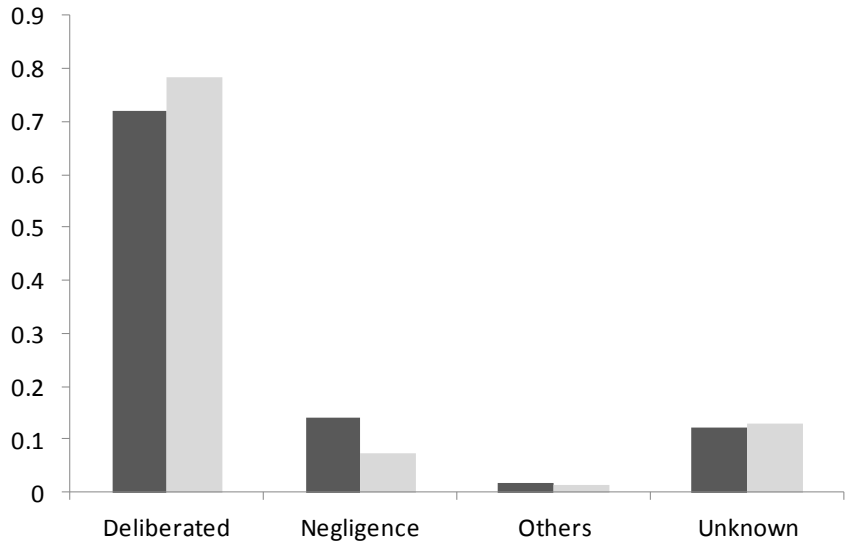

Figure 1. Relative frequencies of wildfire causes in WUI (dark gray) and non-WUI areas (light gray).

Motivations behind deliberate fires differed markedly between WUI and non-WUI areas (G=58.0, 5 d.f., $p < 0.05$), especially in regard to fires caused to chase wildlife away, which were more than 15 times more frequent in non-WUI than in WUI areas (Figure 2). Fires caused by ranchers were also somewhat more frequent in non-WUI than in WUI areas (1.6 and 1.3 times more), whereas those caused by arsonist and farmers showed the opposite pattern (1.6 and 1.2 times more frequent in WUI than in non-WUI areas).

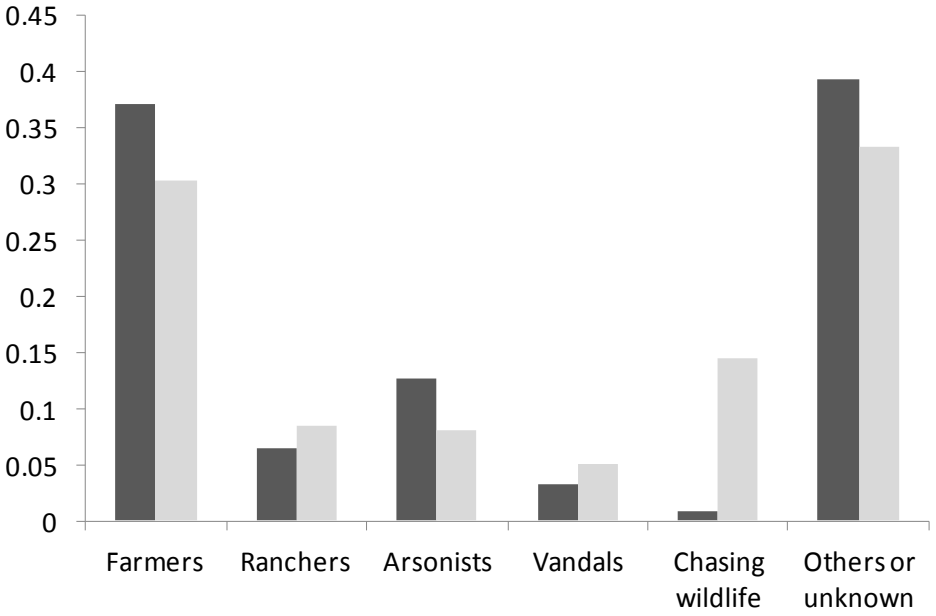

Figure 2. Relative frequencies of motivations behind deliberated wildfire in WUI (dark gray) and non-WUI areas (light gray).

In non-WUI areas, causes of wildfires had similar frequencies among land cover types. However, in WUI areas, the frequency of fire causes in farmlands and plantations differed from the general pattern (pooling together all cover types). In farmlands, deliberated fires and those caused by negligence were the most frequent (87%), but fires caused by negligence were 1.8 times more frequent than expected

by the general pattern, whereas deliberated fires were 13% less frequent than expected. In plantations, deliberated fires were the most frequent (72%), similarly as for all cover types pooled, whereas fires caused by negligence were 25% less frequent than expected.

3.2. Patterns of cover types and wildfire distribution

The coverage of land uses differed between WUI and non-WUI areas, with more land devoted to farms in WUI than in non-WUI (77% vs. 22%) and less to shrublands (3% vs. 26%), plantations (13% vs. 37%), and broadleaves forests (7% vs. 10%).

Table 1. Estimated selection ratio index in WUI and non-WUI in the study area.

Land cover types	Area (%) with respect to total	Ignition points (%) of those randomly selected	w_i
WUI			
Artificial	6	12.8	2.14
Farmland	70	51.0	0.73
Shrublands	3	3.7	1.24
Tree plantations	13	25.3	1.95
Broadleaved forests	7	5.4	0.77
Others	1	1.7	1.7
			G = 21.63*
Non-WUI			
Artificial	5	1.3	0.27
Farmland	22	27.4	1.25
Shrublands	26	29.1	1.12
Tree plantations	37	29.1	0.79
Broadleaved forests	10	12.0	1.20
Others	0	1.0	-
			$G = 5.60^{ns}$

* Significance at 5%.

The proportion of fire ignitions in land cover types differs between WUI and non-WUI areas (G = 108.2, 5 d.f., $p<0.001$), with more frequent fires at shrublands and broadleaved forests in non-WUI areas compared to WUI areas (with fires being 7.8, 2.2 times more frequent in non-WUI than in WUI areas, respectively). However, ignitions are less frequent in artificial areas and farmlands in non-WUI compared with WUI areas (with fires being 9.8 and 1.9 times more frequent in WUI than non-WUI areas). The proportion of fires ignited at tree plantations is similar in WUI and non-WUI areas (25.3% vs. 29.1% respectively).

In WUI areas, the location of wildfire starting points in relation to land cover types differ from that expected by random (Table 1), with artificial areas and tree plantations being positively selected (2.14 and 1.95 more wildfires than expected according to a random distribution), as well as shrublands, in a lesser degree (1.24 times more fires than expected). On the other hand, farmlands and broadleaved forests had fewer fires than expected by random (27% and 23% less wildfires than expected by random; Table 1). In non-WUI areas, the distribution of wildfires did not differ significantly from a random distribution among land cover types (Table 1).

Discussion and conclusions

The great majority of fires are linked to deliberate-caused fires, both in WUI and non-WUI areas, as expected. Looking at the apparent motivations behind deliberated fires, most of them seem to be caused by activities that use fire as a managing tool. Those caused by arsonists or vandals are however less frequent. Farmers and rangers seem to cause most deliberated fires, farmers using fire mostly for clearing and rangers for pasture renewal. In addition, fires related to chasing animals away to avoid damage to crops and livestock may be also cause by farmers or rangers. It is interesting to note the different incidence of negligence and deliberate fires between WUI and non-WUI areas. Outside WUI areas, where the danger of fires due to negligence related to human-activities is lower, there was a higher incidence of deliberate fires, an especially of those related to extensive farming practices. Thus, fires caused to chase animals away or for pastures renewal for livestock were more frequent here than in WUI areas. The higher incidence of negligence in WUI areas might be related to a higher intensity of human activities, for instance related to crop cultivation. Interestingly, in farmlands in WUI areas the incidence of negligence was much higher than in other cover types, this negligence being mostly related to agricultural waste disposal.

Selectivity patterns of fire for particular cover classes were only apparent in WUI areas. Here, the high fire-proneness of artificial areas might be related to a higher human activity concentrated in these areas, which favors human-related fires, either deliberated or due to negligence or accidents. Regarding plantations, the other cover class positively selected by fire, their higher fire-proneness contrasts with the negative selection showed for broadleaved forests (see also Moreira *et al*. 2009, Moreno *et al*. 2011). This might be related to a higher flammability of plantations, which increases the chances for a fire to actually start after a deliberate attempt or a negligent conduct. *Eucalyptus globulus* and *Pinus pinaster* litter is highly flammable (Ganteaume *et al*. 2009), and they can grow more biomass of understory vegetation, which also is dominated by highly flammable species such as Ulex spp. and grasses (Ganteaume *et al*. 2009, Calviño-Cancela *et al*. 2012). This is especially true in the case of *Eucalyptus globulus* plantations with very low-management, which are very common in Galicia due to rural depopulation and land abandonment (Marey-Pérez *et al*., 2006, Robak, 2008; Díaz-Balteiro *et al*., 2009). Broadleaved forests, on the contrary, are more humid and less biomass in the understory (although with higher diversity; Calviño-Cancela *et al*. 2012). The expansion of plantations in many parts of Galicia, especially those of *Eucalyptus globulus* (MAGRAMA 2011), at the expense of broadleaved forests (Marey-Pérez *et al*., 2006) may have contributed to increased fire hazard in this region.

Acknowledgments

This research was funded in part by Ministerio de Economía y Competitividad (Project ECO2012-39098-C06-05). The Spanish Ministry of Agriculture, Food and Environment (MAGRAMA), and the Rural Affairs Department (Xunta de Galicia) provided the wildfire database.

Abstract
Efficient dispatching of firefighting forces to a forest fire and effective management of those requires good knowledge of their capabilities and limitations. The study presented here tries to develop knowledge and equations for evaluating the performance and limitations of the ground forces attacking fires in Greece taking into consideration the firefighting methods used in the country. It is based on a questionnaire with photos of fires that was answered by 67 individuals with varying firefighting experience and involvement in firefighting. Among the results reported here are equations for selecting "direct attack on all points" of a fire as a function of flame length and of rate of spread and equations for estimating the probability that a fire will be considered as being beyond the capacity of any of a series of suggested firefighting resources combinations. Also, equations were developed for estimating the length of fire front and of fire flank that can be extinguished by a light fire truck with a water capacity of 600 liters and a fire truck with a capacity of 2500 liters, as a function of flame length. The results of the study provide useful input for understanding and modelling forest fire suppression in Greece and can probably be useful for other Mediterranean countries as well.

Keywords*: Forest fire fighting, fire suppression effectiveness, fire truck, fire extinction rate, direct attack*

Introduction

Efficient dispatching of firefighting forces to a forest fire and effective management of those forces in the field of operations requires good knowledge of their capabilities and limitations. Numerous studies in international fire literature have been devoted to assessment of the effectiveness of ground and aerial resources and to modelling of firefighting operations. However, such knowledge and models are not universal as performance is affected by various local factors such as firefighting methods, tools and equipment, firefighter training, professionalism and motivation, weather conditions, vegetation characteristics, topography, road network density, etc. (Hirsch and Martell 1996). Consequently, although published work on the subject is certainly valuable, some local knowledge of firefighting effectiveness is definitely required. In Greece, so far, there have been no published studies on firefighting effectiveness. When such knowledge was required for the development of a decision support system for dispatching of ground and aerial resources the required information was obtained from interviews with a small number of experienced foresters (Xanthopoulos 1994). Since then, a lot has changed in the way firefighting is carried out in the country. For example, firefighting responsibility has been transferred from the Forest Service to the Fire Brigades in 1998, the number of volunteer firefighters increased sharply, firefighting techniques and priorities as well as training changed, and the types of resources improved. On the other hand, the lack of formal knowledge on the effectiveness of the firefighting forces did not change.
The study presented here is an effort to fill this knowledge gap. It focuses specifically on the performance and limitations of the ground forces attacking a fire and takes into consideration the firefighting methods used in Greece. Its findings are certainly of value for Greece but they may be relevant in other Mediterranean countries as well.

Methods

Aiming to develop a first overall picture of the effectiveness of the ground forces, it was decided to employ specifically designed questionnaires for collecting the necessary data. The choice of the method took into consideration difficulties encountered in other studies for collecting valid productivity information using traditional data collection methods that has sometimes led to discrepancies and made, for example, Fried and Gilles (1989) to embark on a major expert opinion study on fireline construction rates.

The four options in regard to attack method:
1. Direct attack at all points (front, flanks, heel)
2. Indirect attack at the front, direct at the flanks
3. Indirect attack along all the perimeter (from firebreaks, roads, natural vegetation breaks, etc.)
4. Attack impossible until conditions change

Figure 1. Two of the twelve photos of the first question of the questionnaire and the four options in regard to the method of attack for the type of fire shown in each photo.

2.1. The questionnaire

The questionnaire consisted of two parts. The first part aimed at collecting information about the respondent including age, sex, employment, education level, general training, training about forest fires, years of involvement in fire management, years and way of participating in firefighting operations. Providing the name and contact data of the respondent was optional.

The second part of the questionnaire consisted of three main questions, each presenting a number of cases illustrated by photos. The first question presented 12 photos of fires and provided an estimated flame length and rate of spread (ROS) for each of those fires. These flame length estimates ranged between 0.2 and 50 m, while ROS ranged between 80 and 2500 m/h. The respondent was asked to choose from four options about the type of attack appropriate for the depicted part of the fire (including a "no-attack possible" option), nine options in regard to the required type of resources, and ten options in regard to combinations of resources that would be required at a minimum to control a 100 m wide fire front of the portrayed type of fire from a 6 m wide road (Figure 1).

The second question presented 9 photos of fires with an estimate of the depicted flame length. Assuming scenarios of fighting such flames at the front or at the flanks (2 cases) by a) One driver and two firefighters with a light fire truck having a 600 liter tank and using 25mm diameter hoses, or by b) the same people with a heavier fire truck (2500 liter tank) using 45 mm diameter hoses, the respondent was asked to provide estimates (in meters) of the length of the perimeter (front or flank) that can be extinguished using the water in the tank of the truck. An option was provided to mark X if direct attack on the flames with the particular resource was considered as impossible. Flame length estimates for the fire fronts ranged between 0.5 and 60 m and for the flanks between 0.3 and 30 m.
The third question presented 6 photos of typical vegetation in Greece. The respondent was asked to provide an estimate of the length of a 2 m wide fireline that an 8 person crew could build within an hour for combinations of slope (flat, medium) and time of day (early morning, midday, night).

Analysis and Results

Sixty seven (67) people of varying experience and involvement in firefighting responded to the questionnaire. Forty nine (49) of them work for the Greek Fire Service either as permanent personnel or as volunteers, while fifteen (15) of them belong to the unpaid volunteer groups of the General Secretariat for Civil Protection. Sixteen (16) of the 67 respondents stated that they have high or very high experience in firefighting while 30 more replied that they have average (medium) experience. The data formed a database that was analyzed with the R and SPSS statistical software. Selected results are reported below.
The responses to the first question were examined first in regard to frequencies of selection of certain options (e.g. selection of initial attack). This allowed to investigate trends in the responses versus fire characteristics and to identify certain thresholds. A focal point of the analysis was the assessment made by the respondents about the limits of direct attack. This was done through development of models for the probability of selecting direct attack on the flames on all parts of a fire ($PROB_{direct}$) as a function of flame length (FLAME in m) and of rate of spread (ROS in m/h).
The replies selecting direct attack for the fire depicted in each of the twelve (12) photos of the first question, allowed an estimate of probability of such selection for each flame length. The same was done for ROS. For example, for the upper photo of figure 1, with flame length of 1 m, 88% of the respondents selected the first of the four options "Direct attack at all points (front, flanks, heel)"; no-one selected the fourth option "Attack impossible until conditions change". For the lower photo with flame length of 18 m, only 7% of the respondents selected direct attack; the majority (45%) chose the third option "Indirect attack along all the perimeter" while 21% of the respondents considered this fire as impossible to attack (fourth option).
The probability of selecting "direct attack on all points" of a fire ($PROB_{direct}$) as a function of flame length and of rate of spread was analyzed using the data set of twelve records (N=12), i.e. one record for each of the photos of the first question. Two regression equations were developed with $PROB_{direct}$ as the dependent variable and the natural logarithm of FLAME and ROS. The equations are as follows:

a) $PROB_{direct} = 64.609 - 19.051 * \ln(FLAME)$ with Adj. $R^2 = 0.857$ (1)

b) $PROB_{direct} = 210.999 - 28.389 * \ln(ROS)$ with Adj. $R^2 = 0.814$ (2)

Both equations are statistically significant ($p<0,005$). Plotting of the first equation revealed that the probability of direct attack all around the fire perimeter drops to 40% when the flame length is 3.5 m (Figure 2). Plotting of the second equation showed that $PROB_{direct}$ approaches zero when ROS exceeds 1600 m/h (Figure 3). Actually, the equation produces negative $PROB_{direct}$ values for ROS>1689 m/h.

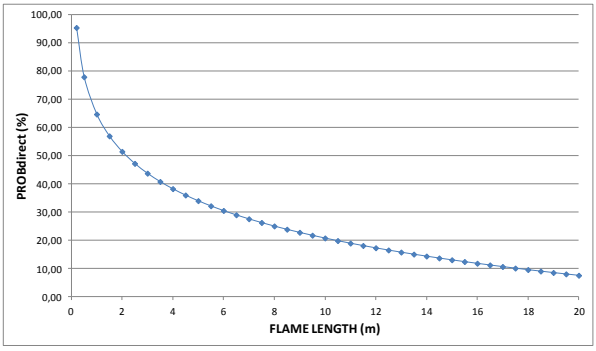

Figure 2. Plotting of the probability to engage in direct attack on all parts of a fire which is exhibiting a particular flame length, according to equation 1.

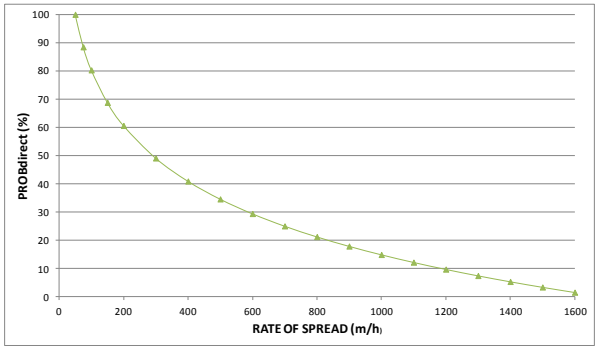

Figure 3. Plotting of the probability to engage in direct attack on all parts of a fire spreading with a particular rate of spread, according to equation 2.

Another important finding, based again on the responses regarding the twelve photos of the first question (N=12), has to do with the probability that a fire will be considered as being beyond the capacity of any of the firefighting resources combinations that were suggested to the respondents (PROB_NO), as a function of FLAME and of ROS. The strongest suggested combination was 4 fire trucks plus aerial resources for fighting a 100 m wide fire front from a 6 m wide road. Again, two regression equations were developed with PROB_NO as the dependent variable and FLAME and ROS as the independent variables respectively. The equations are as follows:

c) PROB_NO = 1.814 + 1.407 * FLAME with Adj. R^2= 0.951 (3)

d) PROB_NO = 6.001 + 0.028 * ROS with Adj. R^2= 0.862 (4)

Both equations are statistically significant (p<0,005).

The second question which focused on the length of extinction of the front and of the flanks of a particular fire, shown in photograph and associated with estimates of frontal and flank flame length. The requested length estimates (m) were for two different firefighting resources as explained earlier. Many respondents omitted providing estimates for some of the photos. Also, many replies were marked X indicating that direct attack on the flames with the particular resource was considered as impossible. The data were analyzed with regression aiming to establish models for estimating extinction lengths of fire front or flank for each resource with flame length as the independent variable. Furthermore, logistic regression analysis provided models for estimating the probability that direct attack is possible. The results are as follows:

Case 1:

Resource: One driver and two firefighters with a light fire truck having a 600 liter tank, using 25mm diameter hoses.

Operation type: Attack to the fire front.

Results: The maximum number of replies from the 67 respondents for the 9 photos was 603. The number of length estimates were 233 while 287 responses were marked with X (direct attack impossible with this resource) and were given a value of 0 for the logistic regression. The number of "no replies" was 83. The equation is:

$EXT_{600L\_Front} = 1.969 + 37.038 / FL_{front}$ (5)

Where the extinction length EXT_{600L_Front} and the frontal flame length FL_{front} are expressed in meters, Adj. R^2 = 0.294, the p-value for the equation is p<0.001, the constant's p=0.282 and of 1/ FL_{front} p <0.001.

The logistic regression equation is:

$$P(EXT_{600L\_Front}) = \exp(1.537-0.,184*(FL_{front}))/(1+ \text{Exp}(1.537-0.184*(FL_{front}))) \quad (6)$$

Case 2:

Resource: One driver and two firefighters with a light fire truck having a 600 liter tank, using 25mm diameter hoses.
Operation type: Attack to the flank of the fire.
Results: The number of extinction length estimates was 333 while 190 responses were marked with X (direct attack impossible with this resource) and were given a value of 0 for the logistic regression. The number of "no replies" was 80. The equation is:

$$EXT_{600L\_Flank} = 6.321 + 27.711 / FL_{flank} \quad (7)$$

Where the extinction length EXT_{600L_Flank} and the flank flame length FL_{flank} are expressed in meters, Adj. R^2 = 0.269, the p-value for the equation is p<0.001, the constant's p=0.019 and of 1/ FL_{flank} p <0.001.

The logistic regression equation is:

$$P(EXT_{600L\_Flank}) = \exp(1.692-0.152 *(FL_{flank}))/(1+ \text{Exp}(1.692-0.152*(FL_{flank}))) \quad (8)$$

Case 3:

Resource: One driver and two firefighters with a fire truck having a 2500 liter tank using 45 mm diameter hoses.
Operation type: Attack to the fire front.
Results: The number of extinction length estimates were 329 while 192 responses were marked with X (direct attack impossible with this resource) and were given a value of 0 for the logistic regression. The number of "no replies" was 82. The equation is:

$$EXT_{2500L\_Front} = 9.354+77.453 / FL_{front} \quad (9)$$

Where the extinction length EXT_{2500L_Front} and the frontal flame length FL_{front} are expressed in meters, Adj. R^2 = 0.292, the p-value for the equation is p<0.001, the constant's p=0.014 and of 1/ FL_{front} p <0.001.

The logistic regression equation is:

$$P(EXT_{2500L\_Front}) = \exp(1,828-0,1 *(FL_{front}))/(1 + \text{Exp}(1.828-0.1*(FL_{front}))) \quad (10)$$

Case 4:

Resource: One driver and two firefighters with a fire truck having a 2500 liter tank using 45 mm diameter hoses.
Operation type: Attack to the flank of the fire.
Results: The number of extinction length estimates were 405 while 120 responses were marked with X (direct attack impossible with this resource) and were given a value of 0 for the logistic regression. The number of "no replies" was 78. The equation is:

$$EXT_{2500L\_Flank} = 20.756 + 57.493 / FL_{flank} \quad (11)$$

Where the extinction length EXT_{2500L_Flank} and the flank flame length FL_{flank} are expressed in meters, Adj. $R^2 = 0.236$, the p-value for the equation is $p<0.001$, the constant's $p=0.001$ and of $1/ FL_{flank}$ $p <0.001$.

The logistic regression equation is:

$$P(EXT_{2500L\_Flank})= \exp(2.444-0.163 *(FL_{flank}))/(1+ Exp(2.444-0.163*(FL_{flank}))) \quad (12)$$

Figure 4 is a plot of equations 5, 7, 9 and 11 showing the quick drop in extinction effectiveness with increasing flame length.

Discussion and conclusions

The results of the study provide useful input for understanding and modelling forest fire suppression in Greece. For example, the result of equation (1) that there is a 40% chance of direct attack on fires with 3.5 m flame length and a 24% chance at 8.5 m flame length, can be evaluated versus the limits of successful attack at the fire front suggested and discussed by Deeming *et al*. (1978), Andrews and Rothermel (1982), Rothermel (1983), Alexander and DeGroot (1988), Alexander and Lanoville (1989), and Hirch and Martell (1996). In interpreting equation (1) it should be taken into consideration that following firefighting practice in Greece the respondents have use of water from fire trucks as the default method of attacking a fire. In general the results of equation 1 appear to be in agreement with the other studies, taking of course into consideration that the photos in the present questionnaire represented various fuel types whereas some of those studies focused on specific fuels types.

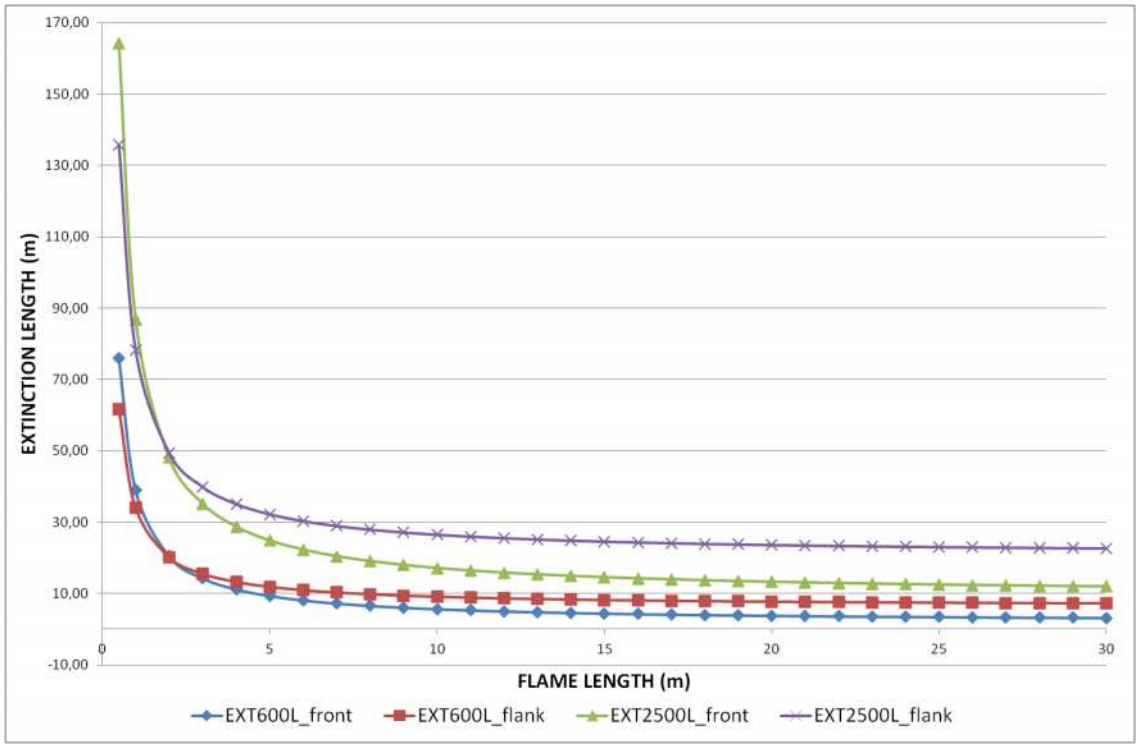

Figure 4.Plotting of the predicted extinction length for a range of flame lengths according to equations 5, 7, 9 and 11.

Equation 2 is also interesting as it provides an estimated ROS limit (1690 m/h) beyond which direct attack is not possible, not taking a particular fuel type into consideration. Such information is less commonly available in the international literature. The results of this equation can be challenged since fast running grass fires can be chased along the flanks by fire trucks equipped with appropriate water spraying capability, aiming to achieve an extinguishing rate faster than the ROS of the fire and ultimately catch and extinguish the head of the fire. Topography, which is generally steep, might make use of such a technique an exception rather than the rule for grass fires in Greece.

Equations 5-12 have generally low Adj. R^2 statistics. This is not surprising as there was a lot of variation in regard to the estimates of extinction length provided by the respondents. Part of this variability is due to the variety of fuel types depicted in the photos. It is well known that the water required to extinguish a grass fire is much less than that needed for a heavier fuel type even if the flame length is the same. The varying background and experience of the respondents is also an important source of variability. Nevertheless, the behaviour of the equations is rational and can provide a good baseline for calculations that will be useful for dispatching of fire trucks for initial attack and for planning extended attack in the future in Greece.

Abstract
Fires on the Wildland Urban Interface (WUI) have caused significant loss of life and colossal property and natural environment damages in numerous countries around the world. The solutions to mitigate this fire problem are complex, as it results from the fuel source changes from vegetation to structural materials in a fire-prone environment and it involves the interaction of several factors that act synergistically to increase the frequency of fires with severe potential destruction. In order to understand how and why buildings are damaged and destroyed under wildland fire attack, several surveys following historical large scale fire events, which resulted in significant building damages and/or losses, have been conducted worldwide. This paper aims to review and analyse the main characteristics of buildings and other structures that contributed to their vulnerability during fires at the WUI, based on the analysis of several post fire studies developed in Australia, United States of America and Mediterranean Europe (particularly Portugal, Spain, Greece). The different building traditions between the selected countries are discussed, as long as they affect building vulnerability to fires.

Keywords*: wildland urban interface, fire, building vulnerability, structure vulnerability*

Introduction

Fires on the Wildland Urban Interface (WUI) have caused significant loss of life and colossal property and natural environment damages in numerous countries around the world. Table 1 shows some of the worst wildland fire events that, recently, reached WUI areas in Australia, United States of America (U.S.A.) and Mediterranean Europe (particularly Portugal, Spain, Greece).

Table 1. Some recent wildland urban interface fires and side effects in Australia, United States of America (U.S.A.), Spain, Greece and Portugal (adapted from Xanthopoulos et al., 2003; Cohen, 2008; CAL FIRE, 2009; Viegas et al., 2009; Galiana-Martín, 2011; Viegas et al., 2011; Tedim et al., 2012; Trindade et al., 2012; Infoplease, 2014)

The solutions to mitigate this fire problem are complex (Kyle *et al.*, 2008), as it results from the fuel source changes from vegetation to structural materials in a fire-prone environment, since the fire travels from a wildland area to a rural, peri-urban and/or urban area which borders the wildland area. Moreover, the fire spread in a WUI area involves the interaction of several factors (such as topography, weather conditions, human behaviour, besides vegetation and building fuels), that act synergistically to increase the frequency of fires with severe fire behaviour and potential destruction (Cohen, 2008; Maranghides and Mell, 2009).

In geographical locations with potential fire risk (e.g. rugged topography), the combination of prolonged drought conditions and particular strong winds, as a result of climate change, leave vegetation particularly vulnerable. Combination of these facts with an increasing number and extent of WUI areas, often leads to fuel accumulation that create conditions that are beyond the fire suppression capacity of any firefighting mechanism (Xanthopoulos *et al.*, 2011).

The most effective ways to improve fire safety are preventive actions (White and Dietenberger, 2010). The knowledge of the critical aspects that make buildings and other structures vulnerable to fires in WUI areas is crucial to reduce or eliminate the risks of ignition, leading to the reduction of their potential losses during fire events (Manzello, 2014).

In order to understand how and why buildings are damaged and destroyed under wildland fire attack, several surveys following historical large scale fire events, which resulted in significant building damages and/or losses, have been conducted worldwide. However, despite these efforts, more should be done to understand the structure ignition potential during fires at the WUI since this problem is getting increasingly worse (Maranghides and Mell, 2009; Manzello, 2014).

This paper aims to review and analyse the main characteristics of buildings and other structures that contributed to their vulnerability during fires at the WUI, based on the analysis of several post-fire studies. In order to carry out this study, some of the post-fire studies developed in Australia, U.S.A. and Mediterranean Europe (particularly Portugal, Spain, Greece) were analysed since these countries have extensive WUI areas with severe fire-prone environments (Xanthopoulos *et al.*, 2011), which resulted in some of the worst fire events in the WUI (Table 1). Moreover, Australia and the U.S.A. have large experience and knowledge in the analysis of fire occurrences (Viegas *et al.*, 2012) and learning from the examples in other parts of the world is of great value.

Building vulnerabilities

2.1. Fire attack mechanisms

During a fire in the Wildland Urban Interface (WUI), buildings may be a fuel source to initial ignition and to the potential for flame-spread. Moreover, some of the components of the building envelope may allow fire penetration into it, and consequently, the ignition of materials inside it.

The main characteristics of a building (and other structures) in the WUI that can significantly contribute to its vulnerability under wildland fire attack are its material characteristics (i.e.

combustible, non-combustible, fire resistant), design features and details of its different parts and the openings or weak points in the building envelope. Furthermore, the susceptibility to ignition of the elements in the building's immediate surrounding may also influence the risk of exposure that a building experience during a fire event.

Post-fire studies have shown that several fire spread mechanisms may be responsible for ignition and propagation of wildland fires into the WUI, as buildings and their immediate surroundings may be exposed to firebrands, radiant heat, and/or flame contact, resulting in building damage or destruction. Firebrands (or embers, or burning debris) may be produced by vegetation of the type that supports fire front spread and/or by the fuel load of other sources from the rural, peri-urban or urban setting. As firebrands can be carried by winds and by convective air rising off the fire front (Fairbanks and Ingalsbee, 2006), they can be transported ahead of the main fire, creating spot fires in the building surrounding close to the building envelope, and even inside the building by entering into it through openings or weak points. As an example, during the 2005 Coimbra fire (Portugal), firebrands (from the main fire front) crossed Mondego river and caused several spot fires inside the urban area (Viegas *et al.*, 2011).

The risk from firebrands attack is complex, as it depends on the vulnerability of the building , as well as from several other factors, such as firebrands quality (i.e. configuration, size), amount and type (source), distance from source, and the duration of the attack (Leonard and Bowditch, 2003; Victorian Bushfires Royal Commission (VBRC), 2009). Furthermore, weather conditions play a relevant role in firebrands propagation (Foote *et al.*, 2011), particularly wind conditions, as it affects firebrands generation, transport, and landing (Koo *et al.*, 2010). Despite the complexity of this fire spread mechanism, it is well understood that firebrands is the most predominant cause of ignition and loss of buildings during fire events at the WUI (Maranghides and Mell, 2009; VBRC, 2009), mainly as this type of attack may occur before, during and after a fire front has passed (Blanchi and Leonard, 2005).

While firebrands offer a discontinuous fire spread mechanism, radiant heat exposure and flame contact are continuous ones, originated from the fire front spread and/or from any combustible elements in building surrounding (VBRC, 2009; Potter and Leonard, 2010). As a result, the external building elements may be ignited or radiant heat and/or flame contact may act on the building envelope until a weak point of it opens up, allowing firebrands' entry into the building and the ignition of building contents (Potter and Leonard, 2010). Radiant heat and flames present a risk based on the level of radiant heat exposure, the time over which this exposure occurs, as well as on the building vulnerability under attack (Leonard *et al.*, 2009).

In the following sections, the main characteristics of buildings (and other structures) and the elements in their immediate surroundings, that contributed significantly to their vulnerability during past fire events, are reviewed and analysed. The different building traditions between the selected countries are discussed, as long as they affect building vulnerability to fires.

Building construction materials

The material characteristics (i.e. combustible, non-combustible, fire resistant) used in buildings construction (and in other structures) influence the ignition of their external and internal components, depending on the material ability to support localised flame development (i.e. material reaction to fire), which may be initiated by firebrands attack, radiant heat exposure and/or flame contact.

In the U.S.A. most buildings are traditionally made with timber (a combustible material). Particularly, for exterior wall cladding, wood or wood based products (such as plywood or oriented strand board) are commonly used, as well as vinyl or other plastics (also combustible materials) (Quarles *et al.*, 2010).

In Australia, building construction traditions changed over years. Early in the 20th Century, with the population growth in coastal areas, traditional buildings (particularly in Queensland) were constructed of timber with a corrugated iron roofing, large verandas all around, and were elevated on stumps above the ground (Xanthopoulos *et al.*, 2011). From the 1930's, in Australian cities (Melbourne, Sydney,

Brisbane), particularly where termites existed, instead of timber (as it is a biological termite-prone material) buildings were constructed of brick or corrugated iron, and cladded with plaster lined fibrocement or brick veneer (Xanthopoulos *et al.*, 2011).
Post-fire studies have indicated that there is a clear relationship between timber buildings destruction and the severity of fire weather conditions, which is a characteristic of fires in the Wildland Urban Interface (WUI), since hot, dry, windy weather dries out timber (hygroscopic material) in the same way that it dries out vegetation (VBRC, 2009). Moreover, during the fire event, radiation heat exposure from surrounding burning fuels also modifies timber temperature and moisture content (Potter and Leonard, 2010). Therefore, in these conditions, timber is more easily ignited. Examination of several fire disasters in the WUI revealed that buildings clad with timber or even fibrocement or cellulose cement sheet, as well as building walls constructed with mud brick (Leonard *et al.*, 2009), have responded significantly worse to wildland fire attack than building walls constructed with bricks (Bell, 1985; Ramsay *et al.*, 1996; Leonard *et al.*, 2009).
In regard to roof covering materials, several researches indicated that untreated timber roofing material (i.e. without impregnated fire retardant treatments), particularly wooden shake and shingle roofs, were a major contributor to buildings destruction in past fire events at the WUI (Foote *et al.*, 1991b; Mitchell and Patashnik, 2007; Quarles *et al.*, 2013). It has been reported that firebrands were the dominating fire spread mechanism on timber roof combustion (Foote *et al.*, 2011). Furthermore, particularly during the 1983 Ash Wednesday fires (in Victoria) and the 1994 New South Wales fires, both in Australia, buildings with masonry tiles or steel deck roofs survived more often than those with corrugated iron or fibrocement roofs (Ramsay *et al.*, 1996).
Taking into account material characteristics, particularly of combustible ones that may be used in building construction in the U.S.A. and Australia, the ignition of the building envelope (cladding and/or roof covering) is a major concern during a fire at the WUI (Xanthopoulos, 2004), as the buildings themselves can easily become fuel. As an example, Figure 1a shows a building envelope damaged that resulted from the 2007 Grass Valley Fire (Southern California, U.S.A.). On one hand, it is visible the burned vinyl cladding and underlayment, as well as the burned timber cladding, which according to Cohen and Stratton (2008) resulted from the thermal exposure from the nearby buildingand the burned surrounding vegetation. On the other hand, it is visible that the burned blackened asphalt shingles in the roof valley resulted from the accumulation of pine needles that ignited due to the flames spread up along the building wall (Cohen and Stratton, 2008).

a **b** **c**

Figure 1. Influence of the construction materials characteristics on building vulnerabilities to wildland fire threats: a) building envelope damage due to the combustible construction materials (U.S.A.) (Cohen and Stratton, 2008); b) buildings destruction due to house-to-house fire spread (U.S.A.) (Cohen and Stratton, 2008); and c) building destruction due to its combustible contents (Greece) (Xanthopoulos et al., 2011).

Therefore, the proximity of more buildings means concentration of fuel loads (Xanthopoulos *et al.*, 2011), thus increasing fire risk propagation. Actually, several field investigations in the U.S.A. (Mitchell and Patashnik, 2007; Cohen and Stratton, 2008; Texas A&M Forest Service, 2012; Colorado

Springs Fire Department, 2013; Quarles *et al.*, 2013) and Australia (Blanchi and Leonard, 2005; Leonard *et al.*, 2009), have evidenced house-to-house fire propagation. This fire spread mechanism acts in the following way: during the fire event, some buildings on fire (due to the main fire front or firebrands attack) provide radiant heat exposure and flame contact to adjacent buildings and/or on their surrounding elements, which in turn ignite adjacent buildings, leading to their destruction (Figure 1b) (Leonard *et al.*, 2009). Moreover, the building itself can become a significant firebrands source (Blanchi and Leonard, 2005; Texas A&M Forest Service, 2012). Besides material characteristics and surrounding elements, the close proximity of buildings and the slope of the terrain also influence this fire transfer mechanism (Quarles *et al.*, 2013). In the 2012 Waldo Canyon Fire (Colorado, U.S.A.), where buildings in peri-urban or urban neighbourhoods were within 10 meters to each other, fire propagated through house-to-house (Mitchell and Patashnik, 2007).

In Mediterranean Europe (particularly Portugal, Spain, Greece), buildings are mostly built with fire resistant materials (Xanthopoulos *et al.*, 2011), such as reinforced concrete frame, bricks, stones, tiled roofs. However, timber may be found in specific building elements, such as in roof structures, window frames, doors, and others (Xanthopoulos *et al.*, 2003).

When compared with the reality in the U.S.A. and Australia, a high density of buildings in Mediterranean Europe generally entails a reduction of the available fuel loads (Xanthopoulos *et al.*, 2011) to fire propagation, due to the construction material characteristics used in the building envelope components. Notwithstanding this, buildings in Mediterranean Europe have also been damaged or destroyed during fires in the WUI, but in most cases, it is a consequence of the ignition of the materials inside it, as the fire managed to enter the buildings through openings or breakthrough weak points (Figure 1c) (Caballero, 2004; Xanthopoulos *et al.*, 2011).

Other difference between the analysed countries arise from post-fire studies in the WUI, as while in the U.S.A. and Australia, a large number of buildings were destroyed and just a few were damaged (VBRC, 2009; Quarles *et al.*, 2013), in Mediterranean Europe, building destruction happens in a minimum fraction of the number of buildings threatened by fire (Caballero, 2004).

2.3. Building design features and openings or weak points

Building design features and details of its different parts play an important role in the survivability of a structure during a fire at the Wildland Urban Interface (WUI), since any part of a building envelope where firebrands can penetrate and/or accumulate is susceptible to ignition and spread, particularly if these building parts are combustible. Some building details are also susceptible to dead vegetation accumulation (e.g. pine needles or other vegetation), increasing the available fuel loads and leading to firebrands spread, thus threatening nearby combustible building elements. Furthermore, openings or weak points in the building envelope entail the ignition of building contents due to the opportunity that they may present to firebrands penetration into the building.

- **Exterior subfloor systems elevated on stumps above the ground**

Subfloor systems of buildings that are elevated on stumps above the ground, revealed to be a vulnerable part of the building during past fire events in the WUI, particularly to firebrands penetration or even accumulation on gaps or crannies (Bell, 1985), as buildings on stumps were more likely to be destroyed than buildings constructed on slab on ground (Ramsay *et al.*, 1996; Leonard *et al.*, 2009). Ramsay *et al.* (1996) reported that, along with combustible material characteristics of stumps (i.e. timber unlike fire resistant concrete slabs on ground), the use of timber gap-boards to enclose the underfloor space of timber and the fibrocement clad buildings appeared to contribute to buildings vulnerability.

- **Windows and external doors**

Windows (either open or closed ones) may be a weak point of the building envelope during a fire at the WUI, depending on their components, such as framing material (Fairbanks and Ingalsbee, 2006) and their conservation conditions (Blanchi and Leonard, 2005), window sills material (Bell, 1985;

Ramsay *et al.*, 1996), shutters material and their conservation conditions (Xanthopoulos *et al.*, 2011), and the use of metal fly wire screens (Bell, 1985). Moreover, glass type (Blanchi and Leonard, 2005), windows dimension (Ramsay *et al.*, 1996), and/or the number of glass panes (Caballero, 2004; Xanthopoulos *et al.*, 2011) may also influence their vulnerability.

Open windows are reported as to be one of the most common entrance point of firebrands in Mediterranean Europe (Xanthopoulos, 2003), which usually ignite nylon curtains, rugs, upholstery, polyurethane and/or timber furnishings, all quite common inside Mediterranean homes (Xanthopoulos, 2004). Besides firebrands attack, nylon curtains may also be exposed to radiant heat from the burning surrounding elements (Xanthopoulos, 2003). Vinyl and old timber shutters are examples of radiant heat sources, as they have shown to be easily destroyed when threatened by fire (Xanthopoulos *et al.*, 2011).

In turn, closed windows are weak points when threatened by flame contact (Blanchi and Leonard, 2005) or by radiant heat exposure (Bell, 1985; Ramsay *et al.*, 1996) from flame front or burning surrounding elements, leading to glass to break, which create an entry point to firebrands into the building (Texas A&M Forest Service, 2012). As an example, a survey after the 2003 Canberra fires evidenced that some windows were broken or cracked from radiant heat, allowing that curtains were heat affected and firebrands entered causing burn marks on carpets (Blanchi and Leonard, 2005). However, there were situations where fire resistant windows shutters (e.g. aluminium, steel) that were closed (either hinged or roll-down), provided optimum protection to glass, timber frames and sills (shutters usually cover window sills). Furthermore, the use of metal fly wire screens on windows seems to have protected them during the 1983 Ash Wednesday fires, as windows unprotected were found apparently cracked and broken by radiation heat exposure (Bell, 1985).

Combustible window frames may also contribute to (closed) windows vulnerability, either due to timber ignition from firebrands accumulation in the re-entrant corner of the window sill, which potentiate glass to break by providing radiant heat exposure and/or flame contact (Blanchi and Leonard, 2005), or due to vinyl melt, causing the glass to fall out (Fairbanks and Ingalsbee, 2006), allowing firebrands to enter into the building. Combustible window sills may also ignite, contributing to window vulnerability (Ramsay *et al.*, 1996). Moreover, gaps around window frames are reported to be common firebrands' accumulation points, as well as around windows and external doors (Blanchi *et al.*, 2006).

In the same way, combustible external doors, frames and even their assemblies increase the risk of ignition and fire spread, as frequently it was observed in re-entrant corners of timber doors, frames, and assemblies, due to firebrands accumulation (Blanchi *et al.*, 2006). Door gaps also present an opportunity for firebrand's entry (Blanchi *et al.*, 2006). Several post-fire field observations evidenced that by screening the external door with non-combustible screen door or using low or non-combustible materials in door assembly, it is possible to reduce the vulnerability of this building component (Blanchi *et al.*, 2006).

Window dimensions may also affect their vulnerability (Quarles *et al.*, 2010). After the 1983 Ash Wednesday fires (in Victoria) and the 1994 New South Wales fires, field observations reported that building destruction increased with the increasing glass area of buildings envelope (Ramsay *et al.*, 1996).

Finally, there are examples where single pane windows revealed to be more vulnerable to cracking and breaking, than dual pane windows (Caballero, 2004; Xanthopoulos *et al.*, 2011; Colorado Springs Fire Department, 2013), such as during the 2011 Texas wildland fire season, where dual pane windows helped to stop fire spread, as the first pane was compromised, but the inner pane withstood facture (Texas A&M Forest Service, 2012).

- **Vents**

Vents revealed to be particularly vulnerable to firebrands penetration into buildings (Quarles and TenWolde, 2004; Texas A&M Forest Service, 2012), specially unscreened ones (Bell, 1985; Blanchi

et al., 2006). Actually, they were one of the most common entrance points to firebrands in past fires in Mediterranean Europe (Xanthopoulos, 2003).
Field observations revealed that vents are also vulnerable to flames penetration (i.e. flames from burning surrounding elements), both vents located in attics or cathedral ceilings, and in crawl spaces under buildings (Quarles and TenWolde, 2004; Quarles *et al.*, 2010).
As an example, the post-fire survey conducted after the 2003 Southern California Fire (U.S.A.) evidenced that several buildings were destroyed due to firebrands and flame penetration through vents located under wide roof overhangs (Quarles and TenWolde, 2004). The combustible items that may be stored in attics or cathedral ceilings, as well as timber trusses, which are easily ignited, due to the lower moisture content (attics or cathedral ceilings tend to be dry spaces) (Quarles *et al.*, 2010), increase the available fuel load to fire propagation, leading to building destruction.

- **Roof systems**

A complex roof design, e.g. with intersections between roof and walls (e.g. a dormer) (Quarles *et al.*, 2013) or geometric features such as valleys or gullies (Blanchi *et al.*, 2006), increases roof vulnerability to fire as it provides the accumulation of firebrands or even dead vegetation (e.g. from overhanging trees), which may be ignited by firebrands. Actually, roofs with multiple ridges (which dictate roof valleys) and gullies appeared to perform fare worse than flat roofs, when threatened by firebrands (Blanchi *et al.*, 2006). Furthermore, roof systems contain several components that proved to be vulnerable to fire penetration into the building (such as roof covering, edge, overhang, gutters, chimneys), depending of their material characteristics, as well as other design features and details of its different parts.
Studies from past fire events at the WUI, particularly in Mediterranean Europe, where tiled roofs are quite common, evidenced that while tiled roofs in good shape and clean from dead vegetation protected buildings from firebrands penetration, along with their fire resistance characteristics, tiled roofs with gaps, dislocated or even broken tiles, that presented a fuel continuity to the building interior (Xanthopoulos *et al.*, 2011) (e.g. dead vegetation accumulation), allowed firebrands penetration into the building (Xanthopoulos *et al.*, 2003), leading to their destruction. It has been reported that the layer of bituminous membrane placed between timber trusses and ceramic tiles (to prevent water leaks), ignited quite easily from firebrands attack, setting the roof on fire (Xanthopoulos *et al.*, 2011). Moreover, poorly maintained timber trusses revealed to increase ignition easiness (Xanthopoulos *et al.*, 2003).
Ceramic roof tiles are commonly supported by timber trusses in southern Europe but concrete roofs covered with ceramic roof tiles may also be found, and past fire events evidenced that the last ones performed better to exterior fire threats, than ceramic tiled roofs supported by timber trusses (Xanthopoulos *et al.*, 2011).
Spanish tiles (or curved or Mediterranean style) roofs contributed to building destruction through firebrands penetration in the 2003 Southern California Fire, as a result of poor construction, missing tiles (which created gaps in the roof covering) and/or dislocated "birdstops" (i.e. cement filler that blocks the eave openings under concave tiles limiting firebrands entry (Foote *et al.*, 1991a)) (Mitchell and Patashnik, 2007). Moreover, they behaved significantly worse than flat-tile/concrete roofs, as well as stone-covered steel roofs (Mitchell and Patashnik, 2007).
Therefore, tiled roofs can be a weak point to the building envelope, during fires in the WUI, particularly when they contain many gaps, typically where the tiles overlap (as tiles rarely fit together tightly enough to maintain a less than 2 mm gap (Blanchi and Leonard, 2005)), and at the roof edge between the roof covering and the roof sheathing (Quarles *et al.*, 2010). Moreover, gaps can also exist at the roof ridge (Quarles *et al.*, 2010), where tiles are dislocated or even broken, creating more gaps.
Roof overhangs may be another weak point of the roof system during fires at the WUI (with or without vents (Quarles *et al.*, 2010)), as combustible soffits can either melt or ignite, leading to firebrands penetration into attic spaces (as it appears that has occurred during the 2011 Texas wildland fire season

(U.S.A.)) (Texas A&M Forest Service, 2012), or eaves area can accumulate firebrands, or even concentrate flames from ignited cladding or burning surrounding vegetation (particularly for open eave construction) (Quarles and TenWolde, 2004), leading to eaves ignition. Actually, during the 2009 Black Saturday Bushfire (Victoria, Australia), eaves were reported to be the part of the building that most commonly caught fire in the first place (VBRC, 2009).
Roof gutters evidenced to be a weak point in the roof system, particularly when filled with dead vegetation (Xanthopoulos, 2003; Quarles *et al.*, 2010), as after firebrands ignition (Blanchi *et al.*, 2006), the flames that may result would provide flame contact to the edge of the roof, particularly to fascia boards (Bell, 1985), which after destruction, may lead to flames entry into the attic space (Quarles *et al.*, 2010).
Chimneys are also pointed out as a weak point, as firebrands proved to be able to enter through them, particularly in the absence of a protective wire mesh (Xanthopoulos, 2003). Actually, they evidenced to be one of the most common firebrands entrance points in past fire events in the WUI of Mediterranean Europe.

2.4. Building immediate surrounding

After past fire events in the Wildland Urban Interface (WUI), field observations reported that, either the elements in the immediate building surrounding played a role of radiant heat barrier to the building, reducing the risk of building destruction (Blanchi *et al.*, 2006), or once ignited, they contributed to fire spread to other elements or even to other buildings, leading to their ignition and consequent loss (Blanchi *et al.*, 2006; Leonard *et al.*, 2009; Texas A&M Forest Service, 2012).
Several post-fire surveys highlighted that buildings were more likely to be destroyed as the vegetation in the immediate surrounding increases in terms of amount or density (Ramsay *et al.*, 1996; Cohen, 2000; Leonard and Bowditch, 2003; Mitchell and Patashnik, 2007). This applies to vegetation in direct contact with buildings (Texas A&M Forest Service, 2012), overhanging (e.g. trees) and immediately adjacent to them (e.g. forest, trees, ground cover such as shrub, mulch bed, dry grass) (Blanchi *et al.*, 2006; Leonard *et al.*, 2009). Thus the distance between vegetation and buildings plays an important role (Blanchi *et al.*, 2006; Leonard *et al.*, 2009). Furthermore, both the type of vegetation (Ramsay *et al.*, 1996) and weather conditions (especially long periods of hot dry conditions) (Potter and Leonard, 2010) influence the fuel loading, fuel moisture content, and heat content (Foote *et al.*, 1991a). Radiant heat and flame exposure play an important role in building ignition from burning surrounding vegetation (Ramsay *et al.*, 1996; Leonard and Bowditch, 2003; Mitchell and Patashnik, 2007).
Poor maintenance of the surrounding vegetation has also shown to affect building vulnerability during fires in the WUI, as it leads to dead vegetation accumulation, alike the accumulation of dead fuel as a result of their cut (Caballero, 2004). Field observations after the 2000 Cerro Grande Fire in Los Alamos (U.S.A.) (Cohen, 2000) revealed that in many areas of buildings destruction, ignition of timber cladding appeared to be triggered by pine needles fuel beds around buildings, while in some cases, whereas pine needles were removed, particularly from the base of timber walls, they did not ignited.
However, well located and selected plants that are properly maintained can reduce the risk of exposure that a building experience during a fire event (Blanchi *et al.*, 2006), e.g., pruning and thinning of ladder fuels in Gambel oak (*Quercus gambelii*) clumps, appeared to be effective in keeping fire on the ground and reducing crown fire potential (i.e. fire spread from treetop to treetop) during the 2012 Waldo Canyon Fire (Quarles *et al.*, 2013).
Generally, timber decks or verandas (either solid or composite products) are attached to buildings. After firebrands attack (common ignition source), decks ignition (particularly of decks untreated with fire retardant products) and even their timber steps (Ramsay *et al.*, 1996), skirting or railings ignition, conducted flames right up to the external parts of the building envelope, leading to building destruction (Texas A&M Forest Service, 2012). However, while in the U.S.A. and Australia, combustible decks are common, in Mediterranean Europe, they do not pose a risk to building destruction, since decks are

mostly built with fire resistant materials (Xanthopoulos, 2004) or they are close to non-combustible walls.
Field observations revealed that decks ignition (through flame contact) may also result from the burning material stored under it (e.g. firewood piles) or on the top of the deck (e.g. combustible garden furniture), or even from burning adjacent vegetation (e.g. trees, bushes) (Colorado Springs Fire Department, 2013).
Timber fencing systems that are adjacent to the buildings, after ignited have the potential to break windows, ignite combustible features of the building itself, and/or even spread fire to neighbourhood buildings, as it happened in the 2003 Canberra fires (Blanchi *et al.*, 2006). Moreover, timber fences with adjacent vegetation are particularly susceptible to ignition (Potter and Leonard, 2010). On the other hand, non-combustible fences demonstrated to provide radiation barriers, as well as timber fences that were regularly wetted (Potter and Leonard, 2010), either to the main fire front or to the burning of an adjacent structure, reducing the potential for fire attack (Blanchi *et al.*, 2006).
Garages and sheds showed to be more readily lost compared with the main structure, since generally they have more gaps and openings, being more susceptible to firebrands' ignition (Blanchi *et al.*, 2006). After ignited, they became localised flame, radiation and firebrands' sources, threatening the main structure, as a function on their proximity, garage or shed design, size, and materials stored inside it (Blanchi *et al.*, 2006). Actually, during the 2011 Texas wildland fire season, garages or sheds after ignited, revealed to generate a tremendous amount of heat, as well as combustible garden furniture, vehicles, and firewood piles (Texas A&M Forest Service, 2012).
Non-combustible retaining walls (e.g. brick retaining walls (Texas A&M Forest Service, 2012)), paths and gravel borders appeared to be effective in stopping fire spread during past fire events at the WUI, particularly in lighter fuel types (Quarles *et al.*, 2013), while combustible retaining walls (e.g. railway sleepers) demonstrated to be easily ignited and burned intensely for long durations (Texas A&M Forest Service, 2012).

Conclusions

The main characteristics of buildings (and other structures) in the Wildland Urban Interface (WUI) that contributed significantly to their fire vulnerability during past fire events are:

- Building material characteristics (i.e. combustible, non-combustible, fire resistant) used in their external and internal parts;
- Design features and details of their different parts and the openings or weak points in buildings envelope, such as gaps or crannies on exterior subfloor systems elevated on stumps above the ground, windows frame, glass and sill (particularly in re-entrant corners), door frames and assemblies (also in re-entrant corners), gaps around window frames and doors, vents, complex roof design with dormers, valleys or gullies, gaps on roof covering and edges, and roof overhang, gutters (particularly filled with dead vegetation), and chimneys.

The building vulnerabilities to fire threats may act by themselves or synergistically with each other and lead to building damage or destruction, depending on several factors, such as topography, weather conditions, human behaviour, and/or fuel loads of the elements in the immediate building surrounding. The elements on, attached to and around buildings most susceptible to ignition and fire spread are live or dead vegetation, untreated combustible decks or verandas and their steps, skirting and railings, firewood piles, timber fences, garages, sheds, awnings, combustible garden furniture, vehicles, and combustible retaining walls.
Despite the colossal property losses that resulted from past fire events at the WUI, several buildings survived. The use of non-combustible or fire resistant materials on buildings envelope appeared to decrease building susceptibility to fire threats, leading to building survivability. Some of the building openings or weak points also appeared to be less susceptible when in good conditions and protected

with particular elements, such as fire resistant windows shutters (that were closed during fire event), metal fly wire screens on windows, fire resistant screens on vents and doors, wire mesh on chimneys, concave tiles filled with cement on eave openings, as well as the use of low or non-combustible materials in door assemblies. Furthermore, an adequate maintenance of live and dead vegetation in buildings' immediate surrounding, non-combustible fences, timber fences regularly wetted, and non-combustible retaining walls, paths and gravel borders appeared to be effective in preventing fire spread.

The materials used in buildings construction (and in other structures) is the main difference observed between the analysed countries (i.e. U.S.A., Australia, Portugal, Spain, Greece), that affected directly building vulnerability to fires. In the U.S.A. and Australia, the use of combustible construction materials, particularly on buildings external parts (i.e. cladding, roof covering and/or decks) clearly increased buildings susceptibility to fire, which most probably led to building destruction, either way through building ignition from the exterior or from inside. Untreated timber elements (i.e. without impregnated fire retardant treatments) were particularly vulnerable to fire, especially as their hygroscopicity allowed it to be easily ignited during severe fire weather conditions (i.e. characteristic of fires in the WUI). In that context, fire ignition of a building may easily lead to fire propagation to adjacent buildings, which was evident in several post-fire surveys. It should be stressed however that the ignition of a building is highly influenced by other variables, besides building materials combustibility, as above discussed.

On the contrary, the building envelope components in Mediterranean Europe are generally fire resistant, leading to a substantial reduction of the available fuel loads to initial ignition and flame-spread to other building components. Actually, from the analysed studies, building destruction in Mediterranean Europe generally happened as a result of fire penetration into the building through openings or weak points (such as open windows, vents, chimneys without a protective wire mesh, tiled roofs with gaps, dislocated or even broken tiles, with dead vegetation accumulation), leading to building ignition from inside.

Abstract:
This paper examined the spatial, temporal and localised context of bushfire fatalities and house loss in Australia. The analysis focused principally on understanding the strength of correlations between location where fatal exposure occurred, fire weather conditions (using the McArthur Forest Fire Danger Index (FFDI) and its individual components), proximity to fuel, proximity to other objects (houses and/or vehicles) and fatality activity and decision making leading up to the death.
The analysis is based on a dataset containing bushfire related life loss and house loss in Australia over the past 110 years (1901-2011). Over this time period 260 bushfires have been associated with a total of 825 known civilian (733) and firefighter fatalities (92), and 8778 houses destroyed. The analysis included spatial, temporal and localised context in which the fatalities have occurred.
The analysis demonstrated that:

- The losses are dominated by major events that have occurred under very severe weather conditions
- The location of fatal exposure provides a useful context to better understand the specific level of shelter a person had when they died with 58% occurring out in the open, 28% occurring inside structures and 8% in vehicles.
- Male and female civilian fatalities within structures were evenly represented, while male fatalities out in the open were approximately 3 times greater than female fatalities out in the open (mainly in earlier years)
- 41% of fatalities within structure occurred in rooms with reduced visibility to the outside
- Fatalities within structures represent over 75% of all fatalities under very severe conditions (weather conditions exceeding an FFDI value of 100). These are associated with people dying while attempting to shelter mainly in their place of residence. Conversely lower values of FFDI are associated with people who are caught outside while defending their property.
- Over 60% of fatalities occurred within 100m of a residence
- 80% of all fatalities and 60% of the house loss occurred within 30 m of the forest.

Keywords*: Wildland fire, Fatalities, WUI, House loss, Risk*

Introduction

In Australia the studies of community safety at the urban interface were mainly based on post bushfire surveys and subsequent analysis to better understand the mechanisms of bushfire attack at the urban interface. The important points of consideration in those studies were on the building design, the immediate landscape, the type of urban interface and human activity and how they significantly influence the risk of loss (e.g. Barrow, 1945; Raphaele Blanchi & Leonard, 2008; Leonard & McArthur, 1999; Ramsay *et al*., 1987).
Some studies have been performed on the behaviour of civilian fatalities during bushfires (e.g. Handmer & Haynes, 2008; Haynes *et al*., 2010; O'Neill & Handmer, 2012; Tibbits, Blanchi, & Gill, 2006). While these studies on civilian fatalities have mainly focused on the behaviour of the victims

and are mainly conducted within the context of the 'Stay or Go' policy[1], they have not included the spatial and environmental circumstances of their death.
Other studies have investigated the circumstances of firefighter fatalities involving entrapment and burnovers (Butler & Cohen, 1998; Cheney *et al*., 2001; Viegas *et al*., 2008). Meanwhile some studies have focused on the influence of environmental circumstances on house loss for individual events or multiple events in Australia (e.g. Ahern & Chladil, 1999; Blanchi *et al*., 2010; Butler & Cohen, 1998; Gibbons *et al*., 2012; Harris *et al*., 2012; Newnham *et al*., 2012) and the US (e.g. Cohen, 2000; Menakis *et al*., 2003; Syphard *et al*., 2012).
This study examined the environmental circumstances of bushfire fatalities and house loss in Australia over the last 110 years, using a specific data set that included spatial, temporal and localised context (Life Loss database). The results presented in this paper are related to the relationship between fatal exposure location, house loss, weather conditions, and proximity to fuel and additional analysis components are presented in Blanchi *et al*. (2014).

Methods and data

The database (Life Loss database) developed for the analysis is a spatial dataset of bushfire related fatalities and related losses (such as house loss) and circumstances, in Australia over the past 110 years (1901-2011). It also captures the circumstances leading up to the fatal exposure such as weather context using the McArthur Forest Fire Danger Index (FFDI) (McArthur, A.G., 1978; McArthur, 1967), fire severity, distance to forest, fatality activity and decision making (Blanchi *et al*., 2014; Blanchi *et al*., 2012).
A number of different data sources were accessed in order to assemble the Life Loss database. This includes coronial inquest records, royal commission reports, journal papers, books, post bushfire study reports, fire agency review documents of major fires, newspaper articles and collated datasets on past bushfire fatalities (Blanchi *et al*., 2012; Haynes *et al*., 2010).
Different types of data have been compiled in the dataset: quantitative variables (e.g. weather information), and categorisation variables (e.g. location of fatality). Some information was categorised to facilitate spatial and statistical analysis. The detail of the data collection is presented in Blanchi *et al*. (2012, 2014).
The Life Loss database contains 825 fatalities, 733 are civilian and 92 are listed as firefighters. Of the fatalities contained in the database 741 were directly related to the fire itself (674 civilians and 67 firefighters). Fifty fatalities were indirectly related to a fire event and the specific cause of death for 34 persons was unknown or unclear.
The data was grouped into three time periods: for the entire time period of data, pre 1965, and post 1965. This segregation of data also happens to be useful in distinguishing some patterns over the years, and provided an opportunity to compare demographic context relating to social behaviour and prevalence of technologies such as automobiles.

The analysis examined the:
- demographics
- distribution of fatalities and house loss in time

[1] Referred to as the 'Stay or Go' policy, the policy recommended that either actively defending a well-prepared home or evacuating/relocating well in advance of a fire threat are the best survival options during a bushfire. formed the basis of the Bushfire and Community Safety Position developed by the Australasian Fire and Emergency Service Authorities Council (AFAC) before the 2009 Victorian fires AFAC (2005) Position Paper on Bushfires and Community Safety. AFAC Limited, Victoria, Australia. This position was translated into the prepare, stay and defend or leave early policy in most jurisdictions.

- location of fatal exposure
- importance of weather conditions on loss
- influence of distance to forest on loss

Results and discussion

3.1. Demographics

The gender and age distribution of all fatalities (civilians and firefighters) was studied to help inform specific trends relating to assumed behaviours or activities. Data was grouped into three time periods; for the entire time period of data, pre 1965, and post 1965. The gender role could also demonstrate an evolution of behaviour in the different roles of men and women over the century.
In summary, in earlier fires a higher proportion of the lives claimed were of young children, whereas more recent fires have claimed the lives of a higher proportion of older people. The distinction between civilians (further broken into gender) and firefighters is shown in Figure 1 for the two periods considered and for all known genders (29 unknown). This figure highlights the significant increase of female civilian fatalities in recent fires.

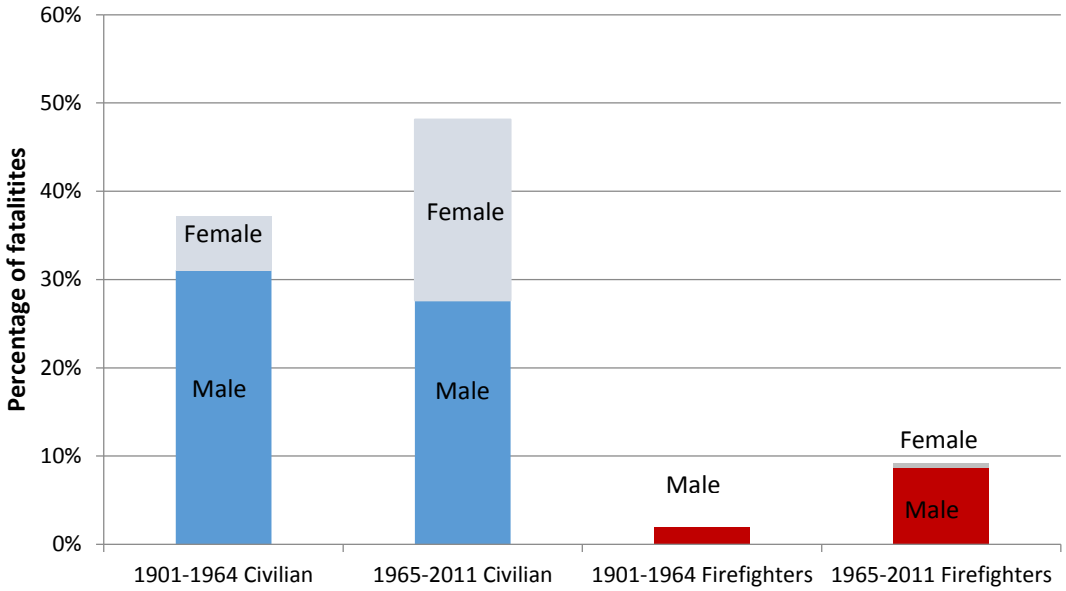

Figure 1. Number of fatalities by gender between the period 1901-1964 and the period 1965-2011 (distinction between civilian and firefighters)

3.2. Distribution of fatalities and house loss in time

The number of fatalities and house loss is dominated by a few major events resulting in large number of the fatalities and house destruction (Figure 2 and Figure 3). This is in accordance with the finding of Haynes *et al*. (2010) and Blanchi *et al*. (2010) which has shown that the losses per event and spatial distribution of loss are strongly influenced by fire weather severity.

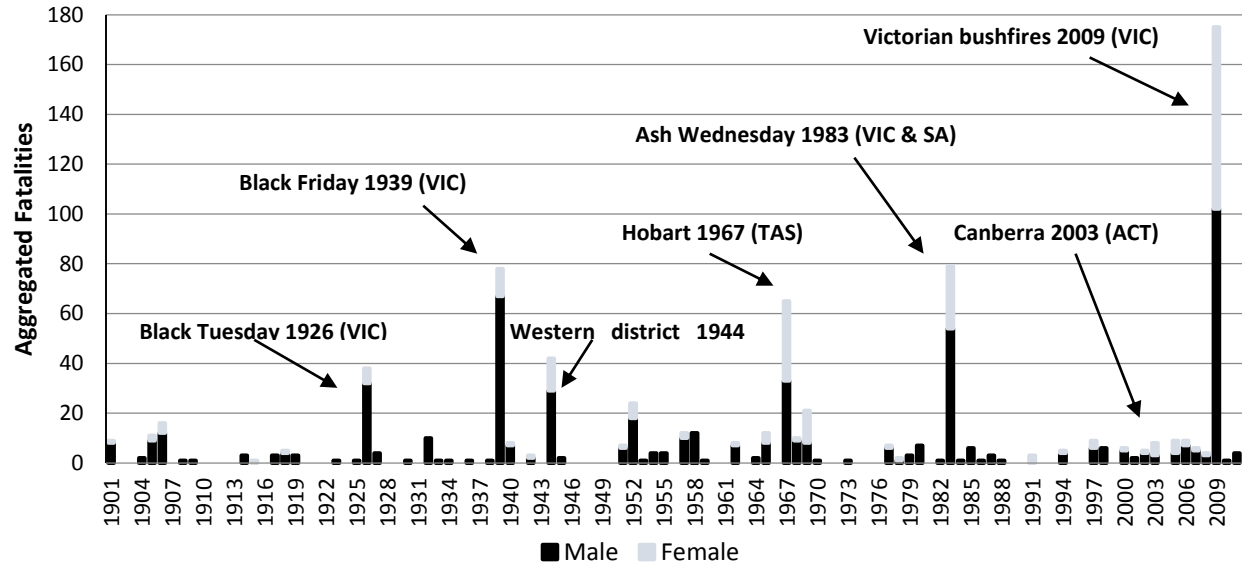

Figure 2. Distribution of number of fatalities over the time period (1901-2011) including civilian and firefighters in Australia

While the graph shows no consistent trend there is an increase in the loss per year rate when comparing the two time period categories (1901-1964 and 1965-2011). For the period 1901-1964, 5.1 civilian fatalities occurred per year and for 1965-2011, 8.6 fatalities occurred per year.
The number of houses lost for the period 1901-2011 shows a similar pattern (see Figure 3) and is dominated by the same iconic events (Blanchi *et al* 2010). There is a more noticeable bias toward losses in more recent years. This is in part due to the lack of house loss data in the 1901-1926 time period and also due to better record of house losses in recent years and an increase of population and houses in fire prone area. Keeping this in mind the 1901-1964 house loss average is 44 per year and the 1965-2011 average is 168 per year.

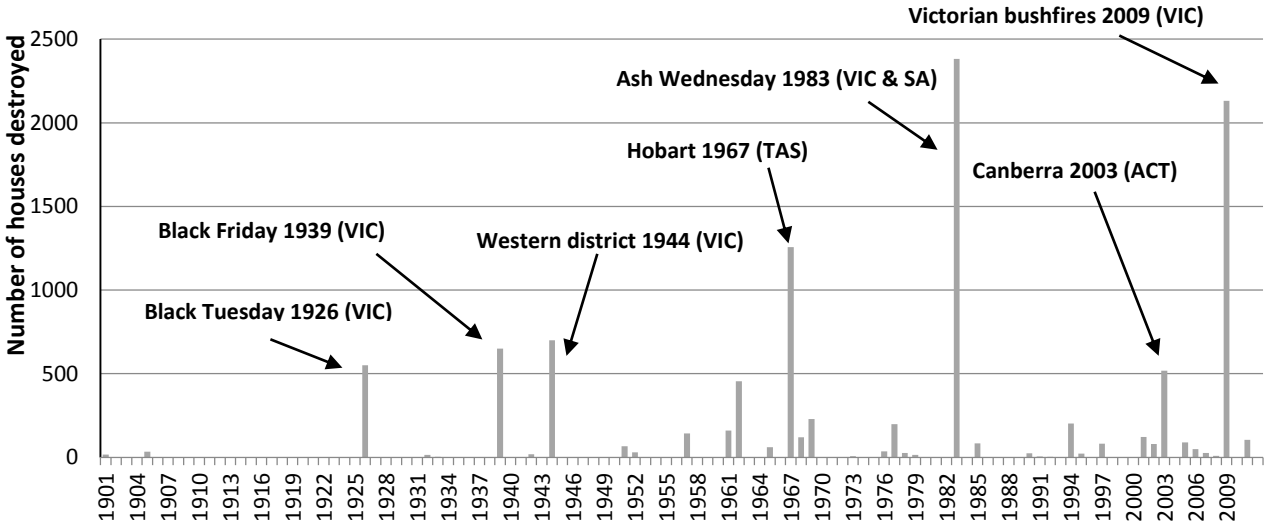

Figure 3. Distribution of number of house burnt (destroyed) over the time period (1901-2011) in Australia

Figure 4 profiles the time of fatal exposure (when known) for both firefighters (44) and civilians (397). This figure shows a clustering of civilian fatalities from 10am through to 11pm with one peak at 10am.

This peak is mainly due to a single loss event, where 17 motorists lost their lives on the Princes Highway between 10am and 11am in the Victorian Lara fire in 1969. Without this anomaly, the civilian fatalities exhibit a normal distribution around 6pm. Firefighter fatalities have a similar fatality time distribution to civilians, with a peak at 3pm and 9pm (which correspond to the Ash Wednesday fire where 12 firefighters died during a burnover).

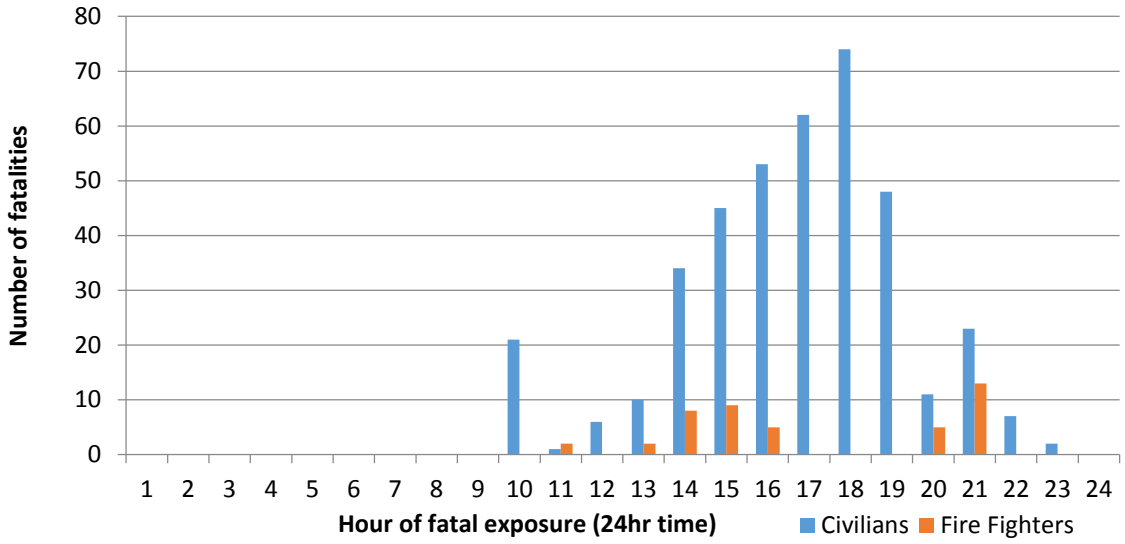

Figure 4. Hour of civilian and firefighter fatal exposure for all directly related deaths

3.3. Location of fatal exposure

The location of fatalities was categorised into 'In structure', 'In vehicle' & 'Open air' to better understand the specific level of shelter a person had when they died. Table 1 summarises the location categories of fatal exposure for the three time periods (1901-2011; 1901-1964; and 1965-2011) with 58% occurring out in the open, 28% occurring inside structures and 8% in vehicles.

A significantly greater proportion of fatalities occurred inside structures or inside vehicles in recent fires, compared to earlier fires. The higher proportion of fatalities inside vehicles in the time period 1965-2011 is explained by higher prevalence of cars and their use during this period. This summary also highlights that in earlier fires a significantly greater proportion of fatalities occurred in the open air, compared to more recent fires.

Male and female civilian fatalities within structures were evenly represented, while male fatalities out in the open were approximately 3 times greater, particularly earlier in the century. This is possibly related to job profiles that involve remote location work such as timber felling where shelter is not easily found or farmers attempting to save livestock (Blanchi *et al*., 2012).

Firefighter fatalities occurred in open air, in fire fighting vehicle burn-over incidents or from falling trees. Sheltering within a structure is a relatively rare and often unavailable strategy for firefighters.

Table 1. Fatal exposure location categories over the three time periods (civilian)

	1901-1964	**1965-2011**	**1901-2011 (total)**
Inside structure	21 (7.1%)	167 (44.4%)	188 (27.9%)
Inside vehicle	11 (3.7%)	45 (12.0%)	56 (8.3%)
Open air	232 (77.8%)	158 (42.0%)	390 (57.8%)
Unknown	34 (11.4%)	6 (1.6%)	40 (5.9%)
Total	298 (100 %)	376 (100%)	674 (100%)

The distance of a fatality to their residence can help qualify the prevalence of behaviours in relation to last minute evacuation or alternative shelter and defence strategies. A sample set of 116 fatalities from the Life Loss database for which residential address and fatal exposure locations were both accurately known was analysed. This sample set included 79 fatalities that occurred in open air, 18 that occurred inside a vehicle and 19 inside a structure (other than their residence, e.g. a neighbouring house, bunker etc). These cases have been plotted as cumulative graph in Figure 5.

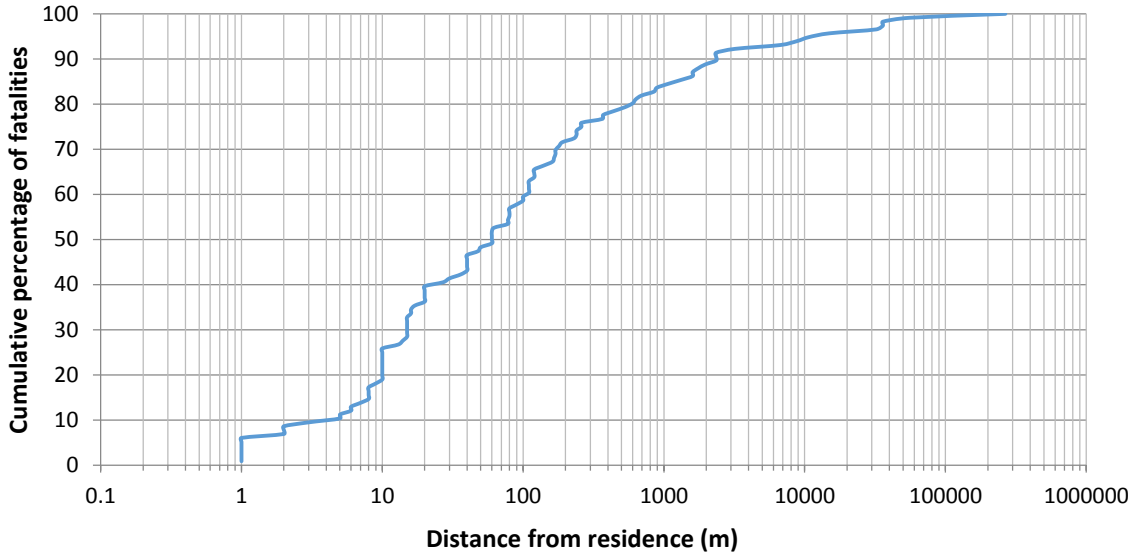

Figure 5. Distance between residential address and fatal exposure location (civilian)

Table 2 shows a close association with the place of residence, with 61% of fatalities occurring within 100m of their location of residence and 84% occurring within 1km. Analysis of the locations of residence of the deceased showed that 10 houses were not damaged and were not used as a shelter, 89 houses were completely destroyed and of these 20 houses were used as a place of refuge during the event. The main activity of the fatalities considered in the analyses was late evacuation (48.3%), followed by saving livestock, livelihood or defending wider property outside (20.7%), and people sheltering as a group (11.2%).

For the fatalities that occurred inside structures it is useful to understand the location within the structure in which the fatal exposure occurred, as this will help to understand the behaviour adopted and the modes in which the house may have lost its tenability. Table 2 shows the location of fatality inside residential structures.

Table 2. Known fatality locations inside residential structures

Location inside structure	Number of fatalities	Percentage of known
Bathroom	36	33%
Kitchen	25	23%
Bedroom	17	16%
Study	10	9%
Enclosure under house	9	8%
Entrance	5	5%
Lounge	4	4%
Laundry	3	3%
Total	**109**	**100%**

Of these cases 33% of the fatalities occurred in bathrooms which typically have no clear visual cues to outside conditions. All other cases either involved an opportunity to monitor outside conditions or be adjacent to an exit to facilitate egress when the house approaches untenable conditions. Eight percent of cases were in either the entrance or laundry: both typically are adjacent to an exit door providing an option to egress if conditions allowed.
Fifty-eight percent involved fatalities in the bathroom, bedroom or study which all typically have only one point of exit to the rest of the house. Twenty-seven percent of cases involved kitchens and lounge areas which usually have opportunities for viewing outside conditions and multiple options to progress through the house towards an exit if it is recognised that the house is losing tenability.
In summary, for 59% of the fatalities there was the opportunity to effectively monitor both the internal and external conditions and make decision to move towards an exit as the house lost tenability. So either people were not aware of this strategy (or the need to leave) or the houses lost tenability at a rate in which safe passage from these locations to an exit door was not possible. This raises several questions in relation to egress, sheltering and the rate of loss of tenability of houses. Also to consider are the air toxic emitted and exposure concentrations inhaled by residents both indoors and outdoors (Reisen, Blanchi, & Tibbits, 2006).

3.4. Weather conditions and loss

The influence of meteorological conditions on loss has been shown in previous studies (Raphaele Blanchi *et al*., 2010; Bradstock, Gill, Kenny, & Scott, 1998). The weather conditions (using forest fire danger index) and aggregated fatalities and house loss by fire event is studied.
The FFDI is categorised according to the existing national danger rating scheme[1]:

- 0-11: low - moderate
- 12-24: high
- 25-49: very high
- 50-74: severe
- 75-100: extreme
- >100: catastrophic (Code Red in Victoria)

The cumulative percentile of both house loss and fatalities is related to the 3pm FFDI on the day of the loss (see Figure 6). Less than 3% of house losses and fatalities occurred when the FFDI was less than 49 (moderate to very high), roughly 7% occurred when the FFDI was between 25 and 50, and 25% of either house or life loss occurred when the FFDI was below 74. Over 60% of all fatalities and 75% of all house loss in Australia has occurred on days where the 3pm FFDI exceed 100.
Three large events dominate the results in the over FFDI 100 category: the Black Tuesday fires (7 February 1967) in Hobart, the Ash Wednesday fires (16 February 1983) in Victoria and South Australia, and the Victorian bushfires (7 February 2009).

[1] http://www.cfa.vic.gov.au/warnings-restrictions/about-fire-danger-ratings/ (accessed 15/06/2014)

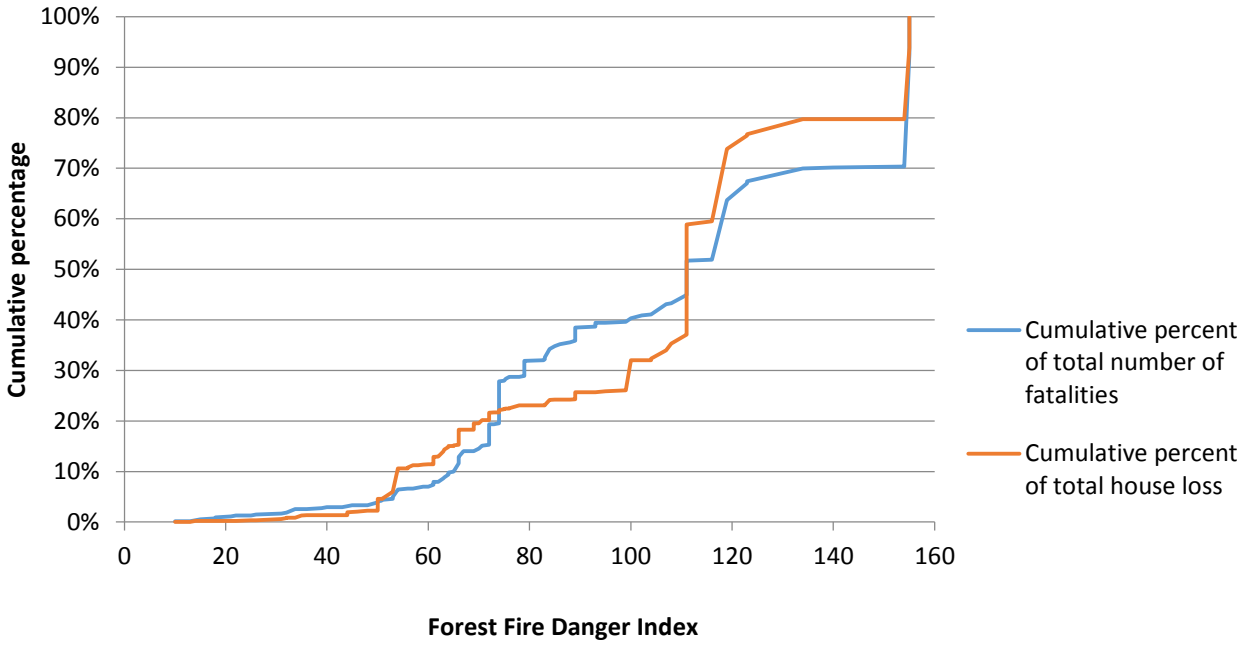

Figure 6. Cumulative percent of total number of fatalities and house loss versus FFDI

The location category of fatal exposure was compared to FFDI classes in Figure 7. There is an expected link with the location of fatal exposure and fire weather severity owing to the different vulnerabilities of each location context. The most noticeable result is the high prevalence of deaths inside structure for an FFDI of 100 plus category (fire danger rating 'catastrophic'). This may be due to a tendency to seek shelter from both the severe weather and the fire under such intense conditions. It also indicates that houses are likely to lose tenability more rapidly under these conditions and cause entrapment. At lower levels of FFDI (0-74) civilians are caught outside as the predominant loss location category.

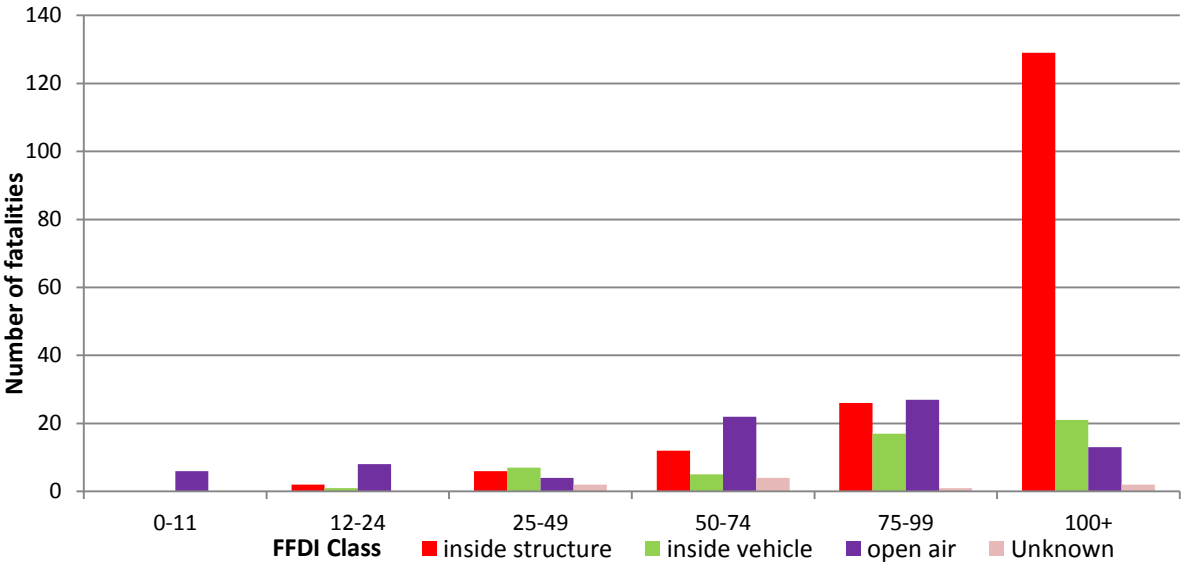

Figure 7. FFDI at 3pm and location of fatality (Blanchi et al. 2014)

3.5. Distance to forest

The separation between bushfire fuels and the fatality is an important risk assessment metric to classify likely exposure levels on the person, vehicle or structure. For the spatial analysis, the forest layer of the closest preceding year to the fire was used to determine the distance to forest. It is assumed that the layer which coincides with the year of the fire has a high likelihood of the fire scar affecting extent of forest for that year.

Of particular interest is the observation that over 50% of all fatalities occurred less than 10m from the forest, 78% in less than 30m and 85% in less than 100m. This provides a strong qualification of the possible influence of forest proximity as a factor in defining exposure resulting in fatal outcomes (Blanchi *et al*. 2014).

Comparing these percentages with the broader dataset of house loss as a function of distance to forest demonstrates that house loss involving fatal exposure are far more dominant in the 0-30m from forest regions. Compared to house losses not involving fatalities, less than 60% of all house losses occurred less than 30m from the forest (Newnham *et al*., 2012). It is to be noted that 30m is a distinctive threshold for direct radiant heat ignition of structures identified by Cohen (Cohen, 2008).

Conclusion

The database developed integrate information on losses including details of fire weather severity (using the McArthur Forest Fire Danger Index (FFDI) and its individual components), fire behaviour, proximity to forest, incident circumstances, fatality details, activities and the location of objects and structures related to the fatality. This paper focused on a subset of the analysis developed in the study, more information is available in Blanchi *et al*. (2012, 2014).

The study provided a better understanding of the circumstances of losses in particular the importance of fire weather conditions and proximity to fuel hazard in setting the context for loss. The findings of the study can be directly integrated in policies and community education initiatives for bushfire related life risk reduction.

Acknowledgement

This research was funded by the Australian Attorney General's Department (via Bushfire CRC). We gratefully acknowledge all the people who contributed to this research from various governmental and research organisations: The Australasian Fire and Emergency Service Authorities Council, Department of Environment and Conservation, Department of Fire and Emergency Services formerly the Fire and Emergency Services Authority of WA, New South Wales Rural Fire Service, Country Fire Authority Victoria, Tasmanian Fire Service, Department of Sustainable Ecosystem, ACT Emergency Services, Queensland fire and rescue service; Coroners Court of Victoria, New South Wales, and South Australia, Public record from Victoria, New South Wales and South Australia; Department of Climate Change and Energy Efficiency, Lucinda Coates and Robin Van den Honert (Risk Frontiers), Chris Lucas (BOM), Joshua Whittaker and John Handmer (RMIT).

Abstract
Large wildfires keep on developing in the French Mediterranean region, regularly threatening responders. We tested if these large fires could be classified into types, and if these types were representative of different environmental drivers. To proceed, we established a database comprising 153 of the largest fires from the last 25 years. For each fire we collected three datasets to describe the environment, the fire behavior and the control operations. We performed a hierarchical clustering analysis followed by a predictive analysis with *Bootstrap Regression Trees*. Fires were classified in 8 types that could a posteriori be reduced to 5 types. The *One-way* type was featured by moderate environmental parameters, the *Multi-way* type was featured by slope, the *Winding* and *Rapid* types were featured by wind, while the *Very large* type was featured by the drought code. Moreover, the probability of having vehicles trapped in a large fire was primarily correlated with the number of vehicles assigned for suppression. This study provides the basis for upcoming trainings of Fire Analyst in France. It paves the way for further research on predictive wildfire danger mapping.

Keywords*: Forest fires, Firefighters, Hierarchical classification, Danger, Wind direction, Propagation rate.*

Introduction

South-Eastern Mediterranean France is the major fire hotspot region in this country since each year it records about two-thirds of the 4,000 fire ignitions, and the mean annual burned area is 20,000 ha (Promethee 2014). Wildfires in this region constitute a major threat to human life and infrastructures thus generating high damages and costs like in other worldwide Mediterranean regions (San-Miguel-Ayanz *et al.* 2013). Fires are also a major landscape driver and the main disturbance for many ecosystems (Keeley *et al.* 2012). Most fires occur during the summer drought period and are crown stand-replacing fires. Wildfires are a major challenge for policy makers due to their costly suppression (San-Miguel-Ayanz *et al.* 2013).
Wildfires are especially active in South-Eastern France because this region encompasses many fire conducive features: the Mediterranean climate characterized by long summer droughts and frequent strong winds (mistral) (Curt *et al.* 2011), a high population density inducing numerous fire ignitions in the road and house vicinities (Curt and Delcros 2010), and large connected stands of flammable forests and wildland fuels due to natural afforestation and a positive fire-fuel feedback in shrublands (Curt *et al.* 2013). The increasing population density and the extension of rural-urban interfaces favor fire ignitions and enhance human vulnerability (Lampin-Maillet *et al.* 2008). Models for the next decades predict the same trends in land cover and land use changes than along the past decades ; therefore inducing an enlarged expected proportion of vulnerable areas (Moreira *et al.* 2011).

Based on the climate part of the global change, increase in mean temperature associated with more frequent heat waves should also extend fire seasons and should in turn generate higher pressure on fire suppression forces (Moriondo *et al.* 2006).

Wildfire size distribution is typically asymmetric with many small fires and few large fires. However, as in many regions around the Mediterranean basin, these large fires are those which threaten the most people and ecosystems (San-Miguel-Ayanz *et al.* 2013). Definitions for large fires vary according to the context: in France fires larger than 100 ha are generally considered as large. They are 741 among the 442,000 recorded from 1989 to 2013 and archived in Promethee database. They are often characterized by spotting and high rate of spread, these characteristics making them difficult to control, and reducing the range of suppression options (Moreira *et al.* 2011).
In 1992 a new policy and strategy for French fire prevention and suppression has been established after a number of large and destructive fires along the previous decades (Battesti 1992). First, it is based on improved prediction of daily fire danger, increased communication on fire risk, and banning of human frequentation in forests during the days at risk. Secondly, it relies on a hard-hitting, initial attack of all fires, concentrating all the fire suppression means available (Direction de la Sécurité Civile 1994). This strategy has been proved effective for small-to-medium fires since the mean annual burned area has decreased since 1992, while ignitions have remained rather constant and population and infrastructures have increased (Promethee 2014). However, large and destructive fires still occur every year escaping initial attack and burning hundreds or thousands of hectares.
We hypothesize that large fires will remain frequent in the South of France for two main reasons. First, the improved fire suppression leads to a negative selection to the benefit of the largest ones. This process paradoxically favored by an efficient fire policy has been referred to as the 'fire paradox' (Sande Silva *et al.* 2010): if fire suppression is effective and reduces the area burned, then wildland fuels accumulate and fuel connectivity increases across the landscape, thus increasing in turn the likelihood of large fires when fire suppression forces cannot control them at the initial stage. Secondly, fire suppression forces will face new challenges: climate change will likely favor more intense and more frequent fires and the extension of the area at fire risk while fire suppression crew and equipment may remain constant due to stagnation of financial resources allocated. The firefighters will have to operate on larger territories, including abroad.
All these arguments pledge for better understanding of the large fires and their drivers. We proposed to build a classification of main large fire types and to explore conditions for their propagation. Such classification has already been established for Catalonia (Spain) (Costa *et al.* 2011). While climate and fuel are similar in both regions, this classification has not been applied for France mainly due to differences in suppression strategies, as well as to coarse database information preventing such analysis. However such knowledge would allow fire brigades to base their intervention on a scientific, fast and robust methodology for forecasting fire risk and fire behavior. This approach is typically that of 'Fire Analysts' whose expertise is to predict the likely behavior and danger of a fire in relation to weather, topography and fuels (Castellnou *et al.* 2010). A high technical level based on scientific analysis has to be promoted to offset the empiric knowledge of local conditions that tends to decrease in Fire Services due to the decline of training over small fires.
In this study we investigated French Mediterranean fires larger than 200 ha that have occurred along the 25 last years in order to answer the two following questions: are there different types of large fires characterized by a typical behavior and typical level of danger for responders? What are the specific environmental drivers (vegetation, topography, fire weather) for these fire types?

Materials & methods

Fire database

293 wildfires larger than 200 ha are reported on the Promethee database for the 1989-2012 period. To proceed, we collected *fire behavior data* describing the fire scenario, *environmental data* describing the fire environment (weather, fuel and topography), and *fire suppression data* in relation with human response to fire. This data collection required to get sufficiently detailed reports on each fire or to interview fire managers and commanders in 15 different fire agencies throughout the South of France. 38 Fire Officers and Forest Officers in charge of key positions during the fires were questioned and 81 paper or computer reports were investigated. We compiled detailed information for a subset of 153 among the 293 fires. The covered area extends from the Alps to the Pyrenean Mountains including Provence and Languedoc limestone plateaus as well as Corsica Island.

Each fire perimeter has been georeferenced on a dataset stored by the French Forest Department (Office National des Forêts). The accuracy of this database has been previously tested (less than 0.05% difference) by comparing ground collected fire perimeters with remote sensing inferred perimeters (Curt *et al.* 2013).

All spatial analyses were performed using the open source Geographical Information System *QuantumGIS 2-2 Valmiera* (http://www.qgis.org).

Fire behavior data

We investigated three variables of fire behavior. The first one was the final area (SURF, in hectares) representative of the total area burned georeferenced. It can be slightly different from the one registered on the Promethee database which is given by responders sometimes with less accuracy, especially for the oldest fires. We interpreted SURF as an indirect and synthetic indicator which differentiates the large fires (hundreds of hectares) from the very large ones (thousands of hectares).

The second variable was the mean rate of propagation (HaH, in hectares per hour), featuring the overall fire increase and not only its axial rate of spread. It was extrapolated from both officer interviews and post-fire reports. The method consisted in rebuilding the isochrones of fire propagation. Assuming that the precise time of ignition and the final time of extinction were difficult to know, we focused only on the 10 to 90% extension of final area burned of each fire. Rapid fires were interpreted as dangerous since they spread more rapidly than the fighting resources can move.

The third variable was the angle change of the main propagation direction (DIRCHG). It was investigated assuming that changes result from specific combination of environmental data. When the main axis of the fire trajectory opened to an angle lower than 60°, it was considered as a non-significant change of direction (coded as 0). When the direction angle change was higher than 60° but less than 90° with constant wind, it was assumed to be a 'winding' fire (coded as 1). In all other cases with angle change higher than 90°, it was coded as 2. These fire direction changes are challenging for responders since they modify the position of active fire lines.

2.3. Environmental data

Weather during a fire event is crucial for explaining its size, its shape, and its danger (Pyne *et al.* 1996). Fire weather is often assessed using the Fire Weather Index (FWI), which is an integrative and unitless index that was designed originally to forecast fire risk in Canada on the basis of daily past and current weather conditions (Van Wagner 1987). The FWI consists of six components accounting for air temperature, relative humidity, surface wind speed, and the last 24-hour rainfall (Groot *et al.* 2007). The FWI and its sub-indices provides a uniform, numeric method of fire danger rating throughout an area and have been extensively used in the Mediterranean basin regions (Giannakopoulos *et al.* 2012). In this study we computed the FWI and its sub-indices for each fire using a daily integrative model on a 2 * 2 km grid. As some fires were very large, each of them was assigned the mean value of the index

within the fire perimeter. We especially focused on: (i) the duff moisture code (DMC), representative of the average moisture content of loosely compacted organic layers of moderate depth, it gives an indication of fuel consumption in medium-size woody material such as shrubs; (ii) the drought code (DC), representative of the average moisture content of deep, compact, organic layers, it indicates the seasonal drought effects on forest fuels. By selecting these two indexes, we integrated together rainfall, temperature and relative humidity. We chose to directly use the wind speed variable (WINDSP in meters per hours) without going through the fine fuel moisture code of the FWI because this last sub-index has been recognized to be nearly saturated during the entire summer season in Mediterranean region. WINDSP values were collected from the closest weather station to the fire (Meteo France 2014).
Vegetation composition within the area burned was characterized using the 1986 and 2006 French Forest Institute maps (Institut Forestier National, BDForêtV1; http://inventaire-forestier.ign.fr). These maps being updated from inventories performed every 10 years, the last statement before fire was considered. The vegetation type of every 2.25Ha forest or natural unit is given from photo interpretation of aerial images in infrared color. Depending on the inventory date, there were up to 75 different fuel classes that we aggregated in only four classes for the purpose of this study: broadleaved forests, pine forests, shrublands and other – this last class covering all agricultural, grassland and urban spaces. The considered data were the percentage of each vegetation class within the area burned.
The average slope for each fire was obtained by crossing the Digital Elevation Model from the National Geographical Institute (Institut Geographique National, BDAlti25; http://www.ign.fr) with the layer of fire final area.

2.4. Fire suppression

We collected the number of vehicles considered as terrestrial resources (RESS) and indicative of the means for suppression. The chosen value represents the maximum number of fire appliances simultaneously committed, excluding logistic support and command vehicles.
Any reported accident injuring a responder or destroying an appliance was finally pointed as a trap (TRAP). The cases of little diseases, very common on such large fires and often linked to warmth and efforts in smoky conditions were not considered. Neither were traffic accidents of responders outside the fire perimeter.

2.5. Data analysis

All statistical tests and modeling were performed using the statistics program R (R Core Team 2013). The final area (SURF) and mean rate of propagation (HaH) variables were both divided into three classes each using the Jenks natural optimization method which minimizes each class average deviation from the class mean, while maximizing each class deviation from the means of the other groups (Jenks 1967).
A first fire classification was performed on fire behavior data, using the R Cluster package (Maechler *et al.* 2013). The Partitioning Around Medoids (PAM) method was used with Euclidean distances and standardized data (Reynolds *et al.* 1992). Results were plotted on a map to identify homogeneous areas in term of fire types.
To assess the influence of the environmental data on each fire class, we used the *Bootstrap Regression Trees* (BRT). This statistical method is particularly suitable to explore ecological drivers and to optimize the predictive performances (De'Ath 2007). Furthermore, it is flexible and easy to read (Elith *et al.* 2008) and it considers any collinearity among variables. We proceeded with the *dismo* and *gbm* packages (Hijmans *et al.* 2013; Ridgeway and others 2013) using a Bernoulli type error. Several regression trees were calculated on calibration data using a "boosting" process. Half the dataset was used to build the model and the other half to test the class accuracy. The number of trees in each BRT was automatically set at 20 with a 0.5 fraction and a 0.005 learning rate. We assessed model prediction

accuracies using the area below the receiving operator curve (AUC) (Pearce and Ferrier 2000). The performance was considered as excellent when AUC>0.9 and weak when AUC<0.6.

In order to assess if the types isolated with BRT correspond to different level of danger for responders, we calculated for each of them the rate of fire where resources were trapped and the Student confidence interval (Eq.1) where this rate would have been statistically supposed to be:

$$CI_{\alpha} = [f - z_{\alpha/2}\sqrt{(f(1-f)/(n-1))} \; ; \; f + z_{\alpha/2}\sqrt{(f(1-f)/(n-1))}] \qquad (Eq.1)$$

with CI_{α} the interval with α probability, f the rate of trap in the database, $z_{\alpha/2}$ Student coefficient, and n number of fires in the type.

Assuming that the probability to have resources trapped (TRAP) is closely linked to the quantity of resources assigned (RESS), the correlation between these two parameters was tested separately with a parametric test of average comparison (Eq.2):

$$H_0: \mu 1 = \mu 2, \text{ with } CI_{(\mu_1 - \mu_2)} = [(\bar{a}_1 - \bar{a}_2) - z_{\alpha/2} * s\sqrt{(1/n_1 + 1/n_2)} \; ; \; (\bar{a}_1 - \bar{a}_2) + z_{\alpha/2} * s\sqrt{(1/n_1 + 1/n_2)}] \qquad (Eq.2)$$

where, for each of both distributions 1 (number of vehicles on fires with trap) and 2 (number of vehicles on fires without trap), μ is the population mean, $\bar{a}$ the observed mean, n number of fires in the distribution and s the weighted variance of both distributions.

Results

Collected datasets

The 153 fire dataset distribution was compared with the 293 fires recorded in the Promethee database (Figure 1). The very large fires, which are generally the best documented, are better represented in the present study: 74% of the > 1000 Ha events *versus* 42% of the 200-500 Ha fires. If geographical distribution of data partly results from the ability to access different regional agency records, the underrepresentation of Haute Corse, where the number of large fire was the most important, is likely explained by the fact that in this territory written reports were few, thus we investigated only through interview and therefore we focused on the post-1995 fires. Moreover, the oldest are the fires, the less information is available, arguing why the 153 dataset includes 37% of 1989-1999 incidents versus 72% of 2000-2012 incidents. Finally, the seasonal variability is clearly represented with 93% of large fire occurrences recorded from June and September.

Dealing with the fire behavior and environmental datasets (Tabl. 1), the windspeed values spread nearly totally on the Beaufort scale, varying from “calm” to “storm” with a mean being “fresh breeze”. The averaged drought index values can be considered as exceptionally high compared to original North-American classification values (Van Wagner 1987). Thus the fires studied here have spread with variable windspeeds but often with important or very important fuel dryness. Shrubland is the most represented vegetation type in areas burned. Most forest stands are dominated by pine, while pines can also be mixed with broadleaved species, generally oak trees.

Data on fire direction change and suppression showed that among the 153 fires, winding was present on 16% of the fires (DIRCHG=1) and a shift on 22% (DIRCHG=2), while 16% of the fires recorded an accident (25 TRAP records).

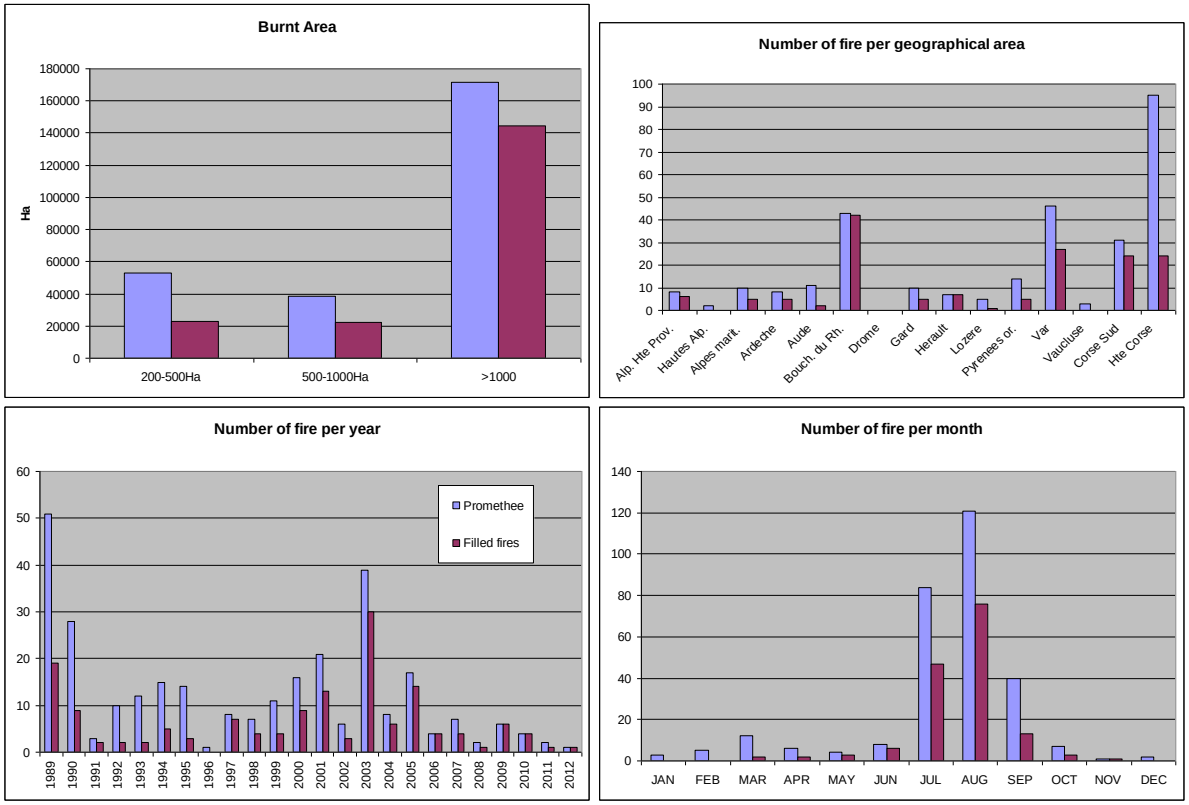

Figure 1 – Comparison of the 153 fires dataset (red bars) with the data recorded on Promethee base (blue bars).

Table 1. Recorded data: windspeed (WINDSP) ; Drought Code (DC), Duff Moisture Code (DMC) ; average slope (SLOPE) ; shrubland (SHRUB), pine (PINE), broadleaved (BRDLV), other fuel (OTHER) ; number of vehicles (RESS) ; prpagation rate (HaH) ; area burned (SURF).

3.2. Fire classification

According to Jenks method results, the final area burnt was splitted in three classes: the 200-1990 Ha class including 84% of the fire, the 2000-7000 Ha class including 15% and the > 7000 Ha class representative of the remaining 1%. In the same way, the three classes for the propagation rate were 1-219 Ha/H for 78%, 220-800 Ha/H for 19% and > 800 for 3% of the fires.

The PAM clustering was optimal with seven groups based on a strong structuration with an average proximity of data of 87% and six of the seven groups with an average proximity > 50%. We gave a describing name to each group based on the three investigated variables (Tabl.2).

In the first three groups, fires have not reached very important area burnt neither very important propagation rate. Among them, the *One-way* represents fires with linear direction, the *Winding* fires with angled propagation axis and the *Multi-way* includes fires that totally changed their propagation axis. The fourth group is named *Vast* because fires have reached an important area with a moderate rate of spread. Finally, the last three groups represent fires that developed the most rapidly, even

extremely quickly concerning the *Mega*. Among these three groups only fires in the *Rapid* did not reach the final area burnt of 2000Ha.
When visually analysed, the spatial distribution of fire groups displays five areas (Figure 2): Western coast (Pyrénées-Orientales, Aude, Hérault and southern Gard), Provence (Bouches-du-Rhône and western Var), Maures/Esterel (Eastern Var and west of Alpes-Maritimes), Mountain (North and east of Alpes-Maritimes, Alpes-de-Haute-Provence, Gard cévenol, Ardèche and Lozère) and finally Corsica (Corse). Three of these areas (Provence, Maures/Esterel and Corsica) seem to be particularly affected by the largest fires but more information would be required to go further in the spatial interpretation, which is out of the present study scope.

Table 2. Fire group based on the PAM clustering and fire number in each group. Each group is assumed to be homogeneous when the average proximity is > 0.5. The group specifications are given for each variable used in the clustering : SURF, HaH, DIRCHG. The final name outlines these specifications.

Gr.	Fire number	Average proximity	SURF *(ha)*	HaH *($ha.h^{-1}$)*	DIRCHG	Name
1	26	0.78	<2000	<800	2	**Multi-way**
2	70	1.00	<2000	<220	0	**One-way**
3	16	1.00	<2000	<220	1	**Winding**
4	10	0.50	>2000	<220	0,1,2	**Vast**
5	16	0.88	<2000	220à800	0,1	**Rapid**
6	11	0.41	>2000	220à800	0,1,2	**Rapide&vast**
7	4	0.79	2000-7000	>800	0,1	**Mega**

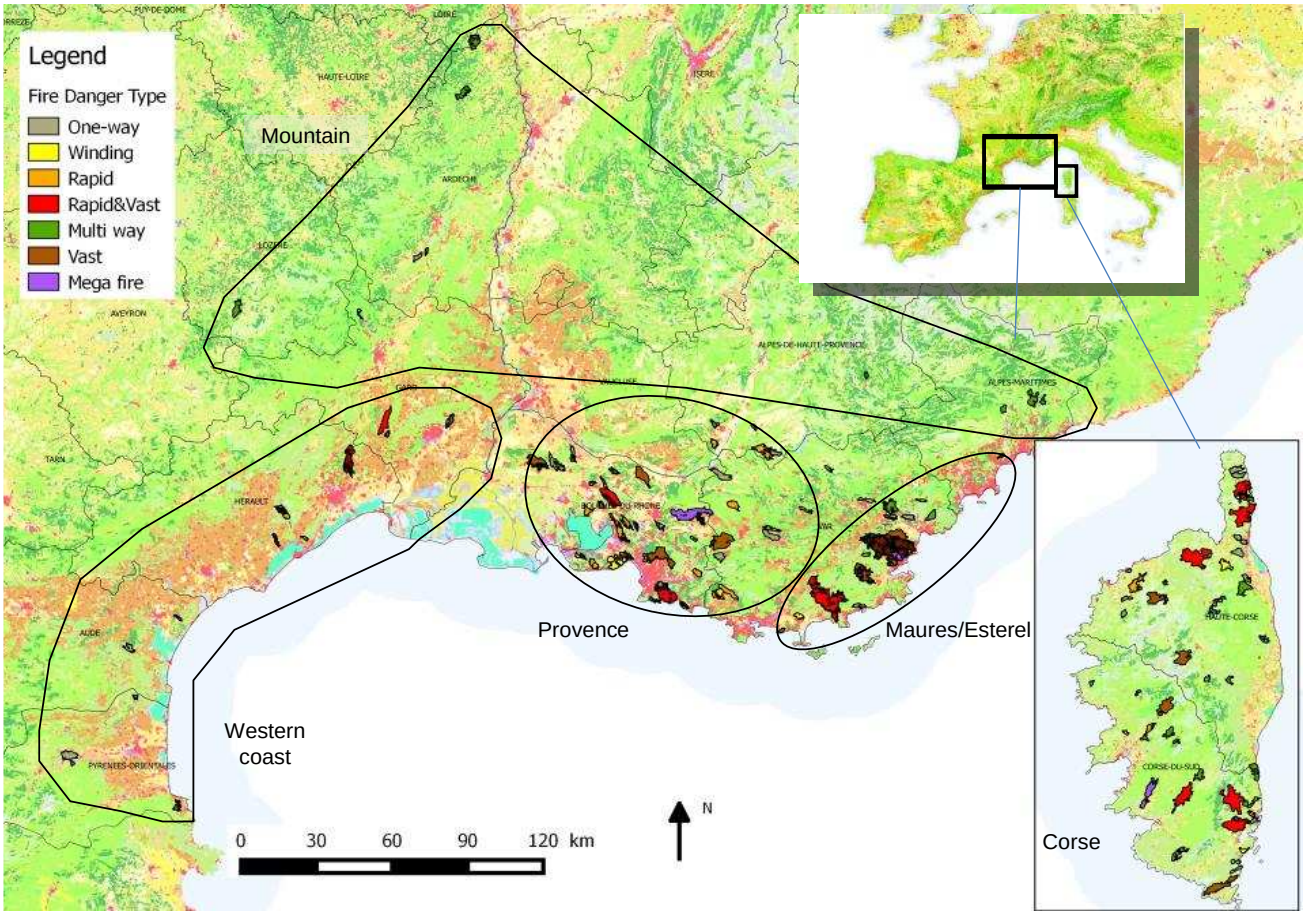

Figure 2. Spatial distribution of fires regarding their group.

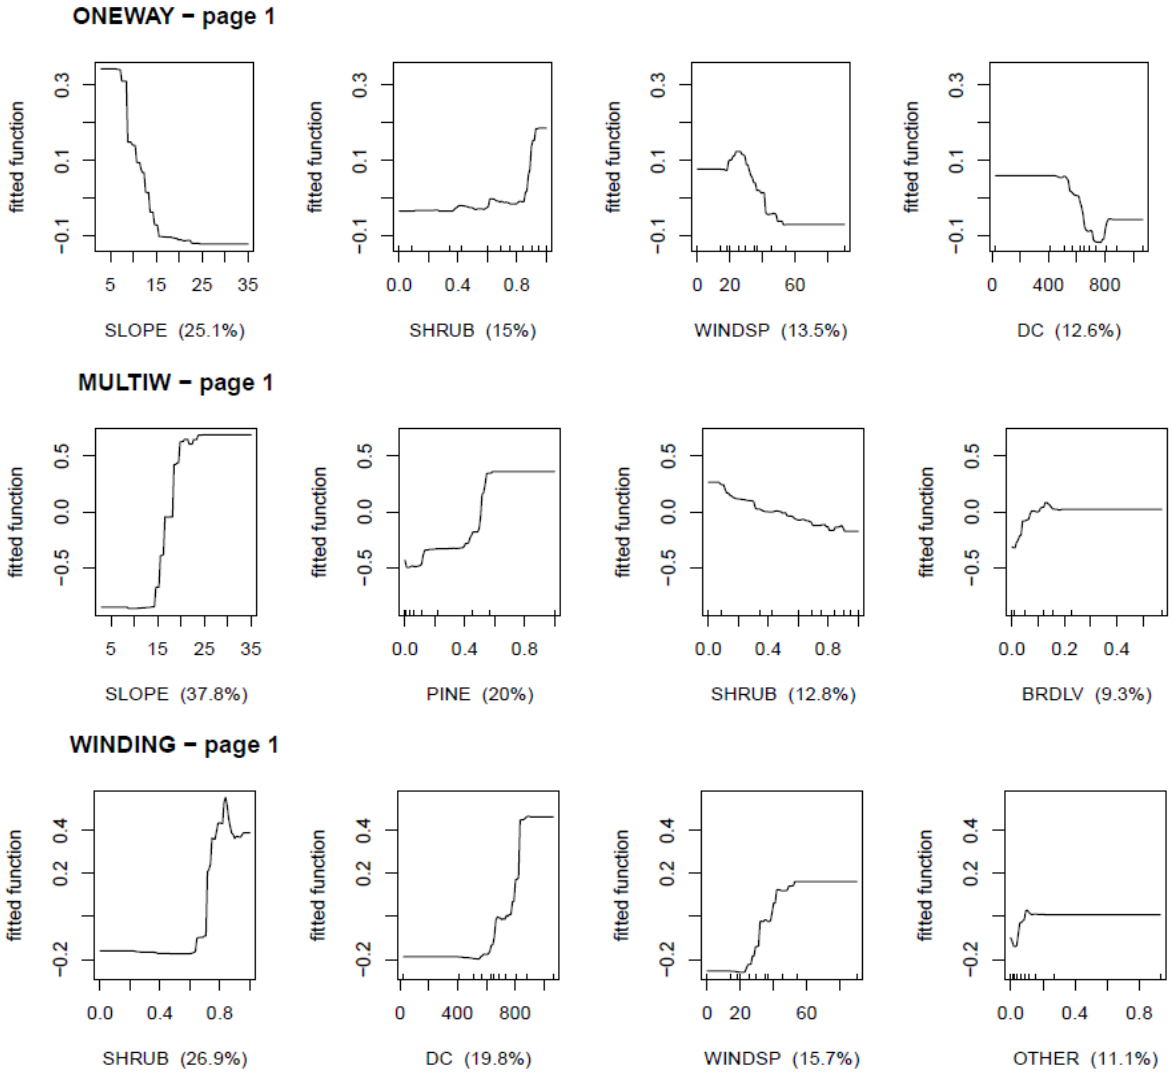
3.3. BRT

The number of fires in groups 4 (*Vast)* and 7 (*Mega)* being insufficient to get convincing results with the BRT method, we gathered all the fires over 2000Ha, ie *Vast*, *Rapid&vast* and *Mega*, in a unique group thereafter called *Very large*.

Positive values of fitted function for each variable determine the data scale linked to the given group (Fig.3). Thus, fires in the *One-way* group are substantially linked to low slope (<12°) with large parts of shrublands (>85%, ie the upper quartile of the distribution), moderate wind (<40 km/h) and low DC (<600 ie the lower third). The *Multi-way* fires are in relation with strong slopes (>17° ie the upper third), >50% of pine and <40% of shrublands. The *Winding* fires occur with >75% of shrublands, DC>750 (extreme value, upper quartile) and significant wind (>30km/h). The *Rapid* fires firstly happen with strong wind (>40 km/h ie the upper third), moderate DC (<500) and slope under 12°. Finally, the *Very large* fires are linked with important DC (>600), between 50 and 90% of shrublands in the landscape and low slope (<13°),.



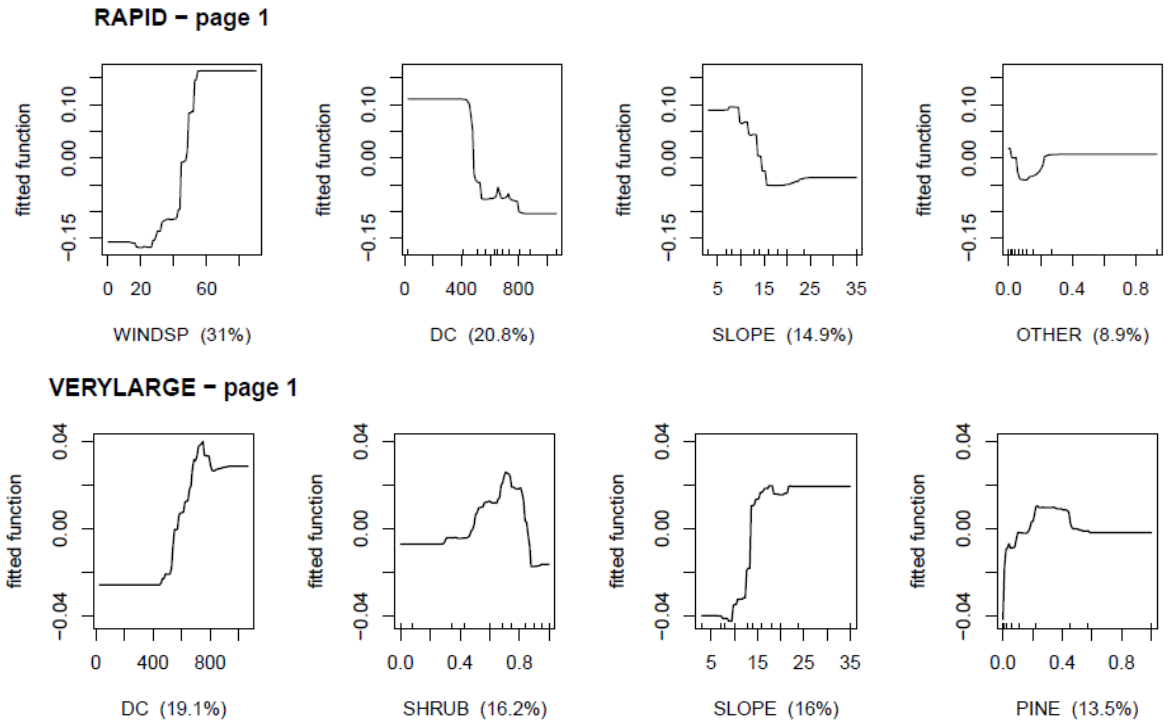


Figure 3. Variance of the 4 most significant variables for each group (horizontal panel including 4 subpanels): One-way, Multi-way, Winding, Rapid and Very large.

We propose in Fig.4 a logical dichotomous synthetizing key to deduce the most likely large fire subtype from environmental data highlighted in the different fire groups. Low DC and low slope will give *One-way* or *Rapid* fire subtypes depending on the wind. High DC values will generate the *Winding* subtype with strong wind and the *Very large* subtype with strong slope. Strong slope will mainly lead in *Multi-way* subtype.

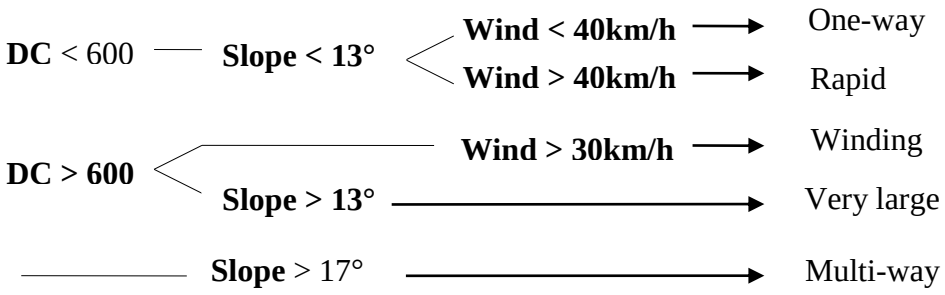

Figure 4. Synthesis of expected fire subtypes according to environmental data.

3.4. **Vehicle traps**

There is no significant difference in any fire group ratio with the overall mean value of 0.16 calculated from the entire studied database, even with a 90% confidence interval (Tabl.3). Nevertheless, based on the regional distribution, we found a significant higher risk in Provence and lower risk in Corsica than elsewhere in average.

Table 3. Accident ratio (TRAP) and 90% confidence interval for each group and area.

	Name	Fire nb.	TRAP ratio	90% C.I.
Group	Multi-way	26	0.11	0.03 – 0.28
	One-way	70	0.17	0.09 – 0.23
	Winding	16	0	0 – 0.32
	Rapid	16	0.31	0 – 0.32
	Very large	25	0.20	0.03 – 0.29
Area	**Corsica**	48	**0.06**	**0.07** – 0.24
	Maures/Esterel	18	0.11	0 – 0.31
	Provence	52	**0.27**	0.07 – **0.24**
	Western coast	18	0.22	0 – 0.31
	Montain	17	0.12	0 – 0.32

Finally, the homogeneity test of mean values of resources assigned with a 99% confidence interval ($CI_{(\mu_1-\mu_2)}$ = [31 ; 119]) showed that there are significantly more accidents in fires with numerous assigned resources.

Discussion

4.1. A suitable classification for France

One of the aims of this study was to check if large fires in South of France could be classified into subtypes. We have found that 46% of them are *One-way* and 10% are *Winding*. That means that 56% of the fires are mainly driven by a constant wind, which may locally take a different direction due to terrain. A small part of fires (17%) belongs to the *Multi-way* subtype. The change of wind direction can either result from a reverse of topographic breeze or from a wind shear, which is frequent in the Maures/Esterel area. Whatever the cause, the fire behavior can be anticipated for this subtype thanks to an adequate knowledge of the local meteorology. Finally, the two last subtypes, *Rapid* (10%) and *Very large* (16%), regroup the fires for which the fighting operations are the most difficult, the less effective and the most dangerous for suppression crews. These fires burned the largest area or reached the fastest propagation rate, sometimes both together.

To our knowledge, there are only similar studies for the Mediterranean region in Catalonia (Spain), conducted by Castellnou *et al*. (Castellnou *et al.* 2010). While we similarly investigated historical fires, we however used a slightly different methodology. Indeed, while the Catalan team considered the synoptic regional weather for each analysed fire, we focused on FWI index parameters in the vicinity of each fire. Moreover, we did not consider the three types of fires commonly accepted (i.e.topographic, wind driven and plume dominated), but we rather observed how our fires were naturally distributed in our study area considering their direction changes and their rate of propagation. Our results are convincing, introducing new subtypes of fires, and call for further research, especially on explosive or convective issues.

4.2. Environmental data as driver of fire types

Our large fire types were driven by environmental data, especially Drought Code, Windspeed and Slope. On The fact that the Duff Moisture Code has not been identified as a driver of any type of large fire could suggest that it may rather characterize smaller fires than 200Ha but this would need more investigations.

We have not kept the fuel composition as a determining factor because the shrubland cover raised as an explaining variable in almost every type. Indeed its fitted functions were all providing information in the same way, with shrub cover being positively correlated to the fire types. *Multi-way* fires are the

exception with shrub cover being negatively correlated to the type and pine and broadleaved cover being positively correlated (the broadleaved signal was nearly flat, so difficult to read). In conclusion, we haven't found relevant to consider forest cover as a driver of *Multi-way* fires since it is an evidence that mountainous areas are the most propitious to this type of fire and together the most forested. The drivers of this fire type are thought to be more likely mountainous environment with wind breezes.

4.3. Link between number of resources assigned and trap probability

No fire type was significantly more propitious to endanger responders. Nevertheless, the trap likelihood was positively correlated to the number of vehicles assigned for suppressing fire. That is likely why accidents are prevalent in Provence area where there is a need to deploy many trucks to protect all the houses threatened by any fire. Conversely, accidents are less frequent in Corsica where the number of engines is much smaller.

4.4. Possible bias in the data

The large fire types we found are based on data coming from reports and interviews that may be partly subjective. Indeed, we called for data records up to 25 years after fires occured in order to rebuild fireline isochrones. Nevertheless, the accuracy of this oral information has been generally tested with crossing the interviews or comparing them to factual archived data.
Moreover, the type of fuel could likely be the less accurate of environmental variables since the vegetation cover was based on geodatabases up to 10 years old. Within this time interval, some land use changes can have occurred such as afforestation of agricultural parcels. That is another reason why fuel data has been interpreted with caution.

Conclusion: implications for fire suppression

In this study we have provided the first classification of large fires dedicated to help fire suppression in South-Eastern France. We have stated several large fire types characterized by their typical fire behavior and environmental drivers. These fire types range along a gradient of difficulty for fire suppression. Some types are predictable using their typical environmental drivers, which suggest that improvements in fire suppression safety and efficiency are possible using this approach.
The basis for classification being established, it is now challenging to have further research on certain types of fire. In particular, we have to investigate 'explosive' fires and convective behaviors to link them to responder traps. Further studies should also focus on the geographical distribution of different groups of fire.
In the workplace, first Fire Analyst trainings are in process in Europe for responders. This study will contribute to set the foundations for training program by proposing a typology related to environmental drivers for Mediterranean France.

Acknowledgements

This study has been funded by the Service Departemental d'Incendie et de Secours (SDIS) 13 through S. LAHAYE's lifelong learning. It would not have been possible without the valuable debriefings of firefighters and foresters from Alpes-de-Hautes-Provence, Alpes-Maritimes, Ardèche, Aude, Bouches-du-Rhône, Corse, Var, Gard, Herault, Pyrennées-Orientales and Var. We thank Marine PASTUREL for her help in data processing.

Abstract
The objective of the study is to present a method for improving the capability of a semi-physical network model to predict large fire patterns in heterogeneous landscapes. The method, which can be viewed as an Autonomous System, consists in generating an amorphous network by sowing vegetation cells on-the-fly. All the information on fire behavior is contained in the very few digital elevation map pixels close to the fire front, in which fuel items are heated or burning. The method is applied to two distinct scenarios: a no-wind and no-slope academic case and a historical Mediterranean fire that occurred in the South-East of France in 2005. Both cases are discussed in terms of CPU time and memory allocation gains.

Keywords*: front-tracking method, meshless method, network model, large fire, autonomous system, amorphous network*

Introduction

As underlined by (Strauss et al., 1989), it is an all too familiar fact that a relatively small number of large fires are responsible for a very high proportion of the total damage. Therefore, simulating the spread of large wildfires, with size up to several tens of kilometers, is a major environmental issue and an active area of research. However this requires the storage and handle of a vast amount of data. As an example, a 10km × 10km landscape, with 60 percent covered by vegetation sites of 2m in diameter, contains approximately 1.5×10^7 sites. Assuming an average number of connections per site of 100, the total number of connections to handle is 1.5×10^9. In order to reduce computational resources, a front-tracking method is here propose.
Another important issue concerns the use of regular lattices (triangular or square lattices) to represent vegetation patterns. However, regular lattices only consider single-class vegetation cover, so they cannot mimic the complexity of natural ecosystems (*e.g.* fuel distribution, polydispersity, mosaic of vegetation types). To overcome this issue, we recommend using an amorphous network.
The combination of the front-tracking method and amorphous network may be viewed as a meshless front-tracking method, hereafter called MFT method.

2. Model overview

Vegetation is here modeled as an amorphous network of cylindrical items where the combustible sites are randomly distributed. A digital elevation model (DEM) represents topography. A weighting procedure on combustible sites is considered in order to account for the effects of ignition and flaming duration (Billaud et al., 2012). The physical model, largely inspired from that of (Koo et al., 2007), is based on the energy balance equation for a control volume of thickness δ located at the top of the cell. δ corresponds to the mean free path of radiation $\delta = 4/\alpha_k\sigma_k$, where α_k is the solid-phase volume fraction, σ_k the surface-to-volume ratio of fine fuel elements. The energy-transfer mechanisms of

preheating considered are the radiation coming from the flame $q^{+}_{rad,fl}(i)$ and the embers $q^{+}_{rad,e}(i)$, and $q^{+}_{conv}(i)$ is the wind-driven convection to the top surface of the receptive cell j

$$\sum_{i=1}^{N_{bc}} \begin{bmatrix} q^{+}_{rad,f}(i) + \\ q^{+}_{rad,e}(i) + q^{+}_{conv}(i) \end{bmatrix} = q^{-}_{rad}(j) + \begin{cases} \rho_{WFF}\ c_{p_{WFF}}\ \alpha_k \dfrac{dT(j)}{dt} & T(j) < 373K \\ -\rho_{DFF}\ L_{vap} \alpha_k \dfrac{dFMC(j)}{dt} & T(j) = 373K \\ \rho_{DFF}\ c_{p_{DFF}} \alpha_k \dfrac{dT(j)}{dt} & 373K < T(j) < T_{ign} \end{cases}$$

$q^{-}_{rad}(j)$ is the radiative heat loss to the ambient, T the fuel temperature, ρ and c_p the density and the specific heat of the solid phase. The subscripts DFF or WFF refer to variables evaluated on a dry or wet basis. L_{vap} is the heat of water vaporization and FMC is the fuel moisture content. The ignition delay is the time required for a site under the influence of N_{bc} burning sites to reach a critical temperature T_{ign}. The dynamic of the system clearly depends on the ignition and flame residence times, t_{ign} and t_c. Details can be found in (Billaud et al., 2012).

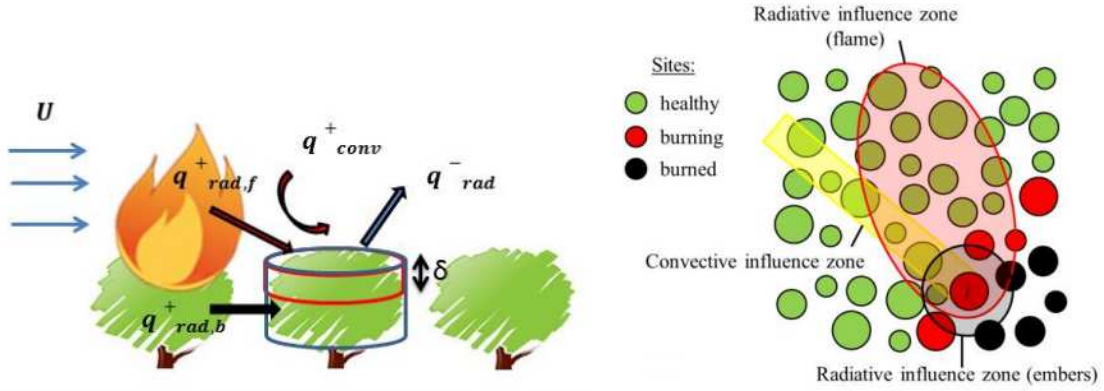

Figure 1. a) Physical problem and b) radiative and convective interaction domains associated to a burning site.

3. Numerical method

The method principle is based on the concept of double indexing: the first is a local indexing of the sites (Holme, 2007), the second is a global indexing of DEM pixels. The main task consists in finding the neighbors of any active site that belongs to a DEM pixel. This can be split into two stages: first, the eight neighboring DEM pixels are identified; second, the sites that belong to these pixels are specifically numbered and stored (Pasquale et al., 2014). If a DEM pixel contains at least one new burning site, the network is updated in order to ensure the continuity of the propagation process. When all the sites of a DEM pixel are burned or too far away from the fire front, the DEM pixel is deallocated.

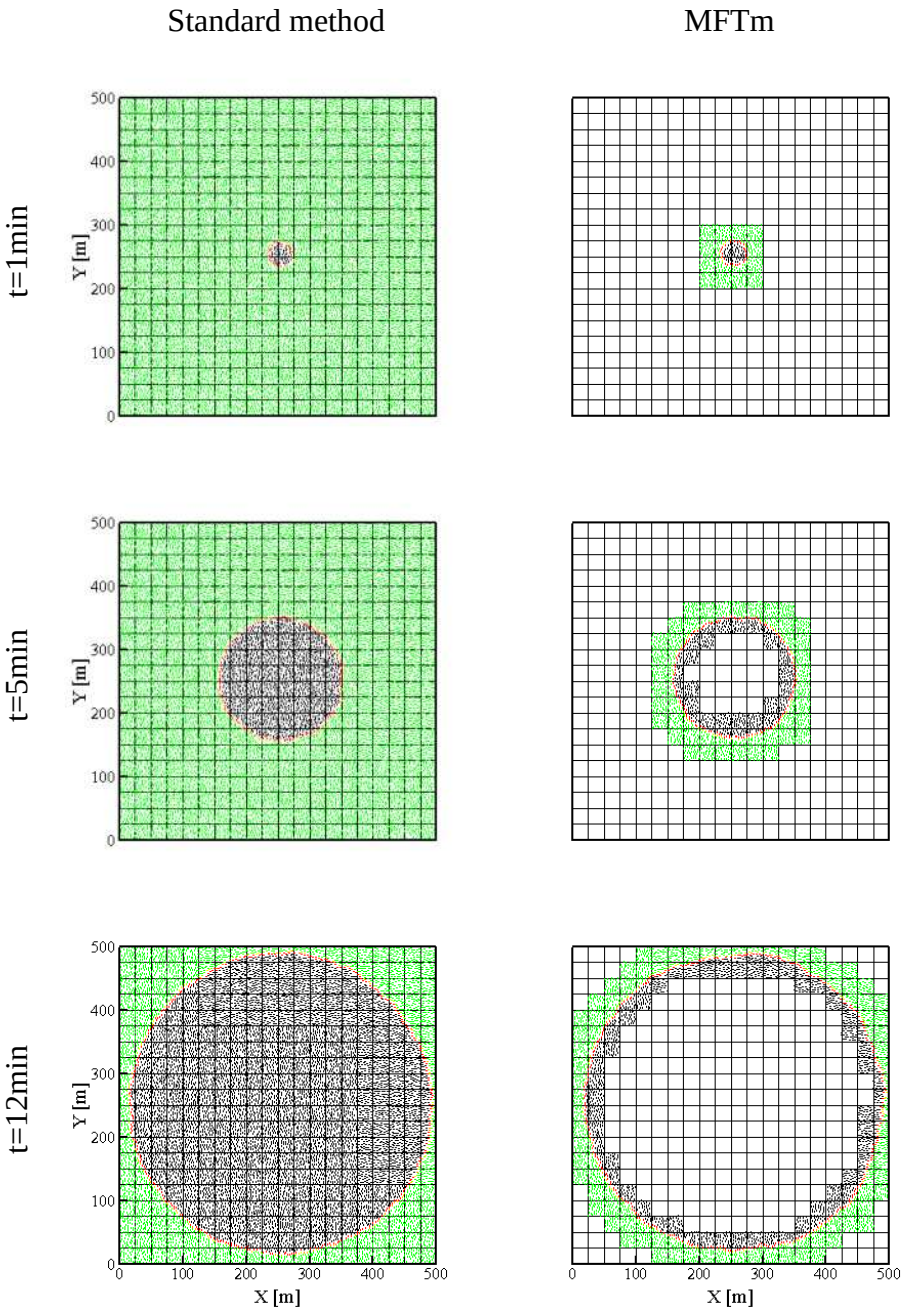

Figure 2. Fire patterns at different instants. Comparison between fire patterns obtained from standard and MFT methods.

Method validation

In order to demonstrate how such a methodology might work in practice, we consider a 500m×500m monodisperse amorphous network of kermes oak shrubs with a diameter of 2m (Figure 2). The terrain is flat and there is no wind. Ignition occurs in the center of the domain. The vegetation coverage is 0.5. Calculation using the MFT method takes 13s on the Intel Xeon CPU E5-3643 (3.30 GHz, 64 bits), whereas it takes 21s using the standard method, leading to a 38% gain in CPU time. As shown in Figure 2, in the early stages of fire spread (*e.g.* t=1min), only 4% of the network is involved using the MFT method. As time progresses, the memory allocation increases due to an increase of active DEM pixels but remains significantly lower than that of the standard method due to the withdrawing of

burned pixels. There are some small discrepancies between the two methods that are due to the stochastic nature of the amorphous network construction.

Small world effects

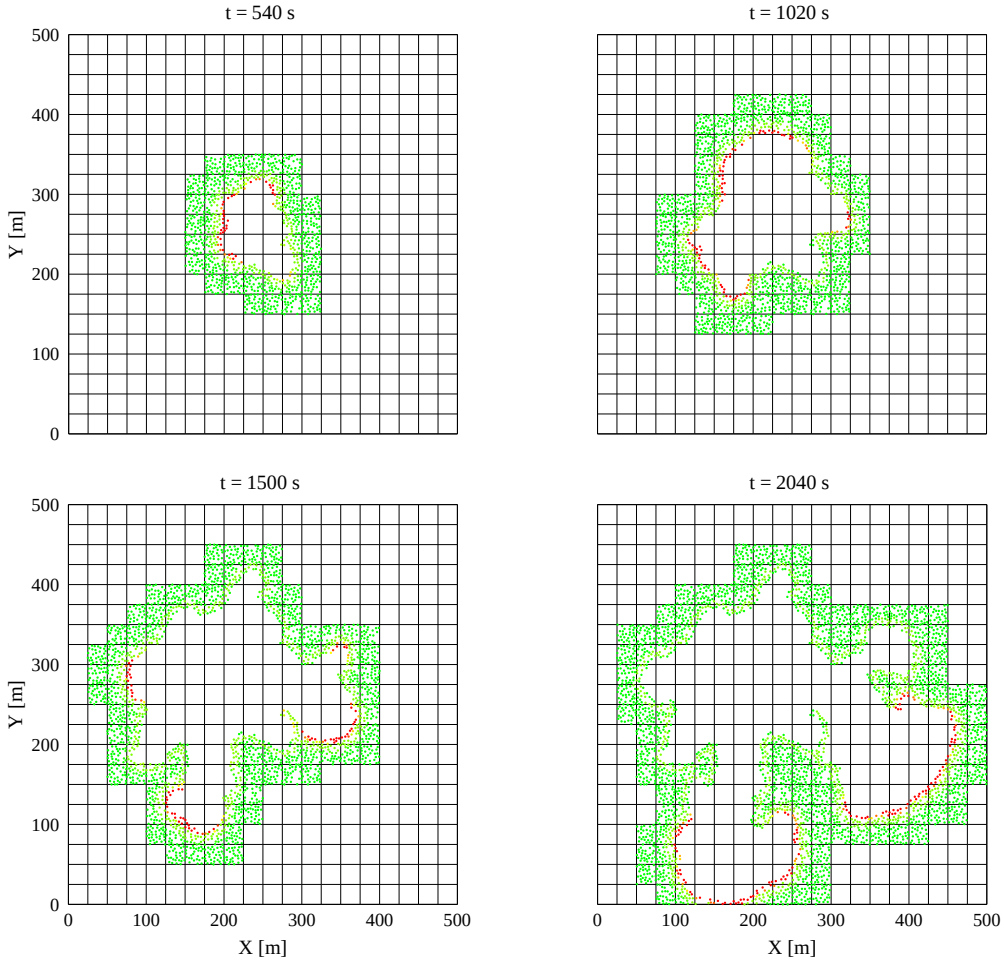

Figure 3. Fire patterns after a) t=540s, b) t=1020s, c) t=1500s and d) 2040s of simulation. The active areas represent about 10%, 17%, 26% and 37% of the total network, respectively.

Here we consider fire spread under the same conditions, except that the vegetation coverage is 0.4. This value is so close to the percolation threshold that small-world effects (clustering, lacunarity, and digitation) occur, as can be observed inFigure 3. Although not shown, similar results are obtained using the standard and MFT methods, with a significant reduction in CPU time and memory allocation.

Large scale simulation

The MFT method is now evaluated by simulating an arson fire that occurred at Lançon de Provence, in France, in July 2005. This fire has been extensively studied and documented by the authors (Adou et al., 2010). Geographical data include a digital elevation model and vegetation map at a resolution of 50 m. The dominant species was kermes oak shrub (*Quercus coccifera*). The weather conditions at the time of fire were: an average wind speed of 46km/h at 10 m above the ground level, an average direction of 330° (NNW), and a dry bulb temperature of 30°C. The CFD program Flowstar© was used to calculate local wind direction and speed from the average wind speed, taking into account the effects of topography and surface roughness of the land site. Two ignition points were reported whose geographic coordinates are 5°11’39’’E; 43°36’6’’N and 5°12’21’’E; 43°35’53’’N.

We consider a 10km×7km monodisperse amorphous network of kermes oak shrubs with a diameter of 3m. The vegetation coverage is 0.5.

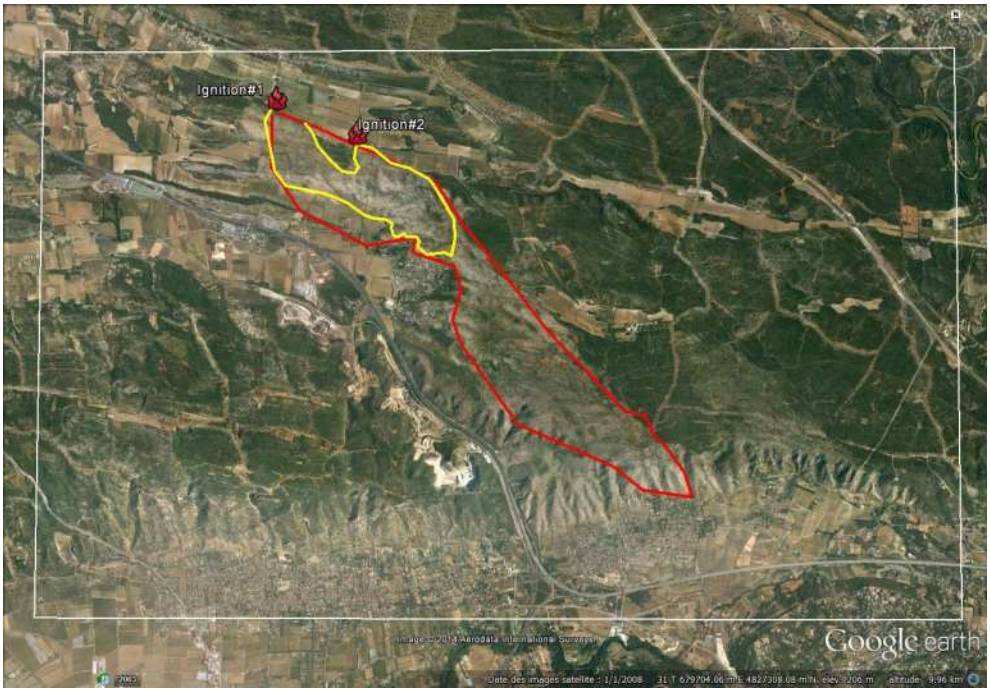

Figure 4. Domain of the study and real fire patterns after t=140min (yellow) and t=300min (red) of propagation.

Contours predicted by the model are compared with field measurements after 140min (Figure 5b) and 300min (Figure 5d) of fire. At t=140min, the average rate of spread is slightly overestimated which leads to a more advanced position of the head fire front. This may be due to time variations in wind properties which are averaged in the model. Integration of time-dependent meteorological conditions is possible but such information is unavailable for the present case. At t=300min, the agreement remains effective. Discrepancies between predicted and real contours, in particular in the lateral extension of the fire, are mainly due to the fire crew intervention which was not introduced into the model because of lack of information on the location and nature of the fire-fighting task force deployed. It may be noted that the model can easily take into account the action of fire fighters by rendering soaked vegetation inactive.

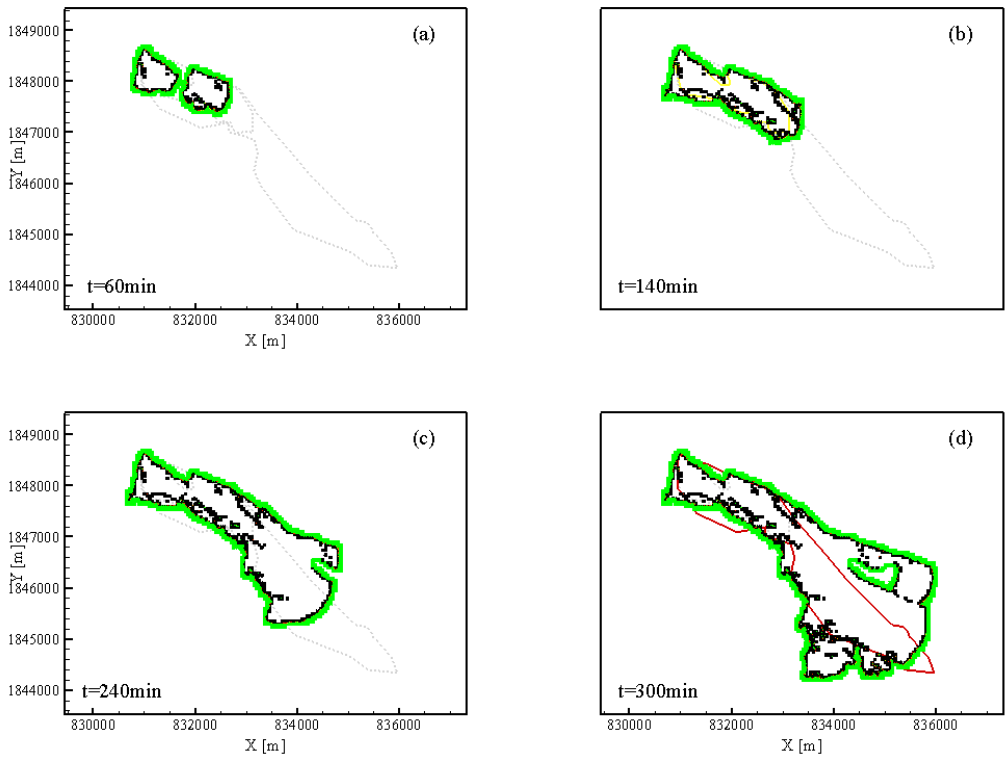

Figure 5. Fire patterns after a) t=60min, b) t=140min, c) t=240min and d) t=300min of simulation. a) and c) are compared with real fire pattern.

As mentioned before, two ignition points were reported for this fire. At t=60min (Figure 5a), the two independent fire fronts interact and merge into a single one. This shows the capability of the method to handle phenomena frequently observed in wildland fire propagation in complex terrains, such as splitting and coalescence of fire fronts. The model can thus be used to evaluate the efficiency of counterfire.

The overall CPU time gains are substantial when using the MFT method as it gives, in the present case, a 450% overall performance gain compared to the standard method. This gain is mainly due to the memory allocation/deallocation strategy, reducing memory allocation and the search space of connections between sites.

Conclusion

A method for improving the capability of a semi-physical network model is used to simulate large fire patterns in heterogeneous landscapes. The basic concepts of the model are recalled and the last improvements, including the use of an amorphous network and the front-tracking method, are presented. The strengths of the meshless front-tracking method are illustrated through an academic case. Method validation is achieved to an acceptable degree through comparison of results with data from a well-documented historical Mediterranean fire. The performance of the method is evaluated in terms of computational resources.

Abstract
Currently available satellite active fire detection products from the VIIRS and MODIS instruments on polar-orbiting satellites produce detection squares in arbitrary locations. There is no global fire/no fire map, no detection under cloud cover, false negatives are common, and the detection squares are much coarser than the resolution of a fire behavior model. Consequently, current active fire satellite detection products should be used to improve fire modeling in a statistical sense only, rather than as a direct input. We describe a new data assimilation method for active fire detection, based on a modification of the fire arrival time to simultaneously minimize the difference from the forecast fire arrival time and maximize the likelihood of the fire detection data. This method is inspired by contour detection methods used in computer vision, and it can be cast as a Bayesian inverse problem technique, or a generalized Tikhonov regularization. After the new fire arrival time on the whole simulation domain is found, the model can be re-run from a time in the past using the new fire arrival time to generate the heat fluxes and to spin up the atmospheric model until the satellite overpass time, when the coupled simulation continues from the modified state.

Keywords*: VIIRS, MODIS, WRF, WRF-SFIRE, Data assimilation, Fire spread, Fire detection likelihood, Fire arrival time, Least squares, Maximum-a-Posteriori estimate, Tikhonov regularization, Bayesian*

Introduction

Active fire detection products using the VIIRS and MODIS instruments provide planet-wide monitoring of fire activity several times daily as detection squares or polygons at a resolution of 375 m to 1 km. Because the data products are continuously available online, they present an attractive data source for automated fire behavior simulations and forecasts. Unfortunately, fire detection errors are frequent (Csiszar *et al*., 2012; Hawbaker *et al*., 2008; Sei, 2011) , and geolocation errors can be significant, up to 1.5 km (Sei, 2011). An improved data product at 375 m resolution and with better error rates exists (Schroeder *et al*., 2014), but it is not available for general use yet. In any case, satellite active fire detection data have significant error rates, and they have much coarser resolution than the resolution of fire behavior models, which is typically few meters to tens of meters.
Fire detection data consist of squares of polygons (from now on, squares) with associated satellite overpass times. A fire detection square means that a fire of sufficient intensity and size was detected somewhere in the square; it does not mean that the whole square is burning. The fire detection squares are in arbitrary locations; a global fire-detection map where every pixel is marked as either fire or no fire is "neither required or desired" by VIIRS Active Fires specifications (Sei, 2011). In addition, an existing fire is often not detected (a false negative). For example, MODIS has a 50% probability of detecting a 100m^2 flaming fire (Giglio *et al*., 2003). The improved 375m VIIRS product has 50% probability of detecting about a 2 m^2 flaming fire at night, and about 40 m^2 flaming fire during the day of (Schroeder *et al*., 2014). False positives are possible, particularly in areas of high contrast (the data products' algorithms are contextual), but less frequent. Finally, if a location is under cloud cover, the

fire detection is turned off completely. Unfortunately, the cloud mask used was not provided in the data products we found, so we could not distinguish between missing data and negative fire detection. Consequently, current satellite fire detection products do not determine the fire area and the fire perimeter to a degree that could be relied upon. Although the use of satellite fire detection to initialize a fire simulation directly was an important advance (Coen and Schroeder, 2013), satellite fire detection is better suited to improve a fire behavior simulation in a statistical sense only, that is, by data assimilation. Data assimilation fuses the forecast obtained from a model with the data by balancing their uncertainties, and it can also take advantage of more reliable fire detection in future by putting more weight on the data and less weight on the model.

Data assimilation modifies the state of the simulation in analysis cycles. Each cycle consists of advancing the model in time and an analysis step, which takes account of the new information. The analysis cycles steer the simulation periodically and help to avoid an accumulation of modeling errors. Analysis steps at every satellite overpass also help to account for uncertainties caused by incorrect fuel information and by fire-fighting efforts. We propose a new data assimilation method for satellite fire detection, inspired by techniques used for contour detection in computer vision, such as in the Microsoft Kinect (Blake, 2014). The method takes advantage of encoding the state of the fire propagation as the fire arrival time (Finney, 2002), which can be modified by an additive correction. We employ a Bayesian approach and obtain a Maximum-a-Posteriori (MAP) estimate as a solution of a generalized nonlinear least squares problem, similarly as in Stuart (2010), to simultaneously maximize the log likelihood of the fire detection (or lack od detection) and minimize the change in the fire arrival time. The method is implemented efficiently using Fast Fourier Transform (FFT), and its computational cost is negligible compared to the coupled atmosphere-fire simulation itself.

Another challenge of data assimilation in coupled fire-atmosphere models is how to change the state of the atmospheric model when the state of the fire model changes in response to data. Atmospheric circulation evolves in response to the heat flux from the fire over time, and when the state of the fire model changes, the consistence between the state of fire and the state of the atmosphere is lost. Encoding the fire model state as the fire arrival time allows to go back in time, blend the new fire arrival time with the original one, and spin up the atmospheric model with heat fluxes generated by replaying the modified fire arrival time instead of running the fire propagation model itself (Mandel *et al*., 2012). Then, at the fire detection time (the satellite overpass time), the fire spread model takes over, and the simulation continues.

Methods

Fire detection data likelihood

We assimilate the fire detection data in the form of a likelihood of the detection data at a location (x, y). The data likelihood is proportional to $e^{f(t,x,y)}$, where t is the number of hours the fire has arrived at the location (x, y) before the satellite overpass time. The function $f(t, x, y)$ is called log likelihood. For locations (x, y) within the fire detection squares, the data likelihood should be high for when the fire has arrived recently, and low otherwise. For locations outside of the fire detection squares, the data likelihood should be high if the fire has not arrived yet, or has arrived long ago, and low if the fire has arrived at the location recently. Of course, this is a very simplified view; more accurately, the fire detection data likelihood depends on the fire behavior (some fires burn longer and can be detected longer after the fire arrival, and some only for a shorter time), the atmospheric state between the fire location and the satellite, and the properties of the sensor and processing algorithms. Some active fire detection products also provide a level of confidence, e.g. Schroeder *et al*. (2014), which should be a part of the calculation of the data likelihood. In this paper, however, we consider only a simple data likelihood functions modelled as in Figure 1.

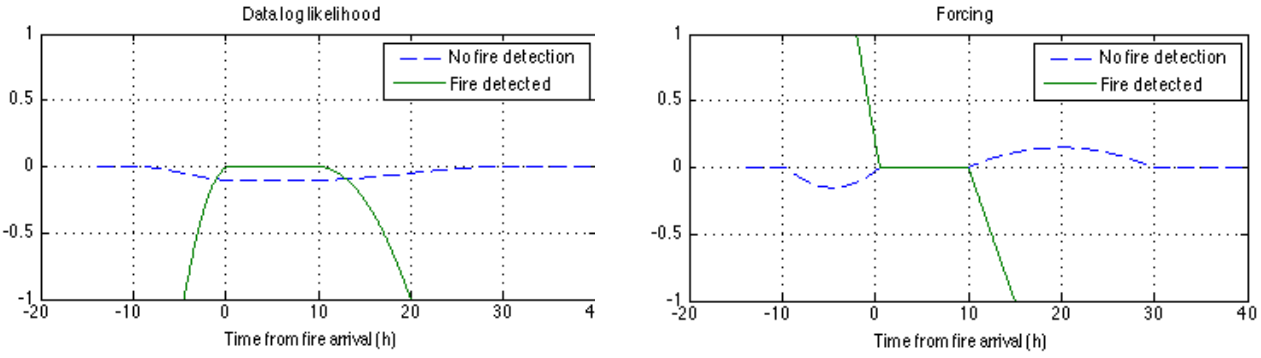

Figure 1. The log likelihood function $f(t)$ (left) and its derivative $f'(t)$ (right) as a function of time t elapsed since fire arrival (hours), in locations inside and outside of fire detection squares.

The model log likelihood f shown in Figure 1 is a function with continuous first derivative in the time t since fire arrival, and it is specified by parameters $T_{\min}$, $T_{\max}$, T_{pos}, T_{neg}, $\gamma > 0$. Within the fire detection squares, we choose $f(t) = 0$ for $T_{\min} \le t \le T_{\max}$, the function f is a quadratic polynomial for $t < T_{\min}$ with $f(T_{\min} - T_{\text{neg}}) = -1$, and a quadratic polynomial for $t > T_{\max}$ with $f(T_{\max} + T_{\text{pos}}) = -1$. Outside of the fire detection squares, $f(t) = -\gamma$ has a constant negative value for $T_{\min} \le t \le T_{\max}$, $f(t) = 0$ for $t < T_{\min} - 2T_{\text{neg}}$ or $t > T_{\max} + 2T_{\text{pos}}$, and f is blended by cubic polynomials in between. However, if the location is under a cloud cover, we would use $f(t) = 0$ for any t.

For the sake of simplicity, the data likelihoods at different locations are assumed to be independent. Then, the overall data likelihood of all detection squares at the satellite overpass time T^S over the whole simulation domain, given fire arrival time $T = T(x, y)$, is proportional to the product of the data likelihoods at all grid nodes (x, y). We also weigh each log likehood by the cell area $\Delta x \Delta y$, which gives

$$p(\text{detection squares} \mid T) \propto \prod_{(x,y)} e^{f(T^S - T, x, y)\Delta x \Delta y} = e^{\sum_{(x,y)} f(T^S - T, x, y)\Delta x \Delta y} \approx e^{\int f(T^S - T, x, y)\, dx\, dy}, \qquad (1)$$

with the understanding that the integral is computed numerically over the fire simulation domain.

Analysis step

In the analysis step, the data likelihood (1) is combined with the forecast fire arrival time $T^f = T^f(x, y)$ to obtain the analysis fire arrival time T^a. For this purpose, we need the probability density of the forecast fire arrival time. We assume that the difference of the fire arrival time from the mean fire arrival time T^f is a smooth random function, and we model the probability density of the fire arrival time as Gaussian, with mean T^f and covariance A^{-1} such that the associated norm

$$\|u\|_A = \langle u, Au \rangle^{1/2}$$

is small for spatially smooth functions u, defined on the model grid, and large for oscillatory u. For this purpose, we choose the covariance A^{-1} as a negative power of a discretization of the Laplace operator

$$\Delta u = \frac{\partial^2 u}{\partial x^2} + \frac{\partial^2 u}{\partial y^2}$$

on the model grid, multiplied by a penalty parameter. Thus, the forecast probability density of the fire arrival time T is

$$p^{\mathrm{f}}(T) \propto e^{-\frac{\alpha}{2}\left\|T-T^{\mathrm{f}}\right\|_A^2}, \quad A=(-\Delta)^p, \quad \alpha, p>0.$$

We also requite that the ignition time of the fire does not change, so $p^{\mathrm{f}}(T)>0$ only if $T=T^{\mathrm{f}}$ at the ignition point. The analysis probability density is obtained from the Bayes theorem as

$$p^{\mathrm{a}}(T) \mu\ p(\text{detection squares}\,|\,T)\,p^{\mathrm{f}}(T) \mu\ e^{\int f(T^{\mathrm{S}}-T,x,y)\,dx\,dy}\, e^{-\frac{\alpha}{2}\left\|T-T^{\mathrm{f}}\right\|_A^2} = e^{\int f(T^{\mathrm{S}}-T,x,y)\,dx\,dy-\frac{\alpha}{2}\left\|T-T^{\mathrm{f}}\right\|_A^2}.$$

The analysis distribution is non-Gaussian due to the presence of the data likelihood. To obtain a single analysis value, we use the standard Maximum-a-Posteriori estimator, which is the maximizer T^{a} of the analysis probability density $p^{\mathrm{a}}(T)$. Maximization of the analysis density is equivalent to the minimization of the exponent, which is the generalized least squares problem

$$J(T)=\frac{\varepsilon}{2}\left\|T-T^{\mathrm{f}}\right\|_A^2-\int f(T^{\mathrm{S}}-T,x,y)\,dx\,dy \to \min_{T:\,T=T^{\mathrm{f}} \text{ at the ignition point}}. \tag{2}$$

Note that the optimization problem (2) can be also understood as the maximization of the log likelihood with a Tikhonov regularization by the added quadratic term. In this context, the matrix A is chosen to penalize non-smooth increments $T-T^{\mathrm{f}}$. To find a descent direction, consider the difference

$$\begin{aligned} J(T+h)-J(T) &= \frac{\alpha}{2}\left\langle A(T-T^{\mathrm{f}}+h),T-T^{\mathrm{f}}+h\right\rangle-\int f(T^{\mathrm{S}}-T-h,x,y)\,dx\,dy \\ &\quad -\left(\frac{\alpha}{2}\left\langle A(T-T^{\mathrm{f}}),T-T^{\mathrm{f}}\right\rangle-\int f(T^{\mathrm{S}}-T,x,y)\,dx\,dy\right) \\ &= \alpha\left\langle A(T-T^{\mathrm{f}}),h\right\rangle+\int\left\langle\frac{\partial}{\partial t}f(T^{\mathrm{S}}-T,x,y)\,dx\,dy,h\right\rangle+O\left(\|h\|^2\right) \\ &= \left\langle\nabla J(T),h\right\rangle+O\left(\|h\|^2\right), \end{aligned}$$

which gives the gradient of J as

$$\nabla J(T)=\varepsilon A(T-T^{\mathrm{f}})-F(T), \quad \text{where } F(T)=\int\frac{\partial}{\partial t}f(T^{\mathrm{S}}-T,x,y)\,dx\,dy$$

is from now on called the forcing function. This gradient direction, however, is not suitable for our purposes, because it is not very spatially smooth, and, consequently, gradient descent iterations converge to the smoother solution of (2) only very slowly and, in addition, they are liable to get caught in local minima. A better gradient direction is obtained by considering the gradient $\nabla^A J(T)$ with respect to the inner product $\langle u,v\rangle_A=\langle Au,v\rangle$:

$$\left\langle\nabla^A J(T),h\right\rangle_A=\left\langle A\nabla^A J(T),h\right\rangle=\left\langle\nabla J(T),h\right\rangle$$

$$\nabla^A J(T)=\alpha(T-T^{\mathrm{f}})-A^{-1}F(T).$$

Now we add the constraint that the increment h is zero at the ignition point and introduce Lagrange multiplier λ, which leads to the saddle point problem

$$\begin{aligned} \varepsilon A h+C\lambda &= \alpha A(T^{\mathrm{f}}-T)+F(T) \\ C^{\mathrm{T}}h &= 0, \end{aligned} \tag{3}$$

for a descent direction h, where C is a zero-one vector such that $C^{\mathrm{T}}h=0$ expresses the condition that h is zero at the ignition point. The saddle point problem (3) is easily solved with access to multiplication by A^{-1} only: Calculating h from the first equation in (3) gives the descent direction

$$h=T^{\mathrm{f}}-T+\alpha^{-1}A^{-1}F(T)-\alpha^{-1}A^{-1}C\lambda=-\alpha^{-1}\left(\nabla^A J(T)+A^{-1}C\lambda\right),$$

where the Lagrange multiplier is determined by substituting in the second equation, which gives

$$\lambda = \left(C^{\mathrm{T}} A^{-1} C\right)^{-1} C^{\mathrm{T}} \left(\alpha(T^{\mathrm{f}} - T) + A^{-1} F(T)\right) = \left(C^{\mathrm{T}} A^{-1} C\right)^{-1} C^{\mathrm{T}} \nabla^{A} J(T).$$

Note that the descent direction h is obtained by a spatial smoothing of the forcing $F(T)$, or, equivalently, from the gradient in the inner product defined by the inverse covariance A, plus an adjustment for the constraint that the fire arrival time at the ignition location should not change. In each step of the descent method, the cost function J is then minimized by a line search over $T + ht$, t real. The first iteration starts from $T = T^{\mathrm{f}}$. Note that the penalty parameter α does not have any effect on the first search direction.

Results

The method is illustrated on two real fires simulated by WRF-SFIRE, with the assimilation of MODIS and VIIRS Active Fire detection data. WRF-SFIRE (Mandel *et al*., 2009, 2011) builds on CAWFE (Clark *et al*., 2004), and it is available from openwfm.org. A limited version from 2010 is currently distributed in WRF release as WRF-Fire (Coen *et al*., 2013).
In both examples below, we have used the parameters

$$\alpha = 1000,\ T_{\min} = 0.5,\ T_{\max} = 10,\ T_{\mathrm{pos}} = 10,\ T_{\mathrm{neg}} = 5,\ \gamma = 0.5,\ \rho = 1.02.$$

2012 Wood Hollow fire

The present data assimilation method was applied to adjust the fire arrival time obtained from a fire simulation up to 24th Jan 2014 23:45 UTC, from 151 MODIS fire detections, which occurred on the same day approximately at 20:00 UTC (Figure 2). The practical implementation of the method implements a line search strategy, in which a maximal step is set (here, 1.0) and the objective function is sampled 6 times in regular intervals. The step with the lowest objective function value and its two neighbors are selected as the new limits and the line search is repeated to determine the best step size with more precision.
In this instance, only the first iteration resulted in an improvement of the objective function, a line search along the second direction did not yield any more improvements, even for smaller step sizes. However, the single iteration has already found a satisfactory modification of the fire arrival time. The seemingly large value of the penalty parameter α was needed to stop the method from adjusting the fire arrival time in later iterations near the fire detection squares only.

2012 Barker Canyon fire

The data assimilation method was applied to a simulation of the 2012 Barker Canyon Fire, 1.71 days from ignition. Figs. 3-6 show how the analysis fire arrival time is obtained from the forecast by adding a correction in the direction of a smooth search direction, which is in turn obtained by the spatial smoothing of the forcing function. Again, a single iteration was sufficient to find a satisfactory solution.

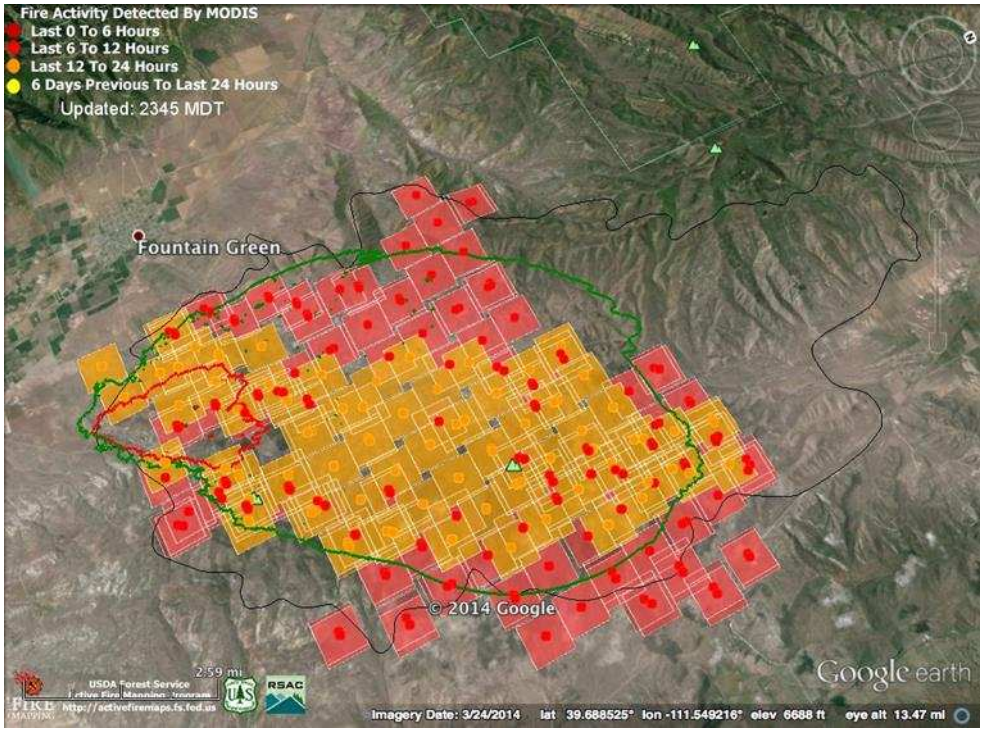

Figure 2. Data assimilation for the 2012 Woods Hollow fire, simulated by WRF-SFIRE, with MODIS Active Fire detection squares. The black contour is the actual fire perimeter on 25th Jun 2012, the red line is the forecast fire perimeter and the green line is the fire perimeter after assimilation, or the analysis. The analysis adjusts the shape of the fire for the fire detection data by a smooth correction, which automatically fills the fire arrival time between the detection squares.

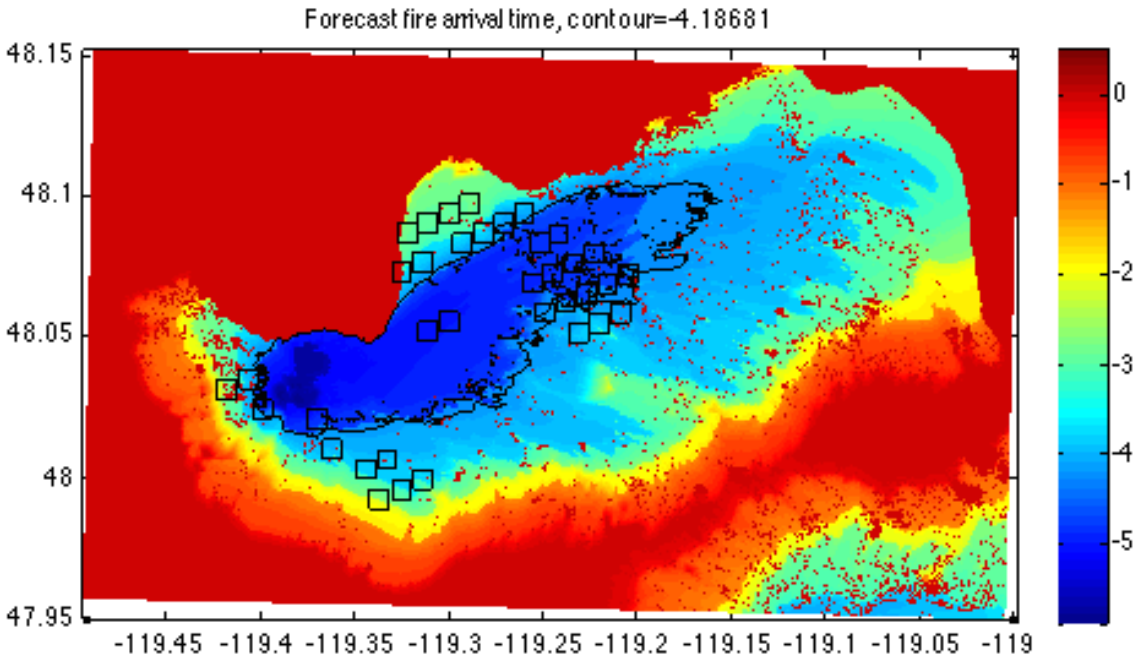

Figure 3. Forecast fire arrival time for the 2012 Barker fire, simulated by WRF-SFIRE, and VIIRS Active Fire detection squares. The black contour is the simulated fire perimeter at the satellite overpass time. The color bar shows fire arrival time in days before the end of the simulation. The axes are longitude and latitude.

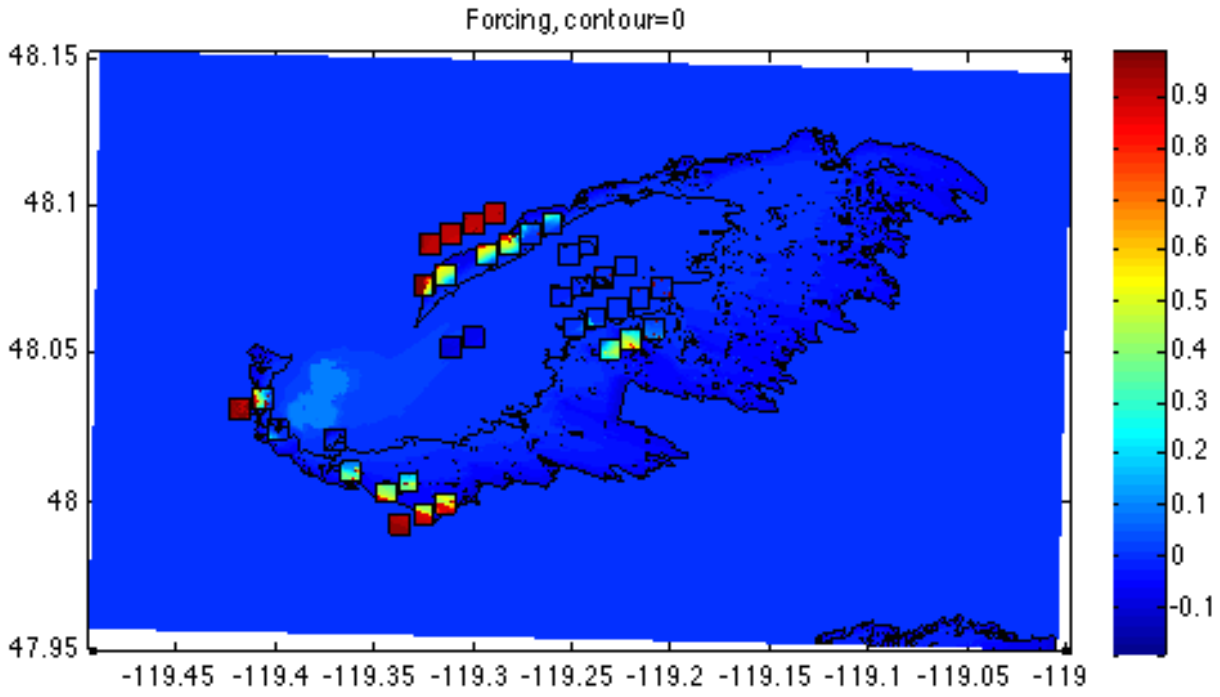

Figure 4. Forcing function F for the forecast in Figure 3. Positive values mean that the fire arrival time at the location should be adjusted down, while negative value mean that the fire arrival time should be adjusted up. The black contour marks the locations where the forcing is zero. Note that the forcing has jumps at the boundaries of the detection squares.

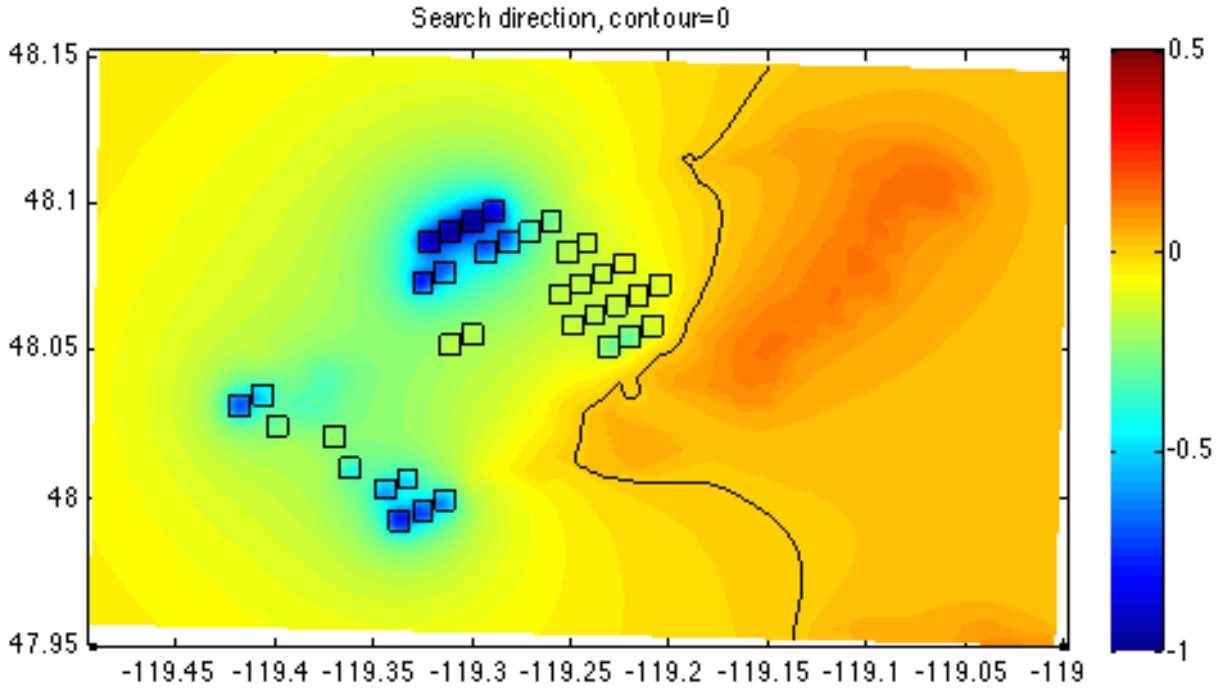

Figure 5. Search direction for the forecast in Figure 3. The forecast fire arrival time will be adjusted by a positive multiple of the search direction. In particular, the fire arrival time at the location of the detection squares colored in blue may be decreased, so the fire will be there at the satellite overpass time. The black line marks the locations where the search direction is zero.

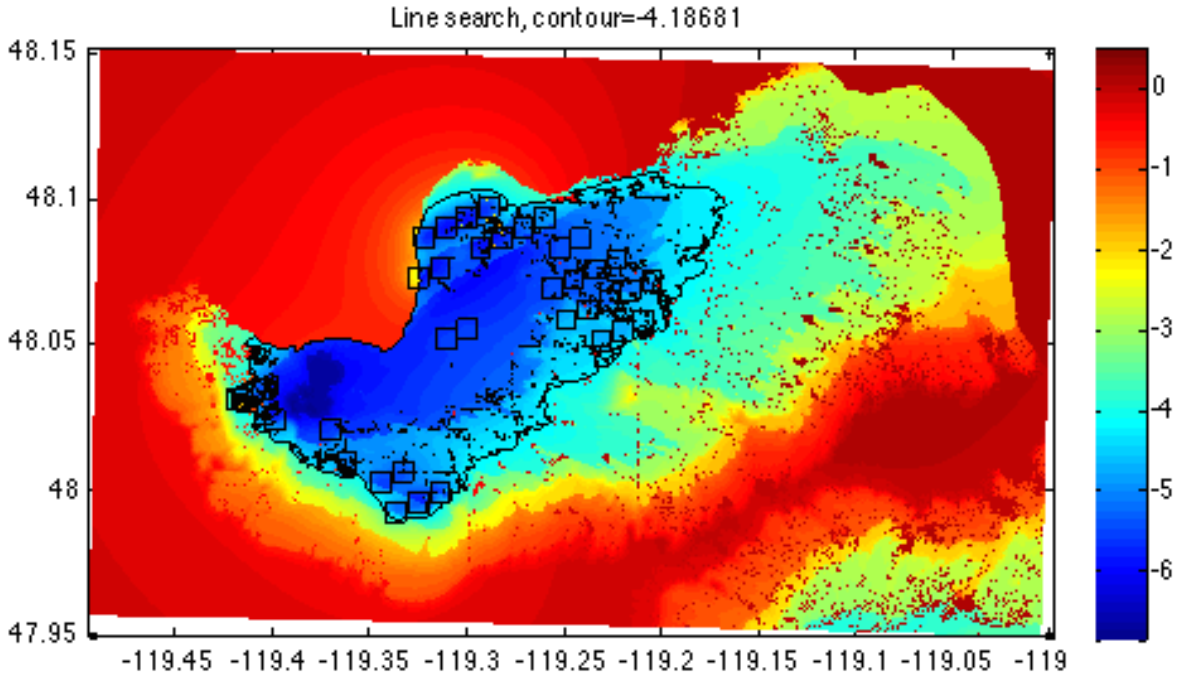

Figure 6. Analysis for the forecast in Figure 3. The method has filled in the fire arrival time based on the forecast from the model and incomplete information from the fire detection squares. The black contour is the resulting analysis fire perimeter.

Conclusion

We have described a new methodology to assimilate satellite active fire detection data into the state of a fire spread model, which is encoded as the fire arrival time. The methodology relies on standard Bayesian framework of data assimilation, which leads to a nonlinear least squares problem to simultaneously minimize the change of the fire arrival time from the forecast in a suitable norm (which penalizes spatially smooth changes less) and maximize the integral of the log likelihood of the fire detection (or non-detection) over the fire simulation domain. An efficient method to solve such problems was presented, which generates smooth increments and it found good approximate solutions in a single gradient descent iteration.

There are many uncertainties affecting fire spread simulations. They are associated with limitations of the fire spread and atmospheric models as well as limited accuracy in the estimate of the initial state of the fuel and atmosphere. As the length of the atmospheric simulation grows, its accuracy deteriorates, and as a consequence, the errors in the fire spread prediction also grow. The presented method allows for objective corrections of the simulated fire progression based on the assimilation of the satellite fire detection data. As the simulation period extends, also more satellite data showing the fire progression becomes available, so the simulated fire may be cyclically nudged to the observations. The method was illustrated on two examples, in which just a single arrival time adjustment to the coupled atmosphere-fire simulations by WRF-SFIRE was made. The same method, however, can be also used for cyclic corrections of the simulated fire progression, where the model continues its fire progression from the adjusted fire state till the new observations become available. A spin-up of the atmospheric state is then needed to restart the coupled model from the modified fire arrival time. An illustration of the cyclic application of this method will be presented elsewhere.

Estimating daily fire risk in the mesoscale by means of a Bayesian network model and a coupled GIS

Panagiota Papakosta, Anke Scherb, Kilian Zwirglmaier, Daniel Straub

Engineering Risk Analysis Group, Technische Universität München, Munich, Germany
panagiota.papakosta@tum.de

Abstract
A probabilistic spatio-temporal model for fire risk prediction based on Bayesian networks is presented. It predicts daily fire risk on houses and vegetated areas in the mesoscale (1 km² spatial resolution). The BN model consists of three parts. (1) The fire occurrence model, which involves as predictive variables the weather conditions (expressed by the Fire Weather Index - FWI), land cover types, population and road density. It predicts the probability of a fire occurring daily in each 1km². (2) The fire behavior model, triggered by the occurrence model, which includes the influence of actual and past weather conditions, fire behavior indices and topography. (3) The damage model, which predicts the expected losses relevant to houses and vegetated areas conditional on a fire hazard. Vulnerability (resistance capacity) and exposure (values at risk) indicators are used to quantify the damage, which also depends on the fire suppression efficiency. The final output of the model are the expected house damage costs (the risk to houses) and the restoration costs for the vegetation (the risk to vegetated areas). The BN model is exemplarily established for Cyprus. The conditional probability distributions of the BN variables are populated with data from the time period 2006-2009, regression model results and expert knowledge. Data from 2010 for Cyprus are used as verification dataset. The results are shown in daily maps with 1 km² spatial resolution.

Keywords*: wildfire risk, Bayesian networks, GIS*

Introduction

Fire risk prediction can support the planning of measures for fire prevention (e.g. thinning, prescribed burning) and risk mitigation (e.g. allocation of suppression resources, raising preparedness). In order to quantify fire risk, the predictive model must include models for fire occurrence, fire behavior and fire consequences. Due to the randomness inherent in the wildfire process and because the modeling is subject to uncertainty in all three stages (occurrence, behavior, damages), fire risk prediction is ideally carried out in a probabilistic format. Fire occurrence is influenced by weather conditions, human presence and vegetation types. Fire behavior is influenced mainly by local weather conditions (e.g. wind speed), topography and fuels (Forestry Canada 1992). Fire damages depend to a large extent on fire severity and the vulnerability of assets (Cohen 2000).
In this study, we focus on the Mediterranean area, where most fires occur due to human intervention as a result of arson or negligence, favored by long dry summer periods (Keeley *et al*. 2012).We propose a probabilistic spatio-temporal model based on Bayesian networks, which predicts daily fire risk on houses and vegetated areas in the mesoscale (1 km² spatial resolution). Bayesian Networks (BN) are graphical probabilistic models that can effectively represent complex processes with multiple random variables, their interdependencies and the associated uncertainties.

2. Methods

The predictive BN model consists of three parts: (1) The fire occurrence model, which includes as predictive variables weather conditions (expressed by the Fire Weather Index - FWI of the Canadian Forest Fire Weather Index System - CFFWIS), land cover types, population and road density, and

which predicts the probability of a fire occurring in each spatial-temporal unit, i.e. daily and per 1km². (2) The fire behavior model, triggered by the occurrence model, which is a function of the actual and past weather conditions, the fire behavior indices of the CFFWIS and the topography. (3) The damage model, which predicts the expected losses relevant to houses and vegetated areas conditional on fire hazard. Vulnerability (resistance capacity) and exposure (values at risk) indicators are used to quantify the damage, which also depends on the fire suppression efficiency. The final results of the combined model are the risk to houses (expected house damage costs [€]) and the risk to vegetation (vegetated area damage costs [€]). After a short introduction to BN in section 2.1, the three parts of the model are presented in sections 2.2 – 2.4, and the combined model is provided in 2.5.

Bayesian networks

Bayesian Networks (BN) are directed acyclic graphs and consist of nodes, arcs and conditional probability distributions attached to the nodes (Jensen and Nielsen 2007). In a discrete BN, which is used in this study, each node represents a discrete random variable, whose sample space consists of a finite set of mutually exclusive states. The arcs qualitatively describe the dependence structure among the random variables.

A conditional probability table (CPT) is attached to each of the nodes, defining the probability distribution of the variable conditional on its parents. If we consider a BN with discrete random variables $\mathbf{X} = [X_1, \dots, X_\mathrm{n}]$, then the full (joint) probabilistic model of these variables is the joint Probability Mass Function (PMF), $p(\boldsymbol{x}) = p(x_1, \dots, x_\mathrm{n})$, which can be specified with the help of the chain rule:

$$p(\mathbf{x}) = p(x_n|x_{n-1}, \dots, x_1)p(x_{n-1}|x_{n-2}, \dots, x_1) \dots p(x_2|x_1)p(x_1) \tag{1}$$

By making use of the independence assumptions encoded in the graphical structure of the BN, this chain rule reduces to

$$p(\mathbf{x}) = \prod_{i=1}^{n} p(x_i|pa(x_i)) \tag{2}$$

wherein $pa(x_\mathrm{i})$, are realizations of the parents of X_i (i.e. the variables with a link pointing to X_i). In words, the joint probability mass function (PMF) of all random variables in the BN is the product of the conditional PMFs of all random variables given their parents. Therefore, the graphical structure of the BN, together with the conditional PMFs $p(x_i|pa(x_i))$, are sufficient for specifying the full (joint) probabilistic model of $\mathbf{X} = [X_1, \dots, X_\mathrm{n}]$.

Inference in the BN model is performed through updating. When one or several variables are observed, this information (evidence e) is propagated through the network and the joint prior probability of all nodes is updated to its posterior. The posterior joint probability of a set of variables $\mathbf{Y} \in \mathbf{X}$ in the network given the evidence $\mathbf{e}$ is:

$$p(\mathbf{y}|\mathbf{e}) = \frac{p(\mathbf{y}, \mathbf{e})}{p(\mathbf{e})} \tag{3}$$

The joint probabilities $p(\mathbf{y}, \mathbf{e})$ and $p(\mathbf{e})$ are computed following Eq. 2. Efficient algorithms for performing these computations in rather complex networks exist, which are implemented in software such as GeNIe (Decision Systems Laboratory 2013) or Hugin (HUGIN EXPERT 2012).

In the context of the proposed model for wildfire risk assessment, the main advantage of the BN is not its computational effectiveness but that it facilitates the combination of information from various sources in a single model.

Fire occurrence model

The fire occurrence model, which is described in detail in (Papakosta and Straub 2014), is based on the assumption that fire occurrences are independent of each other for a given fire rate. Hence the number of fires in an area of size α during one day, N, has the Poisson distribution, with PMF:

$$p(n|\,\lambda) = \frac{(\lambda\alpha)^n}{n!}\exp(-\lambda\alpha)\,, n = 0,1,2,\ldots \tag{4}$$

wherein $\lambda\ \left[\frac{\text{Nr.Fires}}{\text{day}\cdot\text{km}^2}\right]$ is the mean occurrence rate and α = 1km² is the area of the cell.
λ is calculated by a regression model with explanatory variables *FWI*, *population density*, *road density* and *land cover types*. The predictive model based on the regression results of (Papakosta and Straub 2014) is

$$\log(\lambda) = -10.90 + 0.0329 \cdot FWI + 0.3217 \cdot Road\ density - 0.0234 \cdot (Road\ density)^2 - 0.0010 \cdot Population\ density \tag{5}$$

The resulting BN for fire occurrence is shown in Figure 1.The node *fire occurrence rate* λ is a parent of the node *Fires N*, whose CPT is defined by the Poisson PMF, Eq. (4). The fire occurrence rate is a child of the nodes *FWI*, *population density*, *road density* and *land cover types*, following the deterministic relation of Eq. (5). The CPTs of the explanatory variables are learnt from data of the test bed area.

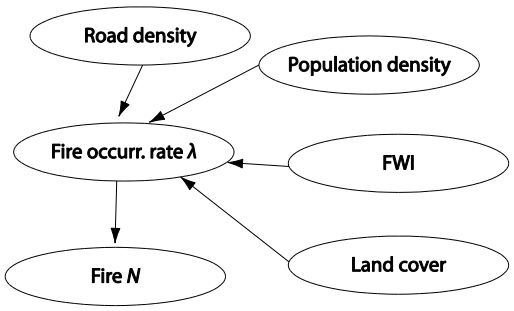

***Figure 1.** Bayesian network for Fire occurrence. The fire occurrence rate $\left[\frac{Nr.Fires}{day\cdot km^2}\right]$ is a function of road density, population density, Fire Weather Index (FWI) and land cover types.*

Fire behavior model

The fire behavior model presented in Figure 2 is adapted from (Zwirglmaier *et al*. 2013). The variables are chosen from a wider range of potential variables to represent the processes influencing the resulting burnt area of a fire. In the fire behavior model, the target/predicted node is *Burnt area*. *Burnt area* is influenced by *fire occurrence*, *land cover types*, *topography*, *recent weather conditions*, and *fire behavior indices*. The latter three are hidden variables, meaning that they cannot be observed. They are included to reduce the number of parents of the node *Burnt area*. *Topography* combines the influence of the variables *Wind Speed* [km/h], *Slope* [°] and *Aspect Minus Wind Direction* [same, opposite, perpendicular]. *Recent weather conditions* summarizes the effect of *Relative humidity* (*RH*) [%], *mean RH over the last 3 days* [%], *mean RH over the last 21 days* [%], *accumulated precipitation over the last 21 days* [mm], *mean temperature of the last day* [°C] and *mean temperature over the last*

7 days [°C]. *Initial fire behavior* influences the three Indices of the CFFWIS, namely *Fine Fuel Moisture Code* (*FFMC*), *Initial Spread Index* (*ISI*) and *Build-up index* (*BUI*).
The BN for fire occurrence (Figure 1) is included in the BN for fire behavior. The variable land cover, which is used for predicting the fire occurrence rate, is also influencing the burnt area directly. However, the node *LC grouped* is introduced to group the land cover types grouped in fewer classes. This reduces the number of free parameters of the variable burnt area and facilitates the parameter learning with hidden variables.

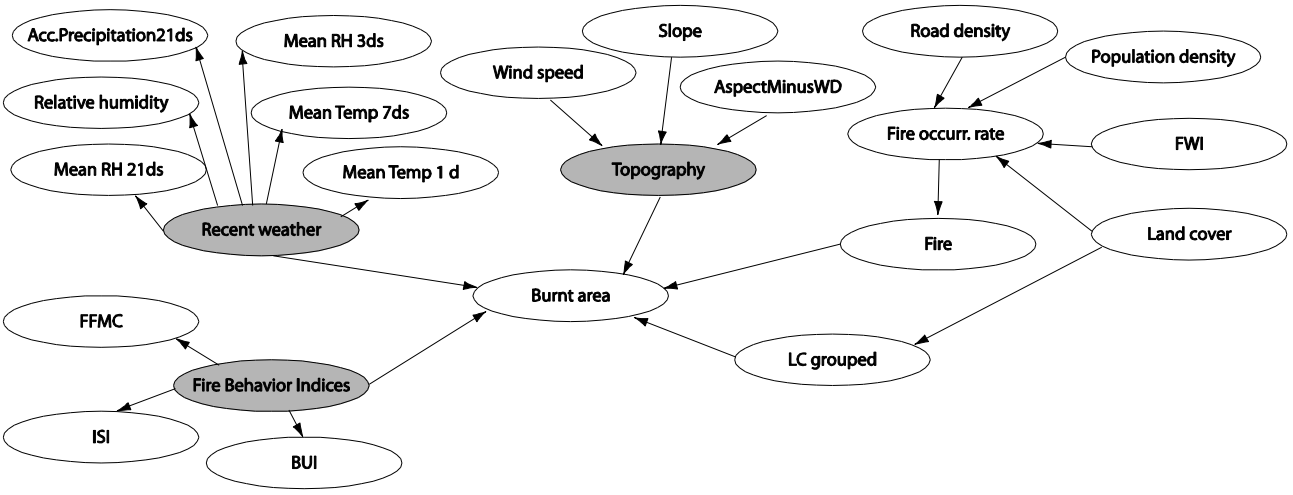

Figure 2. Bayesian network for the prediction of Burnt area. Hidden variables are shown in grey. Indices of the CFFWIS - FWI: Fire Weather Index, FFMC: Fine Fuel Moisture Code, ISI: Initial Spread Index, BUI: Built-Up Index.

2.4. Fire consequences model

The fire consequences model estimates the house damage cost and the restoration cost for vegetated areas. The cost is a function of the hazard characteristics, and the consequences that might occur. Wildfire consequences are a function of vulnerability and exposure of the affected biotic and abiotic systems (e.g. human properties, infrastructure, soil and air quality). Vulnerability describes the degree of expected damage as a function of hazard intensity (UNDRO 1991, Thywissen 2006). Exposure refers to the items at risk, such as house density.
Risk is the expected consequences of wildfires and can be formulated as a function of the hazard H, the resulting damages D and the consequences C as,

$$R = \mathrm{E}_{H,D}[C] = \int_H p(H) \int_D p(D|H) C(D,H) dD\, dH \qquad (6)$$

$\mathrm{E}_{H,D}$ denotes the expected value with respect to H and D. $p(D|H)$ is the probability distribution of damage D conditional on the hazard H, i.e. it describes the vulnerability, and $\mathrm{C}(D,H)$ is the cost as a function of damage and hazard. The inner integral in Eq. (6) describes the expected consequences for a given hazard:

$$\mathrm{E}_D[C \mid H] = \int_D p(D|H)\, C(D,H) dD \qquad (7)$$

In the consequence model, the expected costs conditional on hazard characteristics $E_D[C \mid H]$ are estimated.

We introduce a model to estimate wildfire consequences on house damage and vegetated area damage (Figure 3). The model is based on the assumption that consequences are influenced by the exposure of the items to fire, the flammability of the items and the suppression effectiveness. As with the fire occurrence and behavior models, the modeling is conducted at the mesoscale.
