Let us suppose that we have a region covered by a network of wildfire observers and that certain part could be seen from three different observation points. The biggest problem in visual wildfire detection is still rather high false alarms rate, so any effort in order to minimize false alarm rate is welcomed. A

network of wildfire observers could be used for that, because it is unlikely to have a false alarm on the same location on all three observers units. If observers exchange information about alarms and their estimated locations a simple procedure could be used for additional false alarms reduction.
Also using the wildfire observer network the manual PTZ cameras control could be improved and simplified. An example is 'one click multiple cameras control' principle (Stipaničev et.al., 2009), (Stipaničev *et al*., 2011). One click means that all cameras covering the same region could be controlled by simple click on the map. The system automatically calculate the target point visibility from various observation points and appropriate cameras pan and tilt movements for all those cameras that could see the selected location.

Conclusion

In the future we could expect more and more wildfires, therefore in countries where wildfire risk is high, a lot of time and money is spent to minimize the wildfire effects. Maybe it is difficult to drastically reduce the number of fire ignitions, but the damage could be minimized by early wildfire detection and quick and appropriate intervention. Early wildfire detection is usually organized as a wildfire surveillance service and today this service is more and more based on application of modern ICT technologies, particularly new sensors, processing units, algorithms and calculation procedures. In this paper our focus was on automatic wildfire surveillance systems. They have evolved a lot in the last few years. More and more sophisticated algorithms for wildfire smoke and fire detection were developed, fusion of video detection in various electromagnetic ranges and fusion of video detections with other sensor types are today used, as well as close integration of wildfire surveillance and monitoring and systems with GIS, resulting in new features in both fire detection and distant video presence modes. Last but not least we have discussed a synergy effect of wildfire observer network consisting of mutually connected individual wildfire observers working together in cooperation. Although a lot of new wildfire surveillance systems has been developed and applied in various regions our opinion is that in the future we should expect even greater achievements in automatic wildfire surveillance systems development and implementation. Today human wildfire observers are still dominant (Matthews *et al*., 2010), but we are sure that high definition cameras, more advanced algorithms and powerful processing engines will improve automatic wildfire detection and reduce the difference between human and machine wildfire detection.

Abstract
The maturity of the technologies for the guidance and control of UASs allows proposing innovative operational options such as the ability to spray (a liquid) or spread (a powder) a significant amount of an agent of any sort at a pre-established point in the atmosphere.
This is the case of NITROFIREX, an innovative Spanish project that integrates available technologies from the defense industry to achieve this operational capability

Keywords*: nighttime aerial fire fighting, new technologies, UAS, launcher aircraft, autonomous gliders containers, risky operation, operative and economical efficiency*

Introduction

It may be the controversial climate change or perhaps human pressure on the natural environment but the fact is that, year after year, alarming reports of devastating forest fires monopolize the media. The past summer of 2012 saw how catastrophic fires razed through the U.S.A., Portugal, Canada and especially Spain and in previous summers how Russia, Bolivia, Israel, California, Australia or Greece stood by helplessly before the devastation of their natural heritage. In the coming years, and this is unfortunately more than likely, we shall have to continue suffering from this modern plague that is ravaging our forests.
In facing this bitter reality it is necessary to ask whether political, economic and technical levels are contributing in finding solutions, or at least methods to efficiently avoid and relieve these disasters. Unfortunately the answer is a very clear and definite negative.
According to estimates from the IPCC (Intergovernmental Panel on Climate Change) forest fires create at least 20 % of all CO2 projected into the atmosphere annually. On the other hand, all the activity of commercial aviation worldwide causes only 2 % of all the emission.
For example, the European project CLEANSKY has a budget estimated at 1.600 millions of Euros in order to obtain a higher efficiency of engines, the employment of biofuels, intelligent wings and the reduction of weight, etc. Paradoxically, very little technological effort is being put into research regarding the elimination or the reduction of the 14-20% emission of CO2 that results from wild fires and, above all, the lack of research into aerial fire extinction - the most versatile and effective method to fight fires.
In the face of the social alarm, political upheaval and vast economic losses engendered by these wildfires, why is it that so few technical resources are available to fight these fires with the greatest efficiency possible? Why, for example, having at our finger tips technology that literally allows us to place a guided bomb carrying 200 or 300 kilos of explosives and fired from a warplane some dozens of miles away through a window (see photo below)… why can't we use the same technology to drop, throughout the night, loads of 2,000 to 3,000 litres of water continuously over a burning forest?

Figure 1

Why is it that an aeronautical sector, which internationally moves thousands of millions of $/€, is still confined to using methods, techniques and procedures developed some 60 years ago in extreme high risk operations for their crews? Why not integrate available technology and develop the capacity to drop more fire extinguishing agents in less time, but above all, to be able to do so at night. Have we forgotten that the inability to fly at night is the greatest operative lack in present day fire fighting?

State of the art

The fixed-wing aircraft employed to combat wildfires at present are principally slow-moving turboprops and the majority are planes used exclusively for the job. In isolation and in numerous high-risk operations for crews they visually discharge their loads only between sunrise and sunset.
Apart from the fact that the power plants have changed from piston to turbo, few other technical advances have been applied to the fire fighting fleets since the Second World War. And yet, as we have seen in other fields of aeronautics, the progress has been spectacular.
There is a great concern at the business and academic level to provide answers to the challenge of extinguishing forest fires. In the last decade several solutions have appeared. A good example is the use of huge transport aircraft such as the B-747 Jumbo or DC-10 aircraft, employed by the American Company Evergreen (http://www.evergreen.com), because of their capacity to drop far greater loads of extinguishing agents.
Obviously these aircraft are able to discharge vast amounts of extinguishing agent, but because of their lack of manoeuvrability at low altitudes, their scope of action is greatly reduced. Their excessive length of reaction time and high operational costs render them non-effective in 'first line attack' on the fire. They only become effective once the fire has reached huge dimensions.
But, above all, the use of these big aircraft offers no solutions to nocturnal fire fighting due to their inability to operate visually at night and at low altitude.
Another project also aimed at changing methods and techniques of aerial wildfire fighting is the Precision Container Air Delivery System (PCADS). Supported by Boeing and Weyerhaeuser their method consists of launching, by means of parachutes with no guides of any type, via the rear ramp of heavy-duty transport aircraft a series of biodegradable cubic containers with a capacity of 250 gallons (some 950 litres) each of extinguishing agent from about 500 feet AGL. Once in the air and at about 200 feet AGL these containers open and scatter their cargo over the fire. (web: http://www.flexiblealternatives.com/products/pcads). A similar system is the Israeli Caylym Guardian Deployment System (http://www.caylym.com/the-guardian/). In this case the containers are launched at some 1.500 feet AGL.

The precision of the drop point achieved by a parachute without any form of guidance in an adverse atmospheric environment caused by wind, turbulence and the thermal currents produced by the on-going wildfire, does not appear to be sufficient enough to produce a coordinated and efficient action of extinction. At the same time this concept entails that all the solid components, although biodegradable, will be spread all over the fire zone. It doesn't either permit night-time operation due to the low altitude demanded by the operation.
Another method proposed by Boing is that of using 'water bombs' (bomblets), a type of biodegradable dodecahedra shaped container filled with 50lbs of water (23litres). Using path-calculating systems, 2800 of these 'bomblets' would be launched via the rear ramp of a C-17 from between 1.000 to 2000 feet above the fire to drop freely, with no form of guidance whatsoever. (web:http://www.boeing.com/news/frontiers/archive/2003/august/i_ids4.html).
Assuming that the path calculating systems allow sufficient precision to allow the drop to occur within the designated zone, this would still imply that the impact of the bomblets, dropping at great speed in free fall onto the ground would in the first place result in a high risk factor for ground crews, people and possessions in the fire area. Secondly, the water would on impact extinguish some of the fire but the effect would not be optimal since the always desired atomisation of the water never occurs, therefore the amount of energy absorbed is highly reduced, implying a big reduction in the extinguishing effect.
This concept, as with the two previous ones, is also not applicable to night-time operations because of low altitude flying. Should the altitude be raised to a 'safe altitude' the precision of the drops would decrease and the risk factor increases because of the higher speed at impact of the 'water bombs'.

The NITROFIREX concept

The developing technologies in the control and guiding of UAV's allow for the development of innovative operational options such as the possibility of 'spraying' (a liquid) or 'scattering' (a powdered solid) an important amount of extinguishing agent from a programmed point in the atmosphere.
This is the case of NITROFIREX, an innovative project that integrates the industrial technologies of the Defence Force in order to attain an operative capability that could be applied in the battle against wildfires, to combat against an atomic, chemical or biological emergency, to operate with meteorological phenomena (inducing rain, avoiding hail, dissipating fogs), to fight against plagues or to sow in remote or inaccessible regions and also the fumigation of drug plantations at night.
Discarding all these possible applications, and due to the ecological harm caused, the social alarm generated as well as the human and economic losses that they bring forth, the project that NITROFIREX is developing with maximum priority is the one to combat wildfires. For that very reason NITROFIREX is concentrating on its night-time operations as an indispensible and necessary complement to aerial means already in use during daytime.
Heavy transport planes will be responsible for moving great quantities of useful cargo (extinguishing agents in the case of wildfires) to the operative zone. These planes are designed to transport at great speed big quantities of cargo at a cost per unit far lower to that of a smaller plane.
This is the NITROFIREX proposal: Launcher Aircraft, LAs (the heavy transport aircraft equipped with a rear ramp) will be employed to transport the NITROFIREX Airborne Glider Containers, AGCs (already containing ±2.500 litres of payload) to the programmed drop zone. See figure number 1.
The LA will then launch the AGCs from the rear ramp in a programmed sequence and immediately return to the operation base. Once released, the AGCs will automatically home in onto their programmed target area within the drop zone and, with great accuracy, drop their load in the core of the fire. Once the drop of the fire-extinguishing agent on the fire has taken place, these containers return to base performing an "escape" manoeuvre from the danger zone by taking advantage of the great and sudden loss of weight as well as the extra speed.

Figure 2

Then the empty NITROFIREX AGC begins its autonomous return to the operations base of the launcher aircraft where it can be swiftly reused and loaded into the LA thus beginning a constant turnaround operation until sunrise.

The NITROFIREX Project

Although, as we have seen in the previous paragraph, the concept has a wide application, NITROFIREX is, first and foremost, a completely innovative project focused on night-time aerial wildfire fighting.
As we have seen, the main element used is the NITROFIREX AGC, launched at medium altitude (six to ten thousand feet), from the rear ramp of the cargo bay of a heavy transport aircraft, such as the C-130 Hercules, AN-12, KC-390, A400M, IL-76, C-17 or even aircraft with greater cargo capacity, which perform as the LA (launcher aircraft). These containers, loaded with a fire-extinguishing agent, are capable of gliding in their initial phase and are equipped with a guidance system (satellite, inertial and infrared). They fly automatically into the fire zone and drop their load, in sequence and with great accuracy, on the targeted area.

Figure 3

For safety, but also economic reasons, the NITROFIREX AGC's (Glider Containers) are recoverable. Once the drop of fire-extinguishing agent on the fire takes place, the NITROFIREX AGC performs an escape manoeuvre from the danger zone. Taking advantage of the great and sudden loss of weight as well as the surplus speed, the empty glider container is transformed, thanks to the activation of the small engine that propels it, into an UAV and returns autonomously to the operation base of the launcher aircraft where it can be swiftly reused.
In its guided bomb role the glider container flies no more than 90 seconds from the launcher aircraft to its target over the fire. When compared to a guided bomb, it carries a bigger payload and has more wing surface and but with an equal gliding and guide capacity. After concluding its 'escape' from the

target area and until it lands at the launcher aircraft's operation base, it navigates at night as a UAV at 1,000 feet above ground level and attains speeds of up to 70Kts.

Figure 4

By no means does NITROFIREX want to substitute current aerial means whose efficiency in daytime operations has been demonstrated over decades. The truth is that NITROFIREX aims to be their night-time counterpart in order to achieve H-24 aerial combat against wildfires (24 hour non-stop fighting) and to make use of, as the toiling ground crews well know, the better weather conditions that the night usually has to offer. In the following graphics one can analyse these advantages from:

1. The operative point of view (litres launched per hour of the operation),
2. The economic point of view (litres launched per hour and flight plus the cost of each litre launched)
3. The development of the NITROFIREX concept according to the type of AL used.

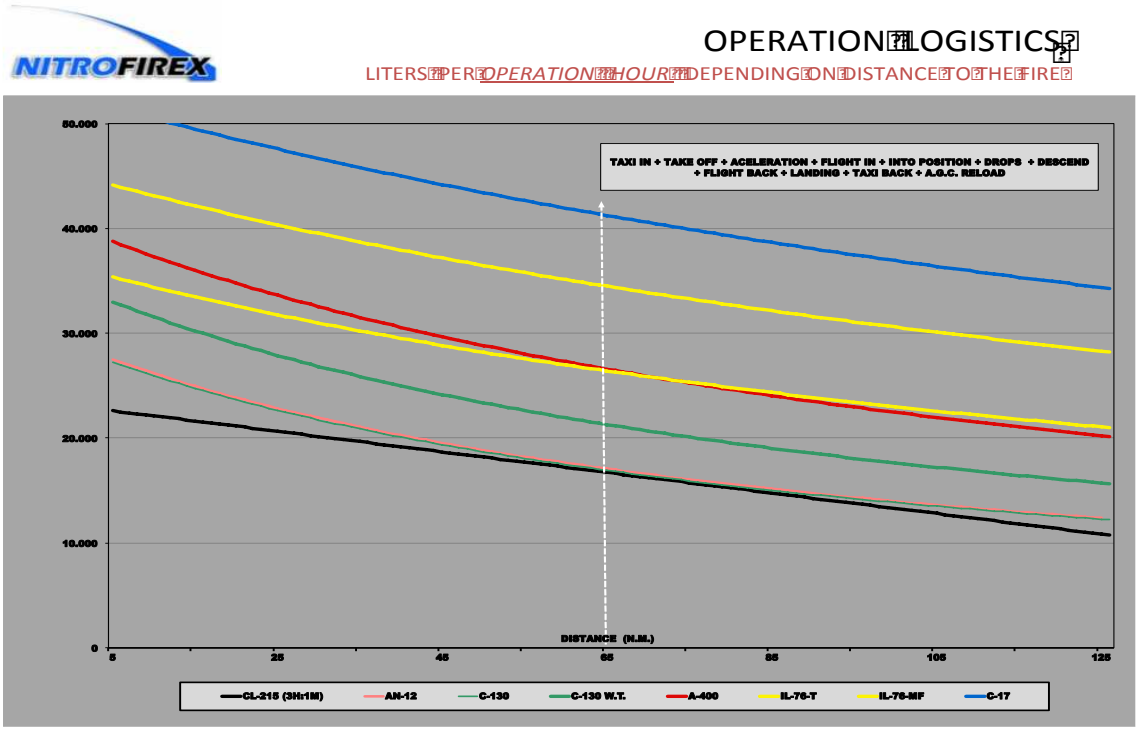

Figure 5

NITROFIREX

OPERATION LOGISTICS

DROPPED LITERS PER FLIGHT HOUR DEPENDING ON DISTANCE TO THE FIRE

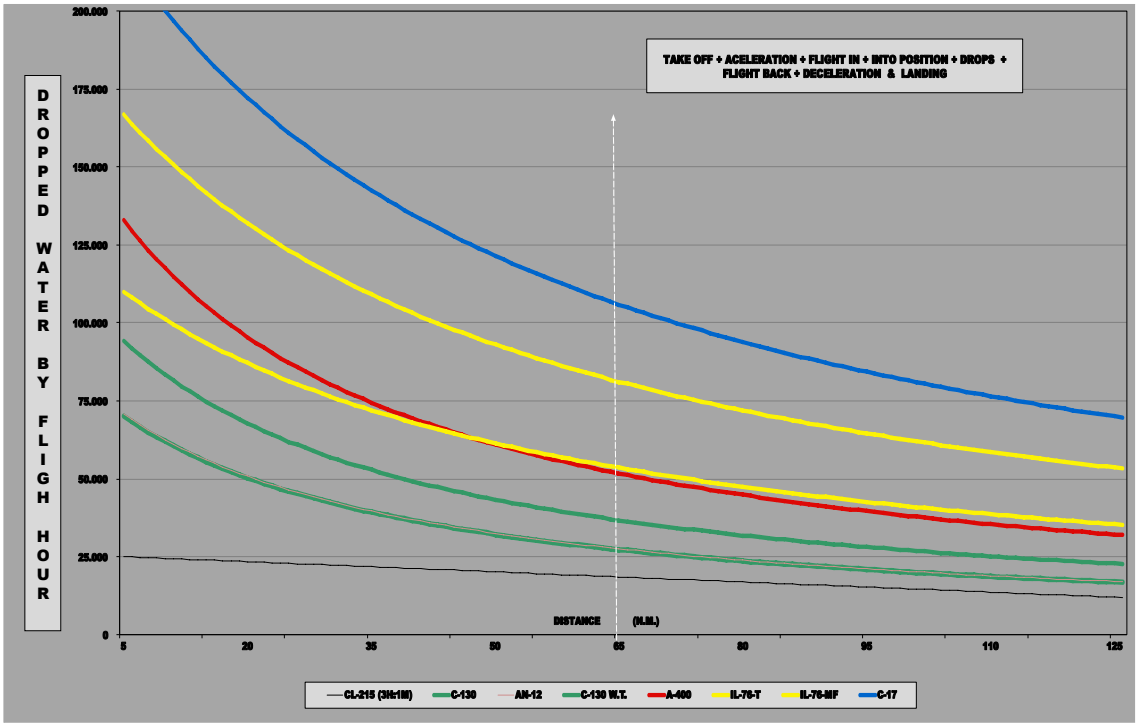

Figure 6

NITROFIREX

OPERATION LOGISTICS

DROPPED LITERS COST DEPENDING ON DISTANCE TO THE FIRE

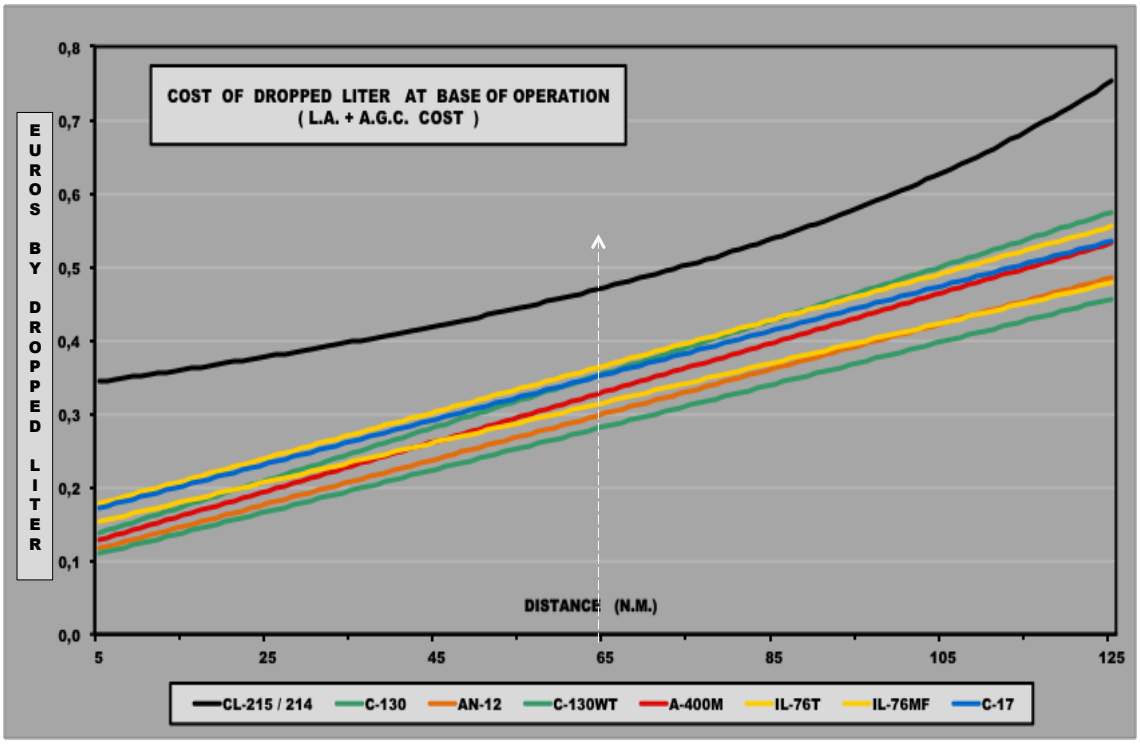

Figure 7

Operational model

Because of the great cargo capability and the increased deployment speed that the NITROFIREX LAs offer, a new operational model will have to be put into use. This will include a regional operational base that could be situated in a strategic site in accordance to the operations area.
Should a supranational operation come to be, the ideal base that would cover, for example, the Mediterranean Basin, would be Marseille in France or Olbia in Sardinia. Since the NITROFIREX operation is nocturnal, we can assure that under normal conditions, at least half a day would be needed to detach the LA to any airport in any country within the Basin.

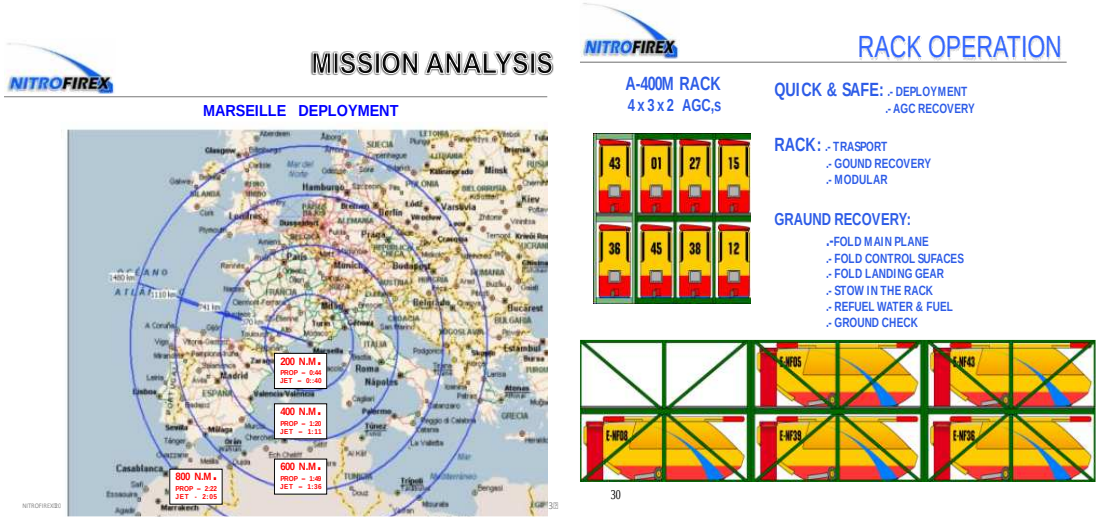

Figure 8

The NITROFIREX AGCs are transported from the regional operational base to the mission base (airport, air base or aerodrome closest to the fire). Two sets of empty NITROFIREX AGCs are stacked on two levels in a 'rack' or specifically designed shelving in the cargo hold of the LA. Later, during the mission this 'rack' will be used for the fast turn-around (pre-flight check, fuelling, loading of extinguishing agent and re-stacking) of the AGCs returning from the fire zone.
Once a wildfire alarm has been activated, the LA fly from their regional base to the detachment base, the airport closest to the fire, where the operation begins by downloading the rack of empty NITROFIREX AGCs and the rest of the necessary equipment so as to proceed with the final preparation. The first set of NITROFIREX AGCs (on the lower level of the 'rack') are filled with the extinguishing agent and are once again stacked in the LA leaving them ready for take off at dusk.
As night falls they fly to the fire zone and, coordinated by the ground teams who provide direct support, the LA begins launching the NITROFIREX AGCs in groups with a 90º 'angle off' to the fire front – the goal being that at the moment of leaving the LA the DPA's make a 90º turn, so that when the 4 or 6 NITROFIREX AGCs leave the LA they can form up in a trail formation and attack the fire. The extinguishing agent is dropped over the area preselected by the fire management officer. In order to maximize the extinguishing effect the drops are overlapped.
Once the first set of NITROFIREX AGCs have left the LA, it returns to base to load the second set of NITROFIREX AGCs so it can then return to the fire area in order to continue the attack on same fire or to attack more than one fire simultaneously. The NITROFIREX AGCs autonomously return to mission-base after each drop.

For example, one could consider an operation of an A-400 with a cargo capacity of 12 full DPA's. Flying to the mission-base with a 'rack' holding 24 empty containers, it starts operating at dusk and launches in each flight 12 containers filled with the extinguishing agent and rapidly returns to load the next 12. In the case of the A-400 the cargo load of each DPA would be 2,583 litres, which

means that a single flight of an A-400 would be approximately equivalent to 6 drops of the Canadair CL-215/415. At a distance of 120km (65 N.M.) between the mission base and the fire zone an A-400 can perform 9 flights in one night dropping 12 DPA's with each flight.
According to operative analyses done by NITROFIREX, and assuming the loading and stowage coefficients for the NITROFIREX AGCs, one can establish that having one LA and its two sets of NITROFIREX AGCs detached to a mission base within 120 km, the operation over the fire zone would be non-stop. The LA turn-around at mission base for loading the NITROFIREX AGCs would ensure a relentless dropping of water over the intended targets. See graphics number 4 and number 5.

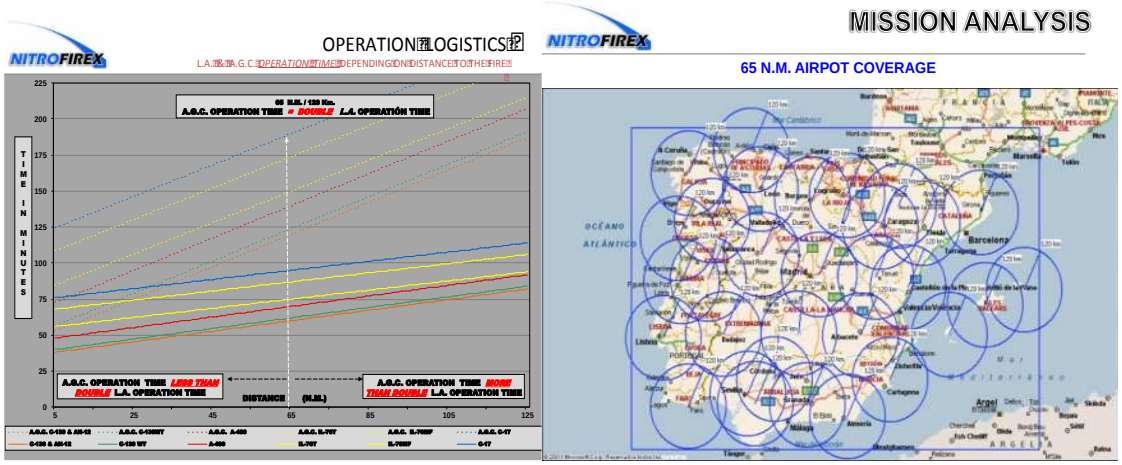

Figure 9

Drop optimization

Present day aerial resources used in fighting wildfires manually execute the drops of extinguishing agent directly over the fire, to either extinguish or to cool down the zone. So the effectiveness and efficiency of a drop depends on the pilot's, as well as the fire management officer's experience and ability.
If the drop is performed at an excessive height, the water is atomized by the fall and because of thermal convection it does not manage to reach the core of the fire thus greatly diminishing the effectiveness of the release. Conversely, if the release is excessively low the water reaches surface still compacted, without atomizing sufficiently. Here it evidently achieves some success but does not reach its full potential.
But if the drop is done at the ideal height most of the atomized water reaches the core of the fire. The maximum transfer of energy is obtained between the fire and the water. The resulting dowsing action of the water mass on the fire can be considered to be ideal.
Therefore we face the problem of drop optimization, which to date has not yet been studied. One has to find the exact point where, during the drop, water atomization allows water droplets of the smallest possible diameter to reach the fire surface, therefore favouring the heat exchange between the agent and the fire.
The fundamental factors for optimizing the release are the height above the ground and the speed of the aircraft/glider container at the point of water release. Relying on these two essential parameters, it is possible to optimize the minimal size of the drops landing on the ground depending on the desired launch strategy.
There are other parameters to be taken into consideration at the moment of optimizing the release. These are the diving angle at the moment of the release and the use of a thickener to change the surface tension of the water at the planned high-speed release from the glider containers so as to control the

minimum size of the droplets at the moment of the impact and thus obtaining a higher capability of penetrating the core of the fire.
In the NITROFIREX project the release from the NITROFIREX AGC will be completely automatic. The research on release parameters (height, speed, diving angle and surface tension) must be undertaken in order to obtain the maximum efficiency from the release.
The release of a considerable mass of water (thousands of litres) from an air vehicle (plane, helicopter or glider container) at a relatively high speed can be studied initially from a theoretical point of view as a problem of fluid dynamics in order to establish a mathematical model that will assist in establishing the ideal parameters of the release.
The idea consists of establishing a simplified model in order to optimize the operation. It is necessary to bear in mind that it is a question of a two-phase flow (air - water), turbulence and having different parameters within the same plume of water. These, the main parameters that determine the nature of the problem, are the dimensionless numbers of Reynolds (turbulence) and Weber (effects of the surface tension), which can be considered infinite to practical effects in the exit area or water door of the glider container.
The subject of the release can be split into several areas ranging from the NITROFIREX AGC to the ground. The first area can be considered of potential flow, just at the exit of the glider container. It is followed by an area where a primary atomization takes place, where droplets of the smallest diameter are obtained. An area starts then to configure where a Rayleigh-Taylor instability prevails after which an area comes forth where a secondary atomization takes place, where you can find droplets increasing in size due to the decrease in the speed of the water plume. Knowing parameters such as speed, height and dive angle, it is possible to estimate an average or statistical distribution of the size of the drops, therefore allowing to adjust this distribution so as to perform each release in the most effective way, under any given conditions.
The study for the optimization of the release is a process requiring both basic research in fluid mechanics and applied research that could also be of great help in improving conventional means of operation.

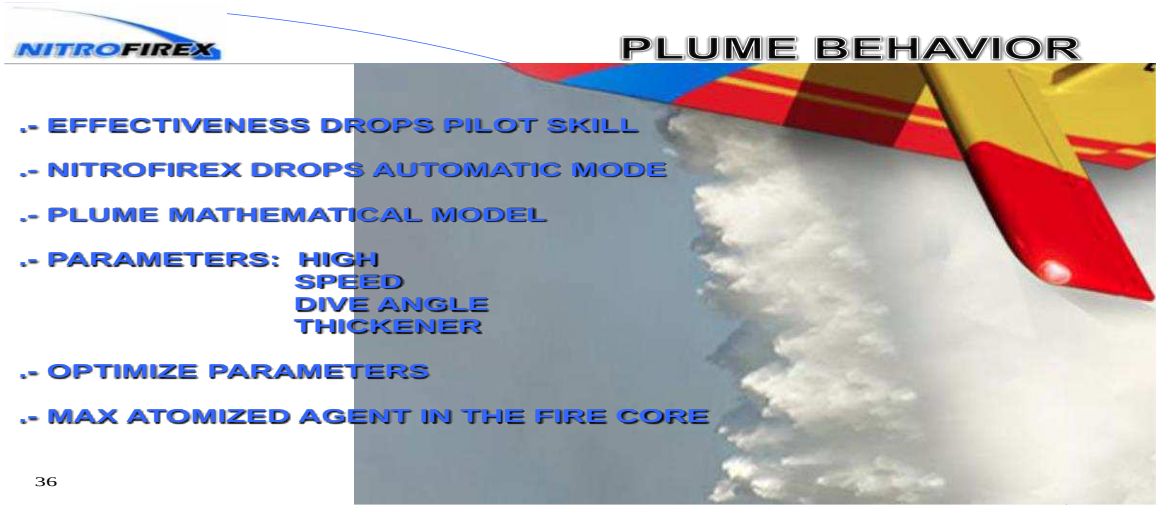

Figure 10

Coordination and safety

Those dedicated to aerial fire fighting know the importance of ground/air coordination to ensure an efficient and safe operation. With this objective in mind NITROFIREX proposes the implementation of new operative protocols and rules of communication with ground crews that are needed to adapt to the requirements of this project.

It should be the fire management officer who maintains radio contact with the LAs and the mission-base to coordinate the whole operation, principally the waiting points of the LAs as well as the approach routes and drop points of the NITROFIREX AGCs.
At night it becomes very important that the ground crews can see the approach and the drop from the NITROFIREX AGCs. For that reason, apart from the standard lights of all aerial vehicles (navigation, beacon, strobe and logo lights), the NITROFIREX AGCs are equipped with lights illuminating the fuselage as well as powerful headlamps. These headlamps are aimed forwards so that ground crews will be able to see them in the far distance and calculate the speed of approach to the drop point. So, ground crews will be able to very clearly see the approach, the actual drop and its effect on the fire as well as the NITROFIREX AGCs departure from the drop point.
In any type of aerial operation safety is of primordial importance at the time of planning, something NITROFIREX is not indifferent to. Consequently the NITROFIREX AGCs in their approach to the drop as well as in the recovery phase to mission base will have their flight parameters programmed and will accomplish them automatically and autonomously. But the safety concept of 'a man in a loop', in the case of having to abort the drop or reprogram the recuperation route, has been considered fundamental for the safety of the operation.
Therefore, during the approach phase, the NITROFIREX AGCs will be capable of manually or automatically aborting their approach to the drop point, releasing their cargo at the abort point and then proceeding automatically into the escape and recovery phase. Should the flight trajectory deviate from the one established or an unexpected event occurs during the approach to the drop point and it becomes advisable not to continue, the abort can be manual, carried out by the NITROFIREX AGCs operators at mission-base or from the LA and decided by anyone of them or by the fire management officer. The NITROFIREX AGC can automatically abort if its flight path does not match with what had been programmed or if it approaches the ground and/or a non-desired location.
In any case, the NITROFIREX AGC never reaches the ground filled with extinguishing agents, because if any thing deviates from what was programmed the cargo is immediately released and it then moves into the recovery phase.
On the other hand, the return route of the NITROFIREX AGCs to mission base will be programmed for the night (they have all day to do it in), at 500ft or less and over uninhabited areas. Should, by chance, the NITROFIREX AGCs engine have a flameout or any other malfunction during the return it is equipped with a parachute and an airbag, which opens up automatically and that allows for a 'soft landing', minimizing any possible damage.

8. Technical regulations for the operation of UAV's

Today the great stumbling block in operating UAVs in purely civilian aerial operations is the lack of rules and regulations controlling the airspace where both manned and unmanned aircraft could operate. For promoting the development of such rules and regulations at an international level two basic kinds of operations have been established: VLOS and BVLOS.
VLOS are those UAVs that operate in 'Visual Line of Sight' conditions, that is to say that at all moments there is visual contact between the vehicle and the operator. The operator's responsibility is to avoid any situation that could endanger any other aerial vehicle (manned or unmanned) or persons or properties on the ground. International regulation of UAVs operating within VLOS is meant to be available by 2015 since no technical or regulatory drawbacks exist, the operator being solely responsible for the safety of the vehicle.
BVLOS are those UAVs that operate under conditions 'Beyond Visual Line Of Sight', that is to say that in given distances and altitudes required for its employment the operator loses sight of the vehicle whilst electronic control is still maintained. These UAVs tend to have a great range and normally require the same airspace and altitudes of operation of manned aircraft.

Therefore regulating BVLOS UAVs is more complex, entailing greater technical requirements that will be needed because of the new players involved. These players range from the UAV operator to the air traffic controllers as well as the pilots of the manned aircraft.
Logically NITROFIREX stands in the second group of UAVs that operate under conditions of 'Beyond Visual Line Of Sight'. But the airspace required by the NITROFIREX project is in fact minimal: A segregated airspace over of the fire would be used for an LA flying at an altitude no more of 6.000 feet and a distance of no more of 6NM in respect to the intended drop zone. The LA will launch the NITROFIREX AGCs that would need no more than 90 seconds with their filled tanks, and finally no more than an hour of navigation at an altitude of 500 feet between the fire and the mission base (the LA operating base).
What manned aircraft could be flying in the proposed zone? That is to say a zone at an altitude of 500 feet or less between a fire and the LA's mission base? It is for this very reason that a night-time operation is proposed, so that the regulations established could serve as a stepping stone for future operational regulations for UAVs in a civilian environment that need more flight time and airspace for manoeuvres.
Understanding the flight envelope proposed, and in context with the BVLOS regulatory authority, the profile of the NITROFIREX AGCs recovery as proposed by NITROFIREX should be the first to be regulated because the operational hours and the airspace required cannot affect manned traffic. This would serve the use of UAVs in a safe and secure manner within the civilian environment of the BVLOSs. At the same time, it may take advantage of using it as a 'launching pad' for future regular BVLOS operations in the upper layers of airspace where safety requirement and coordination are far superior owing to the altitudes and flight times needed for UAV operations.
In one word, if in a BVLOS operation the low altitude profile, as proposed by NITROFIREX, is not regulated and it will be extremely difficult to regulate profiles requiring higher altitudes and longer time spans.

9. The aeronautical industry and UAV's

In the emerging and promising world of UAV's, aeronautical businesses as well as different governments and organizations are vying for good places in this race for the civil & military market of the future that unmanned air vehicles can provide.
The aeronautical industry and her official organizations will participate in this race with different products and business initiatives. But, owing to the on going economic crisis and the lack of rules and regulations, the short and medium future of the UAV's in our country is a singular challenge.
In addition to the profound economic crisis in which we are at present immersed, the defence and social security budgets are the first to be cut and readjusted. So, at the present moment, the UAV industry has to resort to ecological projects and appeal for social and political support to be able to support its participation in the development of the emergent world of unmanned aerial vehicles. The expensive and more complex projects must wait for better times.
Regarding past circumstances and now facing actual circumstances, the approach should be to find low cost projects operating in 'marginal airspace' with the purpose of keeping the regulatory bodies to a minimum.
The NITROFIREX Project entails all the previously mentioned connotations. As an air vehicle, it must obviously fly –both in the glider phase as well as in the UAV phase. Of course the NITROFIREX AGC must be able to navigate and release its cargo as programmed. One could propose an aircraft or a high performance aerodynamic vehicle or high performance aeronautic vehicle that would be evaluated, developed and whose final cost would never reach that of other projects with more demanding technical and operative objectives.
In addition to, and taking into account present circumstances, it should be the responsibility of the organizations and businesses involved in the development of the UAV's to refer to the economic

losses, the political concern and the social fear that wild-fires generate, in order to obtain economic aid and above all political aid that a project of this nature needs for its development.
Given its relatively simple technique and minimum requirements when compared to the other UAV projects, the NITROFIREX project can and should be dealt with solely aeronautical industry, instead of having to resort to complex and problematical international alliances. In these difficult times this would allow companies to find a niche in the complex and competitive world of unmanned aerial vehicles, serving at the same time as a launching pad for the aeronautical industry to find a good position within the UAV world by the time the civil employment of these vehicles becomes standard.
NITROFIREX has been presented in Madrid at the Spanish summit of unmanned vehicles, UNVEX-12 and at the Defence and Security Fair HOMSEC13. In both cases, great interest was shown amongst the official organizations (Spanish and European) as well as private businesses in this sector, especially regarding the exclusive and original approach on the operative and technical levels of the project.
During these two fairs it was obvious that the greater majority of UAV's are conceived for military or paramilitary employment. Consequently they are designed to transport technology composed of sensors and/or cameras with the object of obtaining and/or transmitting information. In order not to be detected or seen they are un-illuminated and are painted in discreet colours.
On the contrary the NITROFIREX AGCs are designed primarily for civil employment and conceived to spray/dust large quantities of non-technological substances at a programmed point of the atmosphere. In order to be seen by all involved in the operation they are illuminated (night flight) and painted in striking colours or marked by smoke generators (day flight).
Likewise, NITROFIREX's presentation at the International Aerial Fire Fighting Meeting in Aix en Provence (Marseille-France) April 2013 and in Sacramento March 2014 awoke enormous interest amongst the international aeronautic community for wildfire fighting. Our presence in the regulatory aspect brought us to give another speech in Eurocontrol in Brussels.
The importance and the concern of night-time fighting was obvious. The need to confront wildfires with security and efficiency is the great operational lack in of aerial means, a shortcoming and a total disregard for its importance!
The NITROFIREX Company has developed the conceptual phase of the project at its technical level as well as the operative and economic levels. It is now in the phase of consolidating the agreements between industrial/technological associates so as to confront the first phase of the construction of a concept demonstrator and subsequently the development of the Project.
The NITROFIREX concept is patented in those countries which have an economic and aeronautic capacity to face this type of project and who also have serious wildfire problems such as the USA, Canada, Australia, the Russian Federation and Europe (Spain, France, Italy, Germany England, Switzerland and Sweden). In addition, NITROFIREX is a member of the European organization EUROCAE and leads the work-group GW93. This group is responsible for editing the rules pertaining to the first phase, a phase that regulates UAS flights in non-segregated airspace in Europe.

10. **Conclusions**

It doesn't make sense that, well into the XXI century, at a time when ecology in all its aspects (climate change, CO2 emissions, deforestation, etc.) becomes a red hot topic on the political, social and economic levels, we've not bothered to integrate these demands in order to combat forest fires by night.
The use of an autonomously guided glider container, such as the one proposed in the NITROFIREX Project, allows for nocturnal aerial fire fighting operations, eliminates risks for crews and increases the accuracy and concentration of the releases. Besides all this, the amount of water dropped both per operating hour and per flight hour is increased with respect to the aerial methods currently used.
In addition, the launcher aircraft to be used are large military transport airlifters that are not single-role and they will continue performing cargo operations for the rest of the year once the summer forest fire

season is over. This will help bring down to a great extent the final flight-hour cost (considering acquisition amortization in addition to maintenance, personnel, etc.) for the part of operations performed on fire fighting, and ultimately the cost of each dispatched litre.
The new technologies have already been developed, matured and made available. It is only necessary to integrate them towards the objective that concerns and worries us. It is therefore up to the politicians and technicians in charge of the operation to accept the seriousness of the problem and to raise a new strategy against the ecological damage, the economic loss and the social alarm that forest fires produce. It is high time for the managerial and academic worlds to take on the challenge that an R&D project of this nature and relevance imposes.
The challenge consists in daring to develop this technological integration here and now with political decision, managerial initiative and technological drive.

Radiative properties of firefighters' protective clothing worn during forest fire operations

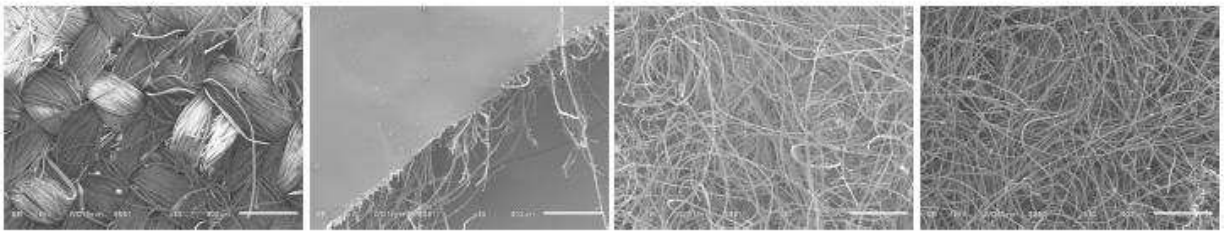
Abstract
The present work addresses the spectral radiative characterization of firefighters' jackets, which are the main component of their Personal Protective Equipments (PPE). During their tasks firefighters have to wear their PPE that must ensure simultaneously comfort, mobility and first and foremost thermal protection. Over time the nature and constituents of the firefighter's coats have strongly evolved. They were made up with leather for a long time, and are mainly designed in multiple-layer fabrics today. Given that, we can find many garments which overcome with one or several specifications in terms of comfort, thermal protection, heat dissipation, moisture barrier, mobility, weight … Numerous studies are found in the literature dedicated to one of these properties. None of the works related to their thermal performance considers the spectral radiative properties, however. Obviously, thermal protection is of primary importance and since firemen may be exposed to various heat threats, which present different spectral characteristics, it becomes also of prime interest to investigate the spectral radiative properties of these new products. To our best knowledge, the last study which referred to the spectral properties dates back to 1974 with the work by Quintiere [1] who provided the spectral radiative properties of several fabrics, within a relatively wide spectral range from 0.3 to 22 μm. The present study aims at investigating the spectral radiative properties of currently available fabrics used by French firefighters in the range from 0.25 to 16 μm covering both IR-Visible range.

Keywords*: Fire protective clothing, radiative properties, absorptivity*

Introduction

A standard fire intervention jacket (fig 1 (a)) is made of four layers (fig 1 (b)): a fire resistant outer layer in aramid (fig 2 (a)), a moisture barrier layer (fig 2 (b)) and a double inner layer for thermal barrier and comfort (fig 2 (c) and (d)). Our study is focused on the measurements of radiative properties of five fire intervention jackets provided by the Rescue Service Department of Meurthe et Moselle and of Vendée, France. Jacket #1 and #2 are blue, #3 is orange and #4 is gold. The fifth fire jacket is made of leather and is no more used in fire intervention in France since 2002.

Figure 1. Standard fire protective jacket (a). Samples of the different layers involved (b)



(a) *(b)* *(c)* *(d)*

Figure 2. The different layers of the jacket zoomed 50x (a) Outermost layer (b) Moisture barrier (c) Innermost layer #1 (d) Innermost layer #2

The experimental set-up used for the radiative property measurement was described in a previous study [2]. The radiative properties measured are the directional-hemispherical transmissivity τ_ν and directional-hemispherical reflectivity ρ_ν. These properties depend on the wavelength. Then, the spectral absorptivity α_ν is deduced from the radiative balance,

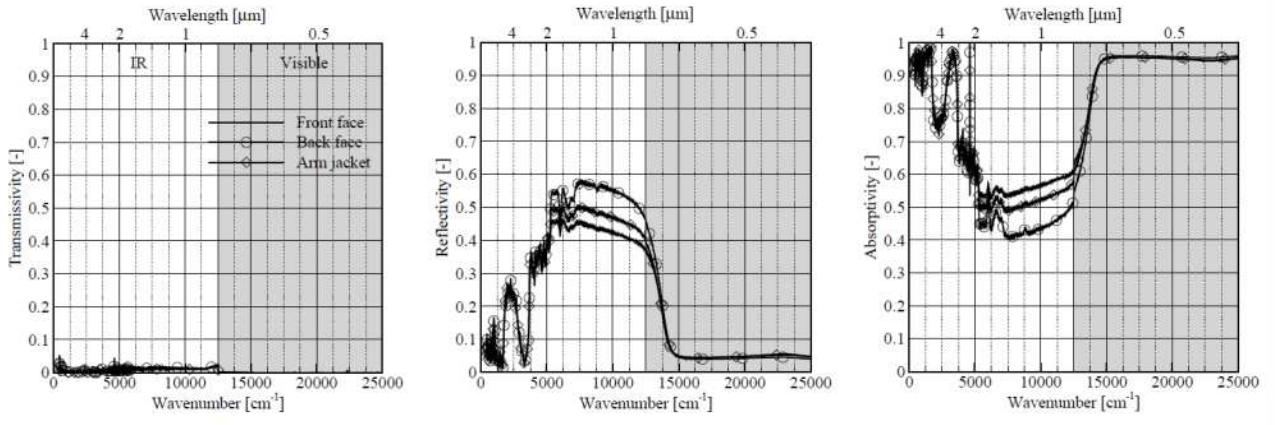
$$\rho_\upsilon + \tau_\upsilon + \alpha_\upsilon = 1$$

Directional-hemispherical transmissivity and reflectivity measurements were carried out in the visible-infrared range from 450 cm^{-1} to 25000 cm^{-1}. An FTIR spectrometer (Vertex 80 Bruker), an IR integrating sphere by Labsphere and an MCT detector by InfraRed Associates were used for the radiative properties in the IR range. In the visible range, a sphere from Labsphere and a spectrophotometer Cary 500 of Varian were used.
In the present study the homogeneity of the radiative properties was tested first. Then, a specific evaluation was conducted on the individual radiative properties of each layer of the fire intervention jacket #1. Finally, the effect of the fabric color and of the dyeing mode was evaluated, comparing the results for the different fire jackets.

Results

Repeatability test

Radiative properties may depend on the localization of the sample on the fire jacket. Three samples were selected from the jacket: on the front face, on the back face and on the jacket arm. The directional-hemispherical transmissivity, the directional-hemispherical reflectivity and the absorptivity for one fire jacket are presented in Figure 3, allowing to check for the homogeneity of the radiative properties on the jacket.

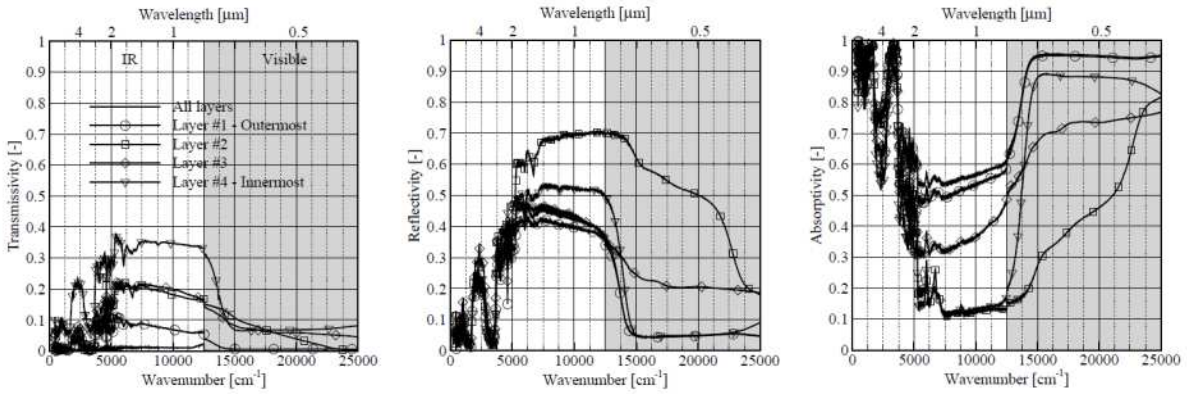


(a) Transmissivity *(b) Reflectivity* *(c) Absorptivity*

Figure 3. Radiative properties of three samples selected on the same fire jacket #1

Results reveal that the properties are quite similar for the three samples and that the radiative properties of the fire jacket are near homogeneous. It can be observed that the spectral transmissivity is quasi-null, whereas the spectral reflectivity can reach up to 55%. The average absorptivities over the whole spectral range are estimated to 80%. Consequently, no direct radiative transfer will occur through the jacket considering the zero transmission, but the high absorptivity will result in heat absorption which will be partly transferred from layer to layer through the jacket.

Radiative properties of the different layers

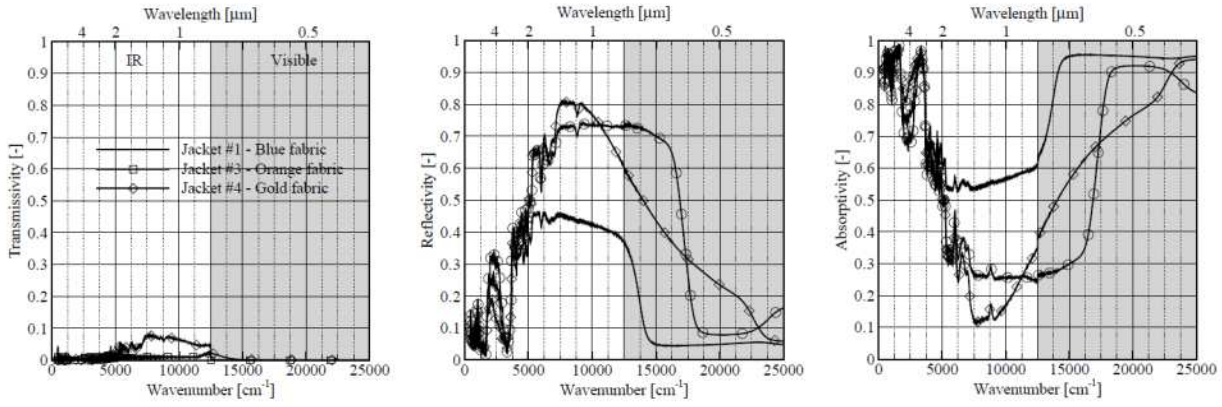


(a) Transmissivity *(b) Reflectivity* *(c) Absorptivity*

Figure 4. Radiative properties of different layers of the fire intervention jacket #1

The jacket #1 is made up with the 4 layers presented previously. Their respective radiative properties are presented in Figure 4 and compared with the complete jacket properties. The first observation is that each layer has a non zero transmissivity, but their product involved in the complete jacket finally results in a transmissivity equal to zero (fig 4 (a)). Note that the transmissivity of the outermost layer is too weak to allow significant multiple reflections inside the jacket. The reflectivity of the fire jacket is mainly due to the outermost layer (the curves of the reflectivity for this layer and the one of the complete jacket are superimposed in figure 4(b)). Strong variations of the absorptivity are observed as a function of the wavenumber (fig 4 (c)). The absorptivity is significantly lower for the inner layers, which results in a global behavior mainly influenced by the outermost layer, in particular in the infrared range. Globally, the radiative heat transfer through the fire intervention jacket is mainly controlled by the outermost layer.

Effect of the fabric color



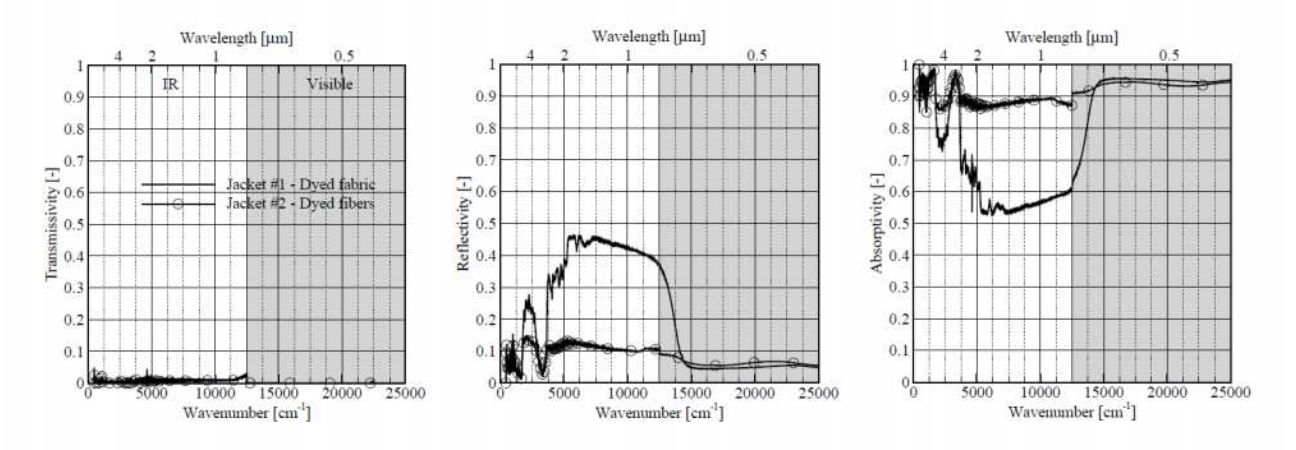
(a) Transmissivity *(b) Reflectivity* *(c) Absorptivity*

Figure 5. Comparison of radiative properties of different sample for a same fire jacket

Three different jackets (jacket #1, jacket #3 and jacket #4) with different colors (blue, orange and gold, respectively) have been tested in order to evaluate the impact of the fabric color.
Transmissivity values are still very low (fig 5 (a)) close to zero, except for jacket #4 for which values up to 9 % are obtained. The effect may due to the weaving mode which produces some little gaps between the polymer fibers, making the surface porous. The reflectivity is larger for the orange and gold jackets than for the blue one (fig 5(b)). Consequently, the spectral absorptivities of the orange and gold jackets are weaker than the one of Jacket #1(fig 5(c)). However, these discrepancies are mainly observed in the near IR and in the visible domain. They are very weak in the middle IR range, which results in close average values for all the jackets, since presented average values correspond to Planck's averaging performed for radiative sources with temperature in the range between 800 and 1400 K. A maximum absorptivity of 80% is finally found for the gold jacket, while a minimum value of 75% is obtained for the orange one. As a summary, the fabric color only slightly modifies the radiative properties in the spectral range concerned by radiative heat transfer and thermal protection.

2.4. Effect of dyeing

The dyeing is the process of adding color to the textile products. There are two dyeing modes involved in the fire intervention jacket manufacturing. The first consists in applying pigments during the polymer fiber production and then in weaving them to form the jacket. The second approach adds pigments after the jacket weaving.
Two different blue jackets (#1 and #2) with the two dyeing modes were compared (jacket #1 is a jacket dyed as a whole and jacket #2 is made of dyed fibers). Figure 6 presents the radiative properties for these jackets. The behavior of jacket #2 is close to be grey with an average absorptivity close to 90% (figure 6 (c)) while jacket #1 shows a weaker absorptivity, close to 80% in average.
Hence, the dyeing mode has a more important impact than the color itself, on the radiative properties of the jacket.



(a) Transmissivity *(b) Reflectivity* *(c) Absorptivity*

Figure 6. Radiative properties of different two jackets with different dyeing mode

3. Conclusions

Radiative properties were measured over the visible-IR range for different Personal Protection Equipments used by firefighters. Results show that fire protective clothings have a high spectral absorptivity in the IR range (between 80 and 90%). This is an important observation since the heat absorbed will be transferred through the jacket by conduction. The thermal protection improvement would require a decrease of the absorptivity, using layers with higher reflectivity. The effect of the

fabric color on the radiative properties is not significant. However dyeing mode of the jacket may have a more important effect: a weakest absorptivity is observed for a dyed fiber jacket.
Future work will be focused on the heat transfer between personal protection equipment and the skin of a firefighter.

Results of the R-20F Method for Measuring the Water Equivalence of the Isolation Effect of Foams Used in Fighting Forest Fires

Agoston Restas

National University of Public Service, Budapest, Hungary, Restas.Agoston@uni-nke.hu

Abstract
Introduction: Aerial firefighting is a very expensive solution; however bombing just pure water is not always enough to suppress the fires. In many cases retardants or special agents are added to water to increase efficiency, wetting it or creating foam. Methods: This research used dried pine wood pieces as samples. Samples were divided into different groups: not treated samples for giving the reference data or treated samples to ensure data for calculating the isolation effect of foam. During the experiment with a randomly chosen foam agent product a 3% foam solution was mixed. From this solution 6 – 9 – 12 expansion rate foams were generated. Samples were also provided with a metal ring to ensure the exact depth of water or foam blanket. Each sample was put in a special heat oven which ensured the permanent 35 kWm^{-2} heat fluxes and measured the different ignition time. Results and discussion: Experiment demonstrated that the ignition times in case of foams are longer than in case of same equivalent pure water. The longer ignition time of foams can be expressed by the pure water amount. Results say that the maximum rate of isolation effect in value of water equivalent is more than 2.3 but always significantly more than just pure water.

Keywords*: isolation effect, foam, water equivalence of isolation effect*

Introduction

Based on author's experience there is no objective method known for measuring the complex effect of the efficiency of foams while suppressing fires. The suppression potential of foams such as Class A foams specially used for structure or forest fires is measured by a special way; bonfires classified by international standards are extinguished by the foams and the potential is evaluated by the size of the bonfires. This method, measuring the active impact of foams is appropriate and accepted as international standards for structure fires.
The standard methods are not measuring the isolation effect of foams, however there were more initiatives regarding this topic (Boyd and Merzo, 1996; STP 2007 Standard Test Procedures). But each manufacturer characterizes their agent with the "*good*" isolation effect. The isolation effect is not an active action against the flame but passive influence of the ignition caused by the blanket covering the surface (Igishev and Portola, 1993; Salgado and Paz-Andrade, 2009).
Since there is no accepted method for measuring the isolation effect of foams, and each producer characterizes its own foam as having "*good*" isolation effect, it is required to develop a process which is objective, practical and ready to demonstrate the different isolation effects of the different type of foams.
To start with, the reference base to which the effect is evaluated and expressed in equivalent must be declared. Pure water is the most frequently used material for fire suppression that is why it was taken as base and the scale of equivalent.
As usual foam is characterised as having passive isolation effect but not as having the active extinguishing potential; this feature also can be very important during intervention, especially in case of forest fires using aerials. The added value of using foam for the fire suppression is not only isolation of the combustible material against heat radiation but it also plays an active role in suppression. If the quality or quantity of foam blanket is not suited for stopping the spread of fire it means that the consumed resources were ineffective, spending on aerials used was wasteful.

Methods

The method was developed in order to measure the extinguishing potential of foam blanket. This procedure following the below assumptions got a fantasy name and was called R-20F method. As usual foam is characterised as having passive isolation effect but not as having the active extinguish potential; however this feature also can be very important during intervention.

Prepare the process

Below is declared the main important things for preparing the test, and some basic process for being ready to measure the ignition time of samples.
Means required for the process:

1. Radiant heater: KAL VK1[1] - with 35 kWm^{-2} heating flux[2];
2. Samples with metal rings – 0,06m x 0,06m x 0,01m dried pine wood samples;
3. Pure water, temperature 293 K;
4. Foams , made from type EVAM[3] agent, 3% mixed rate solution, expenditure rate in series 6 – 9 – 12.

Special metal ring stacked to each sample in order to ensure the same thickness of foam blanket covering the samples. Ring is made of steel, with 0.06m diameter and 0.008m sheet thickness, in series of 2 – 3 – 4 – 5 mm ring height. Rings are fixed by heat resistant stove glue, purchased from the market.

Ignition time

During the experience three different ignition times were measured: A) It is necessary to measure the natural sample for getting the net ignition time; B) The measurement of the sample treated with water gives the reference base; C) The sample treated with foam is measured for the purposes of the test method.
Ignition time of natural sample: Natural sample with metal ring but without any surface treatment is needed to put in to the radiant heater and measured the ignition time. As usual, the space between the foam blanket and the heater is fix and have to ensure that the radiant heat fluxes is 35 kWm^{-2} continuously. At least 3 or more samples are needed for measuring the ignition times.
Ignition time of water treated sample: The effect of water's ignition delay relates to the ability of heat abstraction; it is used as a base, similar to the effect of foam's ignition delay. Ring on sample is needed to fill with 293 K temperature pure water by the volume of rings depending on the series. Sample is needed to put in to the radiant heater and measured the ignition time. As usual, the space between the rim of ring and the heater is fix and have to ensure that the radiant heat fluxes is 35 kWm^{-2} continuously. At least 3 or more samples are needed for measuring the ignition times, in series with 2 – 3 – 4 – 5 mm deep water column.
Ignition time of foam covered sample: From pure water and foam agent have to prepare a solution with 3% mix rate. From the solution different expansion rated foam is prepared in series 6 – 9 – 12. Ring on sample is needed to fill with foam by the volume of rings depending on the series. Sample is needed to put in to the radiant heater and measured the ignition time. The space between the rim of ring and the heater is fix and have to ensure that the radiant heat fluxes is 35 kWm^{-2} continuously. At least 3 or more samples are needed for measuring the ignition times, in series with 2 – 3 – 4 – 5 mm thick foam blanket.

[1] KAL VK1 radiant heater: produced by KALÓRIA Hőtechnikai Kft., H-1071 Budapest, Bethlen út 43 Hungary
[2] Certificated by Szent Istvan University, Ybl Miklos Department, Budapest
[3] Foam agent for universal applications in Hungary and neighbor countries, used also for fighting against forest fire; it is made by EVM Rt., H-1172 Budapest, Cinkotai út 26. Hungary.

The effect of foam is obviously influenced both by the structure made by air bulbs and the solution itself the foam contains (water and agent). Since the R-20F method focuses to measuring typically the isolation effect of foam, influence of the solution is needed to exclude. The effect of solution is taken away from the complex effect; it depends on the different quantity in series of the solution the foam contains. Since the extract rate is very low (3%) the effect of pure water and solution is taken equal.
Based on the measured data, it is required to calculate different parameters. For calculations and evaluating the measured value, notations and different mathematical formulas were used. Because of their complexity, formulas (F.x) can be found in the Appendix separated. These formulas marked in brackets signed in many places (text and tables) make the process of following easier.

Study for ignition time

This study contains only the extracted data meaning usually the average value of measured ignition time but in explanation deviations also mentioned. The whole study located in the author's archive.

Measured ignition times of different treated samples

The first test result used for this study for further calculation. The *Table 1* contains the average value of measured ignition time.

Table 1—Measured data of ignition time.

R-20F		No treatment	Blanket sample covered [mm]			
			2	3	4	5
		Ignition time [sec]				
Nature		19				
Water			108	-	-	-
Foam	Rexp6		45	51	58	60
	Rexp9		42	47	50	53
	Rexp12		36	44	46	44

Legend: Nature: samples without treatment
R_{exp}6/9/12: Expansion rate of foam used for series

Based on the measured data and mathematical formulas different calculations were made. The series of this calculation can be followed in Table 2, Table 3 and Table 4.

Net time of ignition delay

To evaluate the results different calculations were made. Firstly, the ignition delays of differently treated sample were measured; in case of no treatment (nature) *F.13*, water *F.14* and foam *F.16* figures meaning. These results can be evaluated as "net effect" of ignition delay of extinguishing material covering the samples. For the calculations *F.15* (water) and *F.17* (foam) formulas were used (*Table 2*).

Table 2—Net time of ignition delay

No	Height of the ring (F.1) h [mm]	Expansion rate of the foam (F.9) y [-]	Ignition time gross (F.14) (F.16) t [sec]	Ignition time nature (F.13) t [sec]	Ignition time net (F.15) (F.17) t [sec]
1.	2	0 (water)	108	19	89
2.		6	45	19	26
3.		9	42	19	23
4.		12	36	19	17

14.		6	60	19	41
15.		9	53	19	34
16.		12	44	19	25

3.3. Foam's efficiency and expression by water equivalent

Secondly, the water content of the foam, expressed by water column happens (F.19). Logically samples covered with water also belong to this series (F.18). Thereafter the ignition delay of water, foam contains is calculated (F.21). Samples covered with water belong again to this series (F.20). Based on the *F.17* and *F.21* a coefficient created (F.23) expressed the relation between the ignition delay in case of same water quantity but different features (water-foam). As before, samples covered with water also belong to this series (F.15 and F.20) meaning the base to this calculation (F.22) and logically ratio always results *1* (*Table 3*).

Table 3—Coefficient of ignition delay

No	Height of the ring (F.1) h [mm]	Expansion rate of the foam (F.9) y [-]	Ignition time net (F.15) (F.17) t [sec]	Water content in water column height (F.18) (F.19) h [mm]	Ignition time of water quantity (F.20) (F.21) t [sec]	Coefficient of ignition delay (F.22) (F.23) Y [-]
1.	2	0 (water)	89	2	89	1
2.		6	26	0,333	14,8	1,76
3.		9	23	0,222	9,9	2,32
4.		12	17	0,167	7,4	2,3

11.		9	31	0,444	19,8	1,57
12.		12	27	0,333	14,8	1,82
13.	5	0 (water)	223	5	223	1
14.		6	41	0,833	37,2	1,1
15.		9	34	0,555	24,8	1,37
16.		12	25	0,417	18,6	1,34

Table 4—Foam's extra ignition delay and its expression by water equivalent

No	Height of ring (F.1) h[mm]	Expansion rate of the foam (F.9) y [-]	Coefficient of ignition delay (F.22) (F.23) Y [-]	Water content in water column height (F.18) (F.19) h [mm]	Water equivalent of ignition delay (F.24) (F.25) Z [mm]
1.	2	0 (water)	1	2	2
2.		6	1,76	0,333	0,586
3.		9	2,32	0,222	0,515
4.		12	2,3	0,167	0,384
5.	3	0 (water)	1	3	3
6.		6	1,43	0,5	0,715
7.		9	1,89	0,333	0,629
8.		12	2,23	0,25	0,558
9.	4	0 (water)	1	4	4
10.		6	1,3	0,667	0,867
11.		9	1,57	0,444	0,697
12.		12	1,82	0,333	0,606
13.	5	0 (water)	1	5	5
14.		6	1,1	0,833	0,916
15.		9	1,37	0,555	0,76
16.		12	1,34	0,417	0,559

Based on the coefficient (F.23) and water content (F.19) of the foam the ignition delay can be calculated expressed by the equivalent of water column (F.25). This equivalent means that water has *extra ignition delay effect* in case of foam formulas (*Table 4*).

Evaluation

As a first step, the ignition time of samples without treatment (nature) was measured. For the correct base nature samples were measured also during series. Precision of measuring ignition time was below *1* second. Based on 6 samples the average ignition time is 19 seconds with minimal deviation (+3/-2 seconds).
In the series, the samples covered with water were measured firstly. To make measurement more precise, the 2 mm high ring samples were filled with water using hypodermic syringe, to make the volume precise.

$$V = hA = h\frac{d^2\Pi}{4} = 2x10^{-3}m\frac{\left(60x10^{-3}m\right)^2 x3{,}14}{4} = 5{,}652x10^{-6}m^3 = 5{,}65cm^3$$

Based on five measures the average ignition time was 108 seconds, with +15/-18 seconds maximal deviation; the rate of deviation is not bigger than with natural samples.
The speciality of water series was that no more measures with precision could be carried out with higher ring on samples. Unfortunately the rings separated from the sample surface (3 mm) and causing some water leakage during tests spoiled the genuine process. The problem was identified as a minimal deformation of samples' surface caused by water and cement was not enough flexible to compensate the minimal gap. Therefore in case of 3-4-5 mm high ring there was no measured value only calculated in scale based on linear interpolation.
Due to the above, some results can be taken into account with due critical considerations; and additional test series are also required. But results were evaluated as a tendency rather than principle of each measured data.

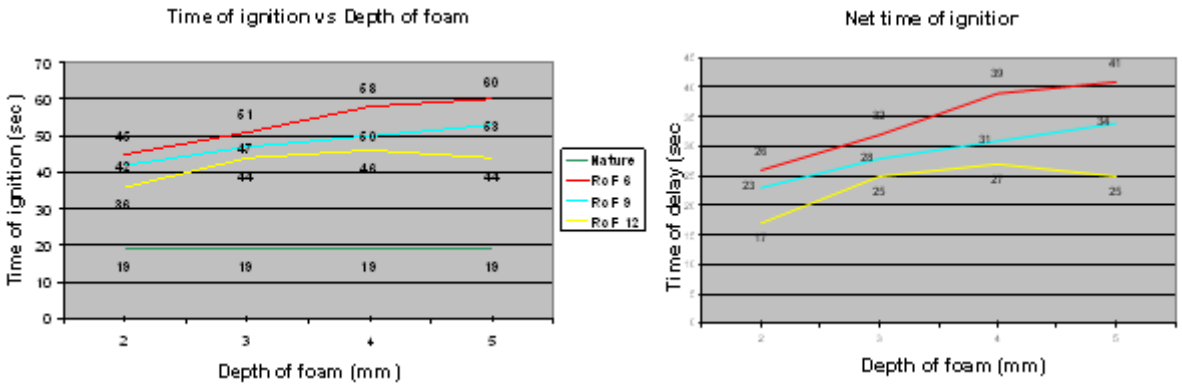

Figure 1. Time and Net time of Ignition versus Depth of foam

In the next series the different expansion rated foams were tested with different depth of blanket covering the samples. The same quantities of foam in each sample were assured by rings. The measured values are in the *Table 1* and *Figure 1* also shows values in the graphics. The graphics show not just the time of ignition but the tendency of the change hanging on the depth of foam covering samples.

The study focused on the inspection of how the ignition delay changed and what is the tendency of it hanging on the own quality of the foams. That is why the ignition time of not treated sample (nature) required subtracting from the ignition time of treated samples (water and foam). In this case the data shows the "net ignition time" of substances hanging on their own features (Figure 1). Based on measured data and graphics next conclusion were stated:

1. Rising the depth of foam covering samples the time of ignition delay also rise. Tendency yes, but exact data for rising characteristic was not established; more test needed.
2. Rising the depth of foam a special symptom, co-called "foam boiling" was observed. This symptom was more intensive during raising the depth of foam, especially in case of 5 mm foam blanket with high expansion rated foam (exp. rate = 12). It modified the result, obviously reduced the delay of ignition time.
3. Taking into account the symptom of foam boiling (see above) and the curve tendency of foams (expansion rate is 6 - 9, and depth of foam is 2-5 mm) the tendency more or less can be also linear.
4. Since the technical difficulties and the assumed rate for higher mistake this study didn't measure the 1 mm high ring samples, however the *Figure 2* generated the data by linear interpolation.

The effect of foam's ignition delay is aggregated by two different factors as below; the first counts with the quantity, the other with the quality:

Factor of quantity: Mechanical foam is made of special solution and air bulbs; solution consists of pure water and special foam agent. The mixture rate hangs on conditions intervention having; ratio is required usually between 0.1 – 6 %. During the study of R-20 method 3 % solution was used. Since the rate was relatively low and the heat capacity of the agent doesn't differ drastically from the water, the value of solution was taken equal to water. Obviously during the test radiation heat evaporated the solution meaning that its heat capacity influenced the ignition time, delayed it similarly to water.

Factor of quality: Foam has a special effect not just having water quantity. Isolation, the additional feature of foam is an extra effect. Fire fighters often use this isolation effect even if the practice does not know exactly what is it or with more precisions what the background of this effect is. Obviously the isolation effect often means defence against radiation heat but also separation between flammable liquid and oxygen. R-20F method focuses on the study of the extra effect caused by the special feature

of foam. The interest focuses not on the feature of foam but finding a common scale expressing this extra effect and measures these with water equivalent, understood by any fire fighter.
If the foam produces longer ignition delay than ignition delay belongs to its own water quantity, it means that this extra effect is caused by the special features the foam has.
In order to reduce the possibility of mistake during test, series started from 2 mm high covering. Value before it was rated logically. *Figure 2* left from the broken line shows the estimated value, right the measured except in case of water. Problem of water was mentioned above.
Based on the own water quantity of foam (F.7) the ignition delay belonged to it was determined by linear interpolation (F.9). Dividing the time of measured ignition delay to its own water quantity results a rate. If the value of this rate is more than *1* means that foam has extra delay effect (F.11).
Based on the R-20F study the analysis of measured data resulted that this rate is significantly always more than *1*. It means that foam has extra isolation effect than just the effect of its own water quantity.

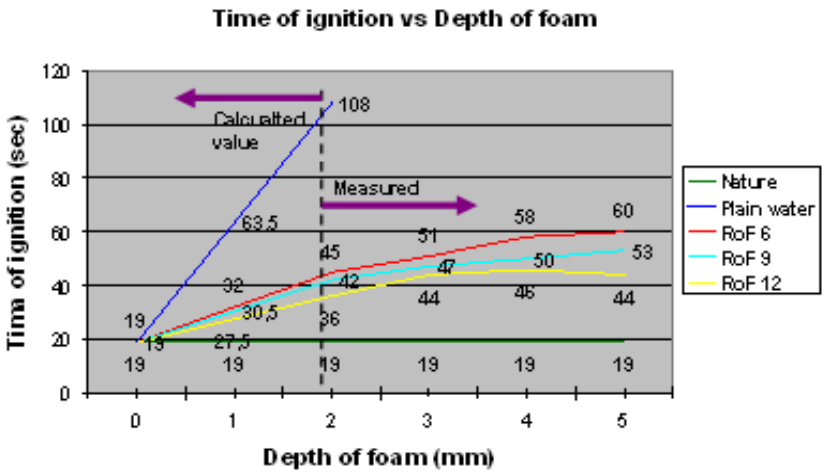

Figure 2. Measured and interpolated value of ignition time

The efficiency of foams with different features is represented in different functions as can be seen below:

1. Expansion rate on "x" axis and hanging on depth of foam efficiency shown in *Figure 3a*;
2. Depth of foam on "x" axis and hanging on expansion rate efficiency shown *Figure 3b*;
3. For better demonstration both diagram were made in 3 dimensional versions using belt diagrams *Figure 4a* and *Figure 4b*.

Based on experience during the test, calculations and graphics there are statements as can be seen below:

1. The efficiency of foam rises with raising the expenditure rate. The characteristic of this raise can't be surely stated; taking into account the deviations from the average, the near linear curve can't be excluded.
2. The efficiency of foam reduces with raising the thickness. The characteristic of this reduce can't be surely stated; taking into account the deviations from the average, the near linear curve here also can't be excluded (but logically in ideal circumstances it must be).
3. Relatively thin foam blanket but high expansion rate results in high efficiency.

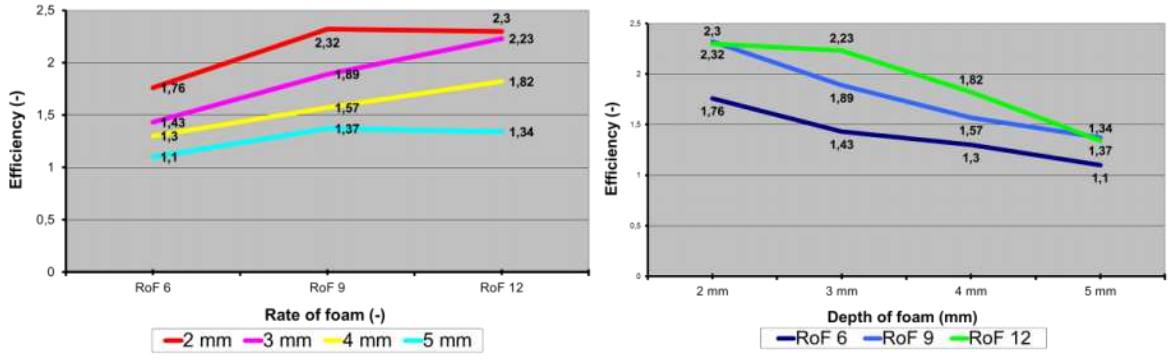

Figure 3. Efficiency versus rate of foam (a) and depth of foam (b)

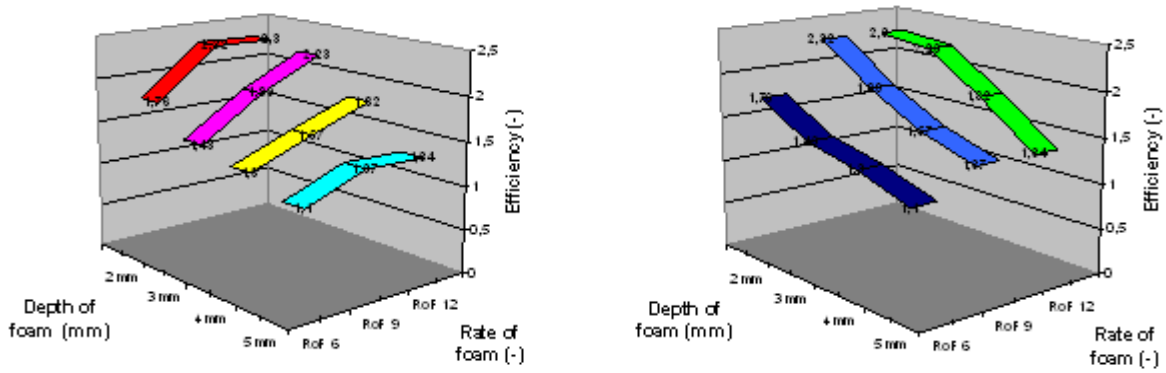

Figure 4. Efficiency versus rate of foam (a) and depth of foam (b); belt diagrams

After determining the efficiency of foams, R-20F method focuses on the expression of this extra effect by practical method; to be able to explain this extra effect also to fire fighters. Water equality as an easiest way can give the solution (F.25). The water equality of foam with its own water quantity can be also demonstrated in a function shown by *Figure 5*. The difference between values in vertical shows also the extra ignition delay effect of foam.

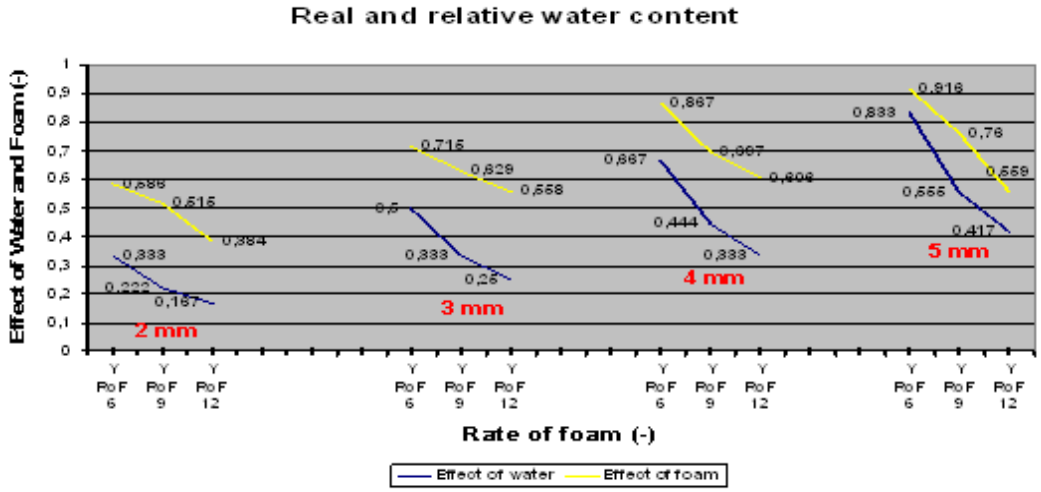

Figure 5. Real and relative water content

The graphic also demonstrates that raising the thickness of foam (2 mm ⇒ 5 mm) moves the curves close to each other; consequently the delay effect reduces. This statement harmonises to *Figure 6*. With fine analysis it can be observed that the angle with "x" axis rises in both case (real and equivalent water quantity of foam's curve) if thickness of foam blank*et al*so rises.

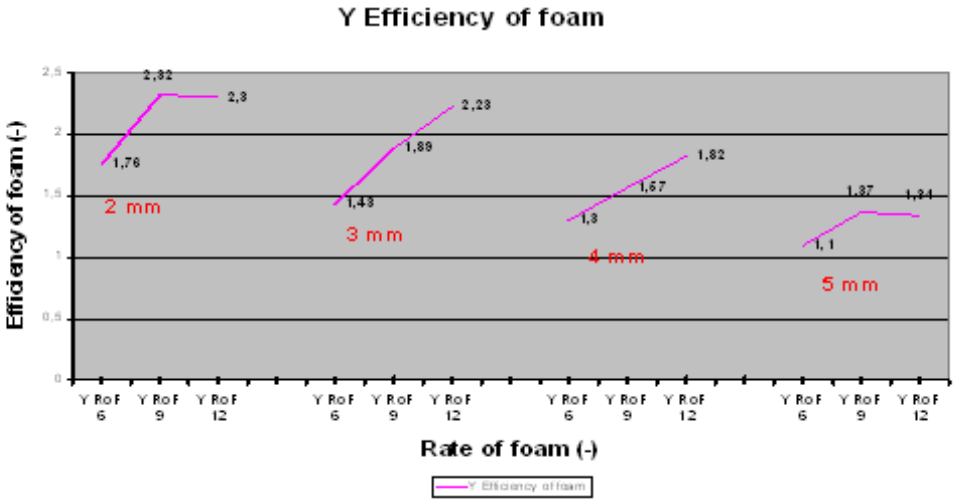

Figure 6. Efficiency of foam

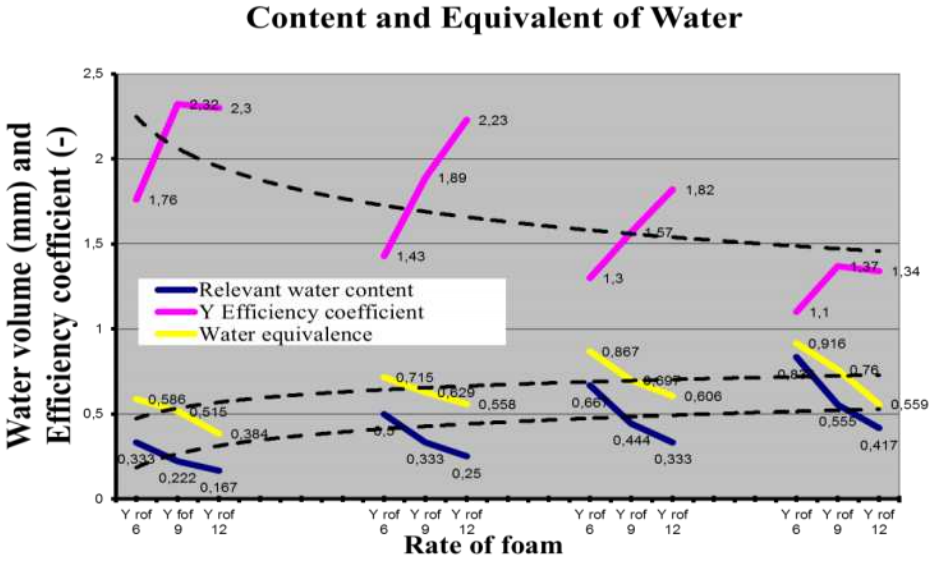

Figure 7. Content and equivalent of water

The coefficient reduces while raising the thickness of foam blanket, parallel to the angle between curves and "x" axis (Figure 7). Harmony is also demonstrated in the function where foams with different features, the real and equivalent water contain of foams and coefficient is represented.

Summarizing

Based on the R-20F method commonly used firefighting foam was tested. There are many experiences after making test series. Main statements:

1. R-20F is appropriate method to determine the extra effect of foam which is caused by the special feature of the structure and resulted longer ignition delay than should by own water contain.

2. R-20F is appropriate method drawing conclusion regarding most effective intervention, determine the quality and quantity of foam used especially in case of forest fire.
3. Results given by R-20F method declare that the most effective structure of foam is a relatively thin foam blanket (≤ 5 mm) but higher expenditure rate than 6.

For better and more precise results additional test are required using different foam concentrate especially used for fighting forest fires even by aerials. Based on the results some traditional tactic can change and cause more effective fighting against forest fires.

Appendix – Mathematical formulas used for calculations

1. h — Height of the metal ring [mm]; (F.1)
2. t — Ignition time [sec]; (F.2)
3. "h" — Upper index, height of water column or thick of foam blanket (height of the metal ring) [mm]; (F.3)
4. "nature" — Lower index, untreated sample; (F.4)
5. "B" — Lower index, gross ignition time [sec]; (F.5)
6. "N" — Lower index, net ignition time (measured ignition time reduced by the ignition time of the untreated sample) [sec]; (F.6)
7. "W" — Lower index, ignition time of water treated sample [sec]; (F.7)
8. "F" — Lower index, ignition time of foam treated sample [sec]; (F.8)
9. "y" — Lower index, expansion rate of the foam [-]; (F..9)
10. W — Water content of the foam/water expressed by water column height [mm]; (F.10)
11. Y — Effect of ignition delay regarding water content [-]; (F.11)
12. Z — Effect of ignition delay expressed by water equivalent [-]; (F.12)
13. t_{nature} — Ignition time, nature sample [sec]; (F.13)
14. t_{BW}^{h} — Gross ignition time, sample covered with "h" mm height water column [sec]; (F.14)
15. t_{NW}^{h} — Net ignition time, gross ignition time reduced by t_{nature}, sample covered with "h" mm height water column [sec]; $t_{NW}^{h} = t_{BW}^{h} - t_{nature}$ (F.15)
16. t_{BFy}^{h} — Gross ignition time, sample covered by „h" mm thick and "y" expansion rated foam [sec]; (F.16)
17. t_{NFy}^{h} — Net ignition time, gross ignition time reduced by t_{nature}, sample covered with "h" mm thick and "y" expansion rated foam [sec]; $t_{NFy}^{h} = t_{BFy}^{h} - t_{nature}$ (F.17)
18. W_{W}^{h} — Water content of "h" mm height water column [mm]; (F.18)
19. W_{Fy}^{h} — Water content of „h" mm thick and „y" expansion rated foam, expressed by water column height [mm]; $W_{Fy}^{h} = \frac{h}{y}$ (F.19)

20. $t^h_{W/W}$ Ignition time measured (2 mm) or linear calculated (3-4-5 mm), sample covered with "h" mm height water column [sec]; $t^h_{W/W} = t^h_{NW}$ (F.20)

21. $t^h_{W/Fy}$ Ignition time calculated with water quantity of foam contains, sample covered by „h" mm thick and „y" expansion rated foam [sec]; $t^h_{W/Fy} = \frac{t^h_{W/W} W^h_{Fy}}{W^h_W}$ (F.21)

22. Y^h_W Coefficient, meaning the effect of water's ignition delay, sample covered with "h" mm water column, evaluated by water equivalent. Rate = 1 [-]; $Y^h_W = 1$ (F.22)

23. Y^h_{Fy} Coefficient, meaning the extra effect of foam's ignition delay correlate to its own water content, sample covered with "h" mm thick and "y" expansion rated foam [-]; $Y^h_{Fy} = \frac{t^h_{NFy}}{t^h_{W/Fy}}$ (F.23)

24. Z^h_{EquW} Water equivalent of water's ignition delay, expressed by „h" mm high water column. [mm]; $Z^h_{EquW} = W^h_W$ (F.24)

25. Z^h_{EquFy} Water equivalent of foam's ignition delay, evaluated by "h" mm height water column equivalent, foam blanket „x" mm thick and „y" expansion rated foam[mm]; $Z^h_{EquFy} = Y^h_{Fy} W^h_{Fy}$ (F.25)

Safety at the WUI: a firefighters view

Clara Quesada-Fernández[a], Daniel Quesada-Fernández[b]

[a] *Universidad de Córdoba, Spain.* claraquesada@gmail.com, danielquesadafernandez@gmail.com

Abstract
Firefighting is a risky task. Every year during an even longer fire season we attend to many injuries and fatalities of civilians and firefighters in the frame of forest fires activities, especially in wildland urban interface fires situations. Every fatality and injury are investigated, in most of cases they are object of scientific research in order to learn from mistakes. Extracting the learned lessons helps to try not to repeat the situation. In case of recurrent risks personnel can be prepared to deal with them safely. Research in materials, procedures, protocols and many others, most of them are measurable aspects. State and regional agencies invest resources in education and training of its personnel in fire situations. However, in some cases it is not assessed enough those involved (firefighters) on their own identification and perception of risks.

Keywords*: communities, fire emergency, emergency evacuation, emergency preparedness, firefighting, fire prone areas, fire risk, forest fires, hazard, how to prevent, human behavior, personnel safety, prevention, risk, safety, wildland urban interface fire hazards.*

Introduction

Firefighting is a risky task. Every year during an even longer fire season we attend to many injuries and fatalities of civilians and firefighters in the frame of forest fires activities, especially in wildland urban interface fires situations. Every fatality and injury are investigated, in most of cases they are object of scientific research in order to learn from mistakes. Extracting the learned lessons helps to try not to repeat the situation. In case of recurrent risks personnel can be prepared to deal with them safely. Research in materials, procedures, protocols and many others, most of them are measurable aspects. State and regional agencies invest resources in education and training of its personnel in fire situations. However, in some cases it is not assessed enough those involved (firefighters) on their own identification and perception of risks.
Sometimes an excess of confidence or a lack of it due to a misperception of risk involve the occurrence of an accident. They are very little analyzed the so-called almost accidents. This situation is particularly relevant in wildland/rural urban interface areas.

Methods

The current situation about safety risks in the firefighting tasks shows identified risks and other unknown or not identified as risks. It is discussed the risk perception/vision of firefighters fronting fires in wildland urban interface areas.
The study examines the case of several working groups. In particular we study cases in Spain, located in different areas of the territory (peninsular, islands) with different working protocols to fighting fires in the WUI areas as common work situation to all of them. We show the analysis of different Fire Services situations all of them in fire prone areas throught the view of their firefighters.
Collected data were obtained from a 151 firefighters sample in Spain from base to higher levels in the firefighting scale. They collaborated in a extended survey during six months. In some of the cases firefighters had a specialized work in forest fires, following a Forest Model. In others cases existed a structural fire-based Service fronting forest fires.
The process consisted of a survey containing 50 questions about risk perception in firefigting tasks at the WUI. Each thematic block in which was divided the survey was presented with some introductory comments that summarized the contents. The first section of topics was dedicated to recognising the

main activity of firefighters at their Service structure, experience in fighting fires, personal data (sex, age). The second part followed knowledge on the topic of forest fires from the perspective of fire management, fire fighting, wildland urban interface and the state of the art in their territories and others places. We asked about the perception of risk levels and existence of aditional types and risks levels working at forest areas and wui areas. The third part analyzed the perception of human relations between professionals and citizens. The last section was dedicated to a miscelanea of questions about the perception of firefighting future at the WUI.

Results and discussions

The first section dedicated to recognising the main activity of firefighters showed 151 firefighters (141 men, 10 women) working on preventing and fighting forest fires (97% of them, 3% only prevention tasks) with more of ten years of activity. They described their activity as interesting (35%), usefull (33%) and risky (28%) and by calling as firefighting (70%). A minimun of 4% considered the activities as no risky tasks.

The second part followed knowledge on the topic of forest fires from the perspective of fire management, firefighting, wildland urban interface and the state of the art in their territories and others places. It was carried out using a four-level grid consisting of progressive steps of assessment from level 1 (no fires) to level 6 (catastrophic). The Do not know (Dk) answer was also avalaible. As shown in *Figure 1* the most popular argument tended to be referred to levels 3 (medium) to 6 (catastrophic) in the own country (Spain, 94% of data collected), the region (82%), working areas supossed to be well known (77%) and other places in the world (32% of referred data "Do not know" and 62% referred to levels 3 to 6).

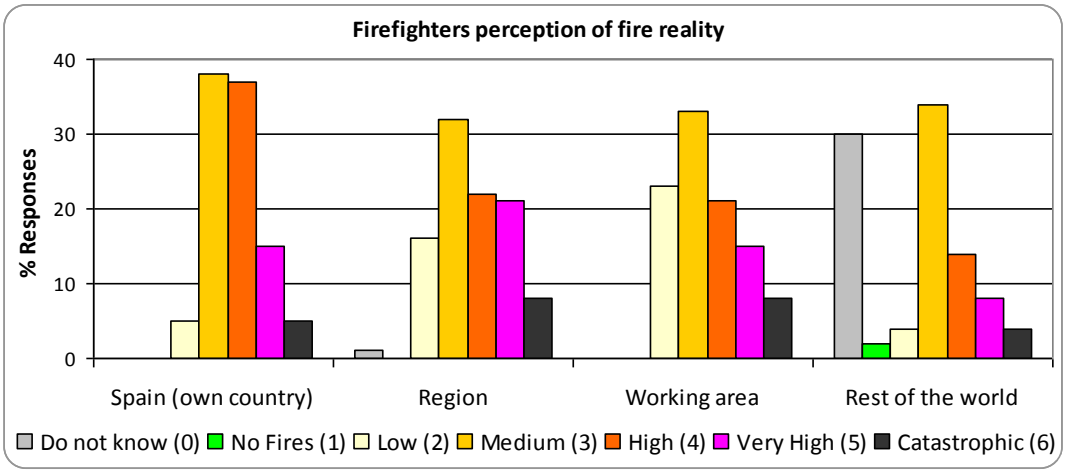

Figure 1. Perception of fire reality. Source: Quesada, C. & Quesada, D., 2014.

We asked about the perception of risk levels and existence of aditional types and risks levels working on fires in forest areas and WUI areas in Spain. To the question "Special risk at wui firefighting tasks" a number of 18% answered that the risks at the WUI were exactly the same as those on fighting forest fires. It is pretty clear to them the number of aditional risks as seen in *Figure 2*.

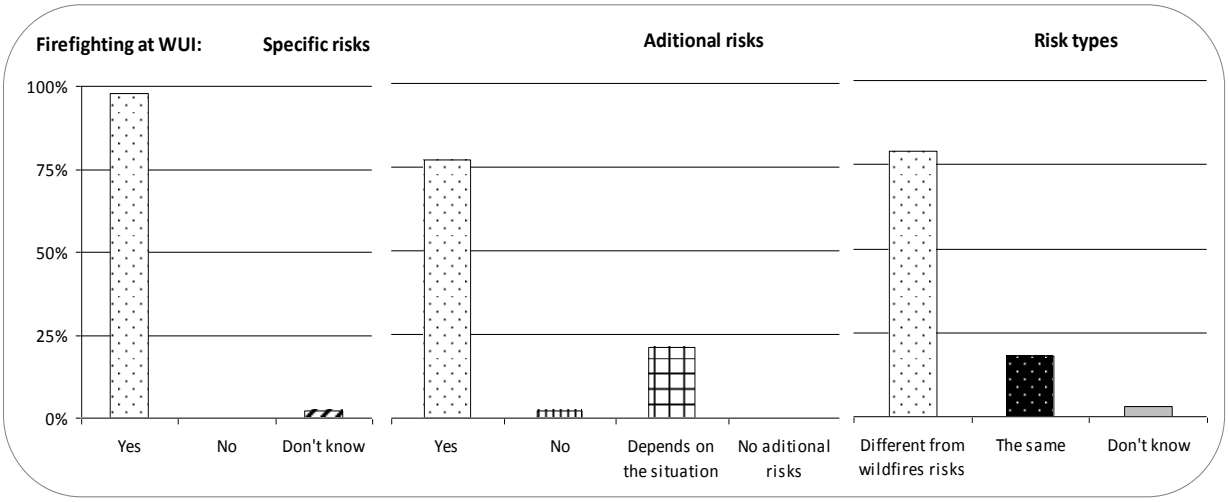

Figure 2. Perception of firefighting risks at WUI. Source: Quesada, C. & Quesada, D., 2014.

The third part analyzed the perception of human relations between professionals and citizens. A number of 28% admited that they ignored if civilians (residents, owners, tourists) had been previously informed about prevention and fighting policies and activities at WUI areas. More than 30% of professionals perceived that civilians didn't know about firefighting tasks neither who were the professionals responsible for that. If they did (firefighters fight forest fires and WUI fires) they didn't recognize their work as relevant or even consider that as an important task. This fact was specially relevant at WUI and rural areas.

Asking about WUI areas a number of 11% didn't know what WUI meant. This data corresponded to those professionals working in forest areas with an inexistent participation in fires in those areas. However, most of firefighters have expressed their lack of knowledge and how to proceed in a WUI fire. Referring to firefighing strategies and tactics at WUI areas a high number answered about an inappropiate situation in terms of not specific tools with their actual PPE (37%), hand tools (26%), trucks, engines or vehicles on the road (25%) and a general lack of eficiency (41%).

The last section was dedicated to a miscelanea of questions about the perception of firefighting future at the WUI. More than 69% of professionals answered they didn't feel recognised in their work by superiors into the organizational structure.

Conclussions

It would be reasonable to think that a 4% of participants considering the firefighting activities as no risky tasks is a difficult situation even with a low porcentage. The special risk at wui firefighting tasks, with a number of 18% answering exactly the same risks as those on fighting forest fires, it is understandable from the point of view of personal safety and related risks of this type of activity.

The situation in nearest places (provinces, regions, own country) is perceived as worse than in the rest of the territories (other countries, other regions, rest of the world). This perception is not necessary related to real situation is some cases. Some example cases as australian (Victoria State) and north and south american fire seasons (USA, Canada, Chile) are not seen as specially relevant situation from the point of view of fires and related events by an important part on the participants in this study.

It should be necessary to facilitate more oportunities to see greater exchange and more numerous examples of collaborative activities between professional and citizens (civilians, owners, residents, tourists) including knowledge and information sharing, research and training in WUI areas assessing wildland fire safety programs and firefighters and public safety in the WUI.

At the same time those professionals working in forested areas need to know that the emergency response services are more and more directed to a global situation (forest areas, civilians, buildings, engines) and not only the forest one that they are used to. These experiences can also contribute to prevent safety lapses, to create a new crew cohesion and wildland firefighter safety. Firefighters can increase feelings as recognised professionals in their work by superiors into the organizational structure.

Future works

We are now extending the study to other areas of the Mediterranean (France, Greece and Portugal), other Mediterranean climate areas in other latitudes (United States and Australia) and places with similar problems in fighting fires at the WUI (Chile). One interesting fact will study two cases analyzing the situation of a Fire Service confronting the challenges of all fire emergencies (Portugal, France) not only forest fire Services neither those Services mostly specialized in urban and structural fires.

Abstract
Although slope and winds are common factors in most wildland fires, current guidelines for safety zone dimensions used in the United States assume flat ground and do not consider wind speed as a factor. Similarly, while convective heat transfer is an essential part of fire behavior and is often highly significant to firefighter safety, it has not been considered in past work establishing safety zone criteria. In recent years, 3D, dynamic, physics-based dynamic fire models have been developed which can help us to understand fire behavior and firefighter safety. Here, we used a 3D dynamic fire model, WFDS, to explore different factors influencing potential burn injuries that could arise from both radiative and convective heat transfer over a range of heat sources, slopes and wind speeds. In the present study, we considered a fixed (non-moving) heat source on an inclined plane. Above this heat source, at regular intervals along the slope, synthetic "sensors" tracked wind velocities, temperature, radiative and total heat fluxes, facilitating analysis of potential burn injury as a function of distance from the heat source, analogous to the radius of a safety zone. Our primary finding was that convective heat could result in burn injuries at distances several times what would result from radiation alone. We also found that, while all factors were important, the nature of the heat source (heat release rate per unit area, flaming zone depth and residence time) had more pronounced effects on potential burn injury than slope or wind speed. Both of these findings have significant implications for how we think about firefighter safety, both in terms of how big safety zones might need to be to protect firefighters from convective heat, and in terms of characterizing the fuel as a heat source. This is a new arena of research investigation, and our work is just an early step; more work is needed to fully understand the implications of convective heat for firefighter safety and decision support.

***Keywords**: Firefighter safety zones, fire behaviour, fire safety, fire modeling*

Introduction

The United States Forest Service defines safety zones as "a preplanned area of sufficient size and suitable location that is expected to protect fire personnel from known hazards without using fire shelters" (National Wildfire Coodinating Group 2004). Subsequent definitions in 2012 added detail and broadened this concept to include safety zones more typically encountered operationally, "an area cleared of flammable materials used for escape in the event the line is outflanked or in case a spot fire causes fuels outside the control line to render the line unsafe. In firing operations, crews progress so as to maintain a safety zone close at hand allowing the fuels inside the control line to be consumed before going ahead. Safety zones may also be constructed as integral parts of fuelbreaks; they are greatly enlarged areas which can be used with relative safety by firefighters and their equipment in the event of blowup in the vicinity." (National Wildfire Coodinating Group 2012).
Although institutional culture and policy, firefighter safety training and tactical approaches have significantly improved over the years, often in response to firefighter fatality incidents (e.g. McArdle 1957), recent tragedies such as the June 2013 Yarnell Hill fire in Arizona underscore the ongoing need

for continued improvement in consideration of the potential risk exposure of firefighting personnel in wildland fire incidents and how such risks can be mitigated.

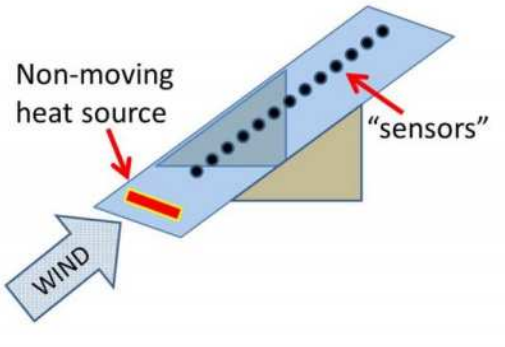

Figure 1. Schematic diagram of general experiment, consisting of a heat source at the lower end of an inclined plane. Above the heat source, sensors record key quantities used to evaluate incident heat flux. Slope was modeled through modification of the gravity vector rather than as shown here.

Most of the firefighter fatality or near-fatality events that have occurred in the United States and elsewhere over the last several decades have taken place in conditions in which slope and winds significantly influenced observed fire behaviour. Well documented examples include, among many others, the August 1949 Mann Gulch (Rothermel 1993), the 1994 South Canyon (Butler *et al* 1998), and the July 2001 Thirtymile fires (USDA Forest Service 2001) in the US; the 2003 Freixo de Espada-a-Cinta fire in Portugal (Viegas *et al* 2005), the 1998 Kareas fire in Greece (Xanthroupolous 2007), as well as the 1983 Grays Point, 1998 Johnstones Creek and 1998 Linton fires in Australia (Cheney *et al* 2001).

While slope and wind have been recognized as critical factors in fire behaviour for some time (Rothermel 1972), most research work examining safe separation distance characterizing safety zone dimensions to date has focused on radiation as the primary mechanism of heat transfer (Albini 1986, Rossi *et al* 2011, Zarate 2008); convection has often been considered as a less significant influence, with a common assumption that the buoyancy of heated gases would result in vertical transport, reducing the effect on persons or objects located some distance laterally from the flames (e.g. Gettle and Rice 2002). Consequently, current guidelines for safety zone dimensions used in the United States assume flat ground and do not consider wind speed as a factor (Butler and Cohen 1998a, 1998b). Recent work, however, suggests that convective heat transfer is more important to fire behaviour than had been thought in the past (Frankman *et al* 2010, Frankman *et al* 2012), with potentially significant implications for firefighter safety. A recent review of safety zones and entrapment incidents suggests that safety zone specifications can be improved through inclusion of convection (Butler 2014).

In recent years, dynamic fire behavior models have emerged which model the dominant physical processes driving fire behavior; unlike simpler semi-empirical models (e.g. Rothermel 1972), different mechanisms of heat transfer are modeled, facilitating detailed analysis of the roles and impacts of radiation and convection in fire behavior. Two such models are HIGRAD/FIRETEC (Linn *et al* 2002; Linn and Cunningham 2005; Linn *et al* 2007) and WFDS (Mell *et al* 2007; Mell *et al* 2009). Due to their dynamic nature, these models offer potentially valuable insights in examining interactions between fire, the atmosphere, vegetation, and topography to help improve our understanding of fire behavior and firefighter safety.

Our objective in this study was to use a physics-based fire model, WFDS, to explore the relative impact of different factors influencing potential burn injuries over a range of heat sources, slopes and wind speeds. A secondary objective was to assess the relative contribution of radiative vs convective heat in potential burn injury over a range of conditions. Using thermal dosage, an integrative measure based on magnitude and duration of exposure (Eisenberg *et al* 1975) which has been correlated to different burn injuries (Hymes *et al* 1996), we examined potential burn injuries resulting from either radiative

or convective heat alone, or both mechanisms of heat transfer in combination, over a range of distances from the heat source.

Methods

Using WFDS, we carried out 288 simulations with a rectangular domain measuring 252m in length, 40 m wide in width and 35m in height, with a constant resolution of 1 m in x, y and z dimensions. These experiments spanned a range of levels for several key factors, two representing key aspects of the fire environment (slope and wind) and three representing key aspects of the heat source, presented in Table 1, below. Our simulations spanned environmental conditions ranging from no-wind, no-slope up to substantial winds (10 m/s) on 50% slope.

Table 1. Factors used in numerical experiments examining safe separation distance from a non-moving heat source. For each factor, the number of different levels is presented in parentheses before the values.

Factor Group	Factor and units	Levels
Environment	Slope (%)	(6) 0,10,20,30,40,50
Environment	Wind speed, m/s	(4) 0,2.5,5,10
Heat Source	HRRPUA[1] (kW/m^2)	(3) 550,1500,2500
Heat Source	Heat Area Depth (m)	(2) 5,10
Heat Source	Duration (s)	(2) 30,60

[1]Heat Release Rate Per Unit Area

We used mirror boundary conditions on lateral boundaries to emulate a fireline of infinite width; the ceiling boundary was open. Within this domain, an inclined plane was simulated by altering the gravity vector. Winds were represented with an atmospheric profile with simple laminar flow. A fixed (non-moving) heat source, perpendicular to the wind flow, was located at ground level several meters from the inflow boundary along the inclined plane. Each heat source case was characterized with three variables: heat release rate per unit area (kW/m2), depth (width in meters) and duration in seconds. A ramp function was used to both initiate and terminate the heat source in time. Beyond the heat source, at regular 3m intervals along the slope, synthetic "sensors" tracked wind velocities, temperature, radiative and total heat fluxes. We calculated convective heat fluxes through standard heat transfer coefficient calculations based on cylinder geometry with a characteristic diameter of 0.1m and a length of 0.65m, intended to represent a person's arm.

To assess the relative contribution to potential burn injury from different heat transfer mechanisms, for each sensor over time, we calculated the thermal dosage from radiation only, from convection only, and from the two mechanisms of heat transfer combined. Thermal Dosage, V, is calculated as $V=tI^{4/3}$ where t is time, I is total incident heat flux, and V is the thermal dosage, measured with Thermal Dosage Units (TDU); one TDU = 1 $(kW/m^2)^{4/3}$.s (Eisenberg *et al* 1975, Tsao and Perry 1979, Torvi *et al* 2000). We used three thresholds of Thermal Dosage which have been identified to correlate with burn injuries (to exposed bare skin) as follows: 550 TDU indicates onset of 1st degree burns, a value of 1050 represents onset of 2nd degree burns, and a value of 2300 corresponds to full depth 3rd degree burn, as well as 50% lethality TDU for a typical subject (Hymes *et al*. 1996).

Summarizing the Thermal Dosage at each sensor over the time interval extending from the start of heat release from the heat source until thirty seconds after heat release terminated, we assessed the farthest sensor from the heat source experiencing each of the three thresholds. This provided us with a means of assessing potential burn injury as a function of distance from the heat source as well as the other factors in the experiment.

Results

Figure 2 shows a series of graphs for an individual simulation. The top three panels show convective, radiative and total incident fluxes with different coloured lines for each sensor over time. The bottom panel shows thermal dosage (for total incident heat flux) as a function of distance from the heat source for the slope and wind conditions of that simulation; different symbols correspond to different thresholds of potential injury as quantified with Thermal Dosage.

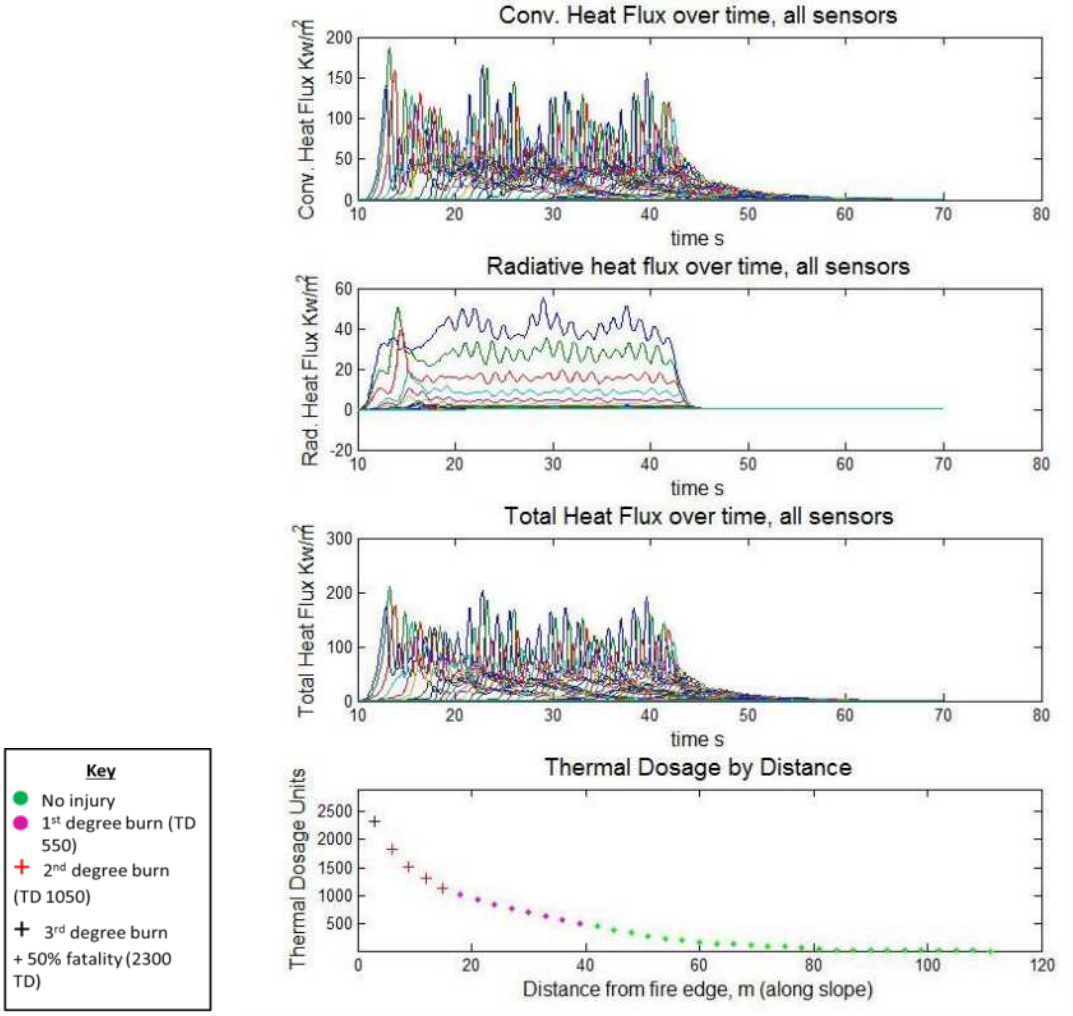

Figure 2. Simulation output for a given simulation. Top three panels show plots of convective heat flux, radiative heat flux and total heat flux over time at points spaced along the slope a fixed height above the ground. Bottom panel shows thermal dosage for each point over distance from heat source. Thermal dosages are very high close to the heat source but diminish with distance; markers in bottom panel correspond to injury key, shown above

In this example, at distances 40m or greater from the heat source, no injury is predicted to occur; injuries increase as sensors approach the heat source, with 1st degree burns predicted for 18 to 39 m, 2nd degree burns predicted from 6 to 15 m from the heat source, and full depth 3rd degree burns and 50% mortality predicted at distances below 6 m.

The range of conditions examined resulted in a wide range of outcomes, with very little predicted injury under more mild heat source cases, light winds and low slopes, ranging to very extreme effects at great distances from the heat source under high winds, high slopes and more severe heat source cases. The relative contribution of radiative vs convective heat transfer to Thermal dosage varied as well with the conditions. In the case shown in Figure 2, convective heat flux was typically around twice the radiative heat flux.

Heat fluxes from the numerical experiments were similar to values reported in measurements. For example, radiative heat flux for Figure 2 is in a similar range to values reported for measurements taken in burning pine needles and oak branches in southern France (Silvani and Morandini 2009).

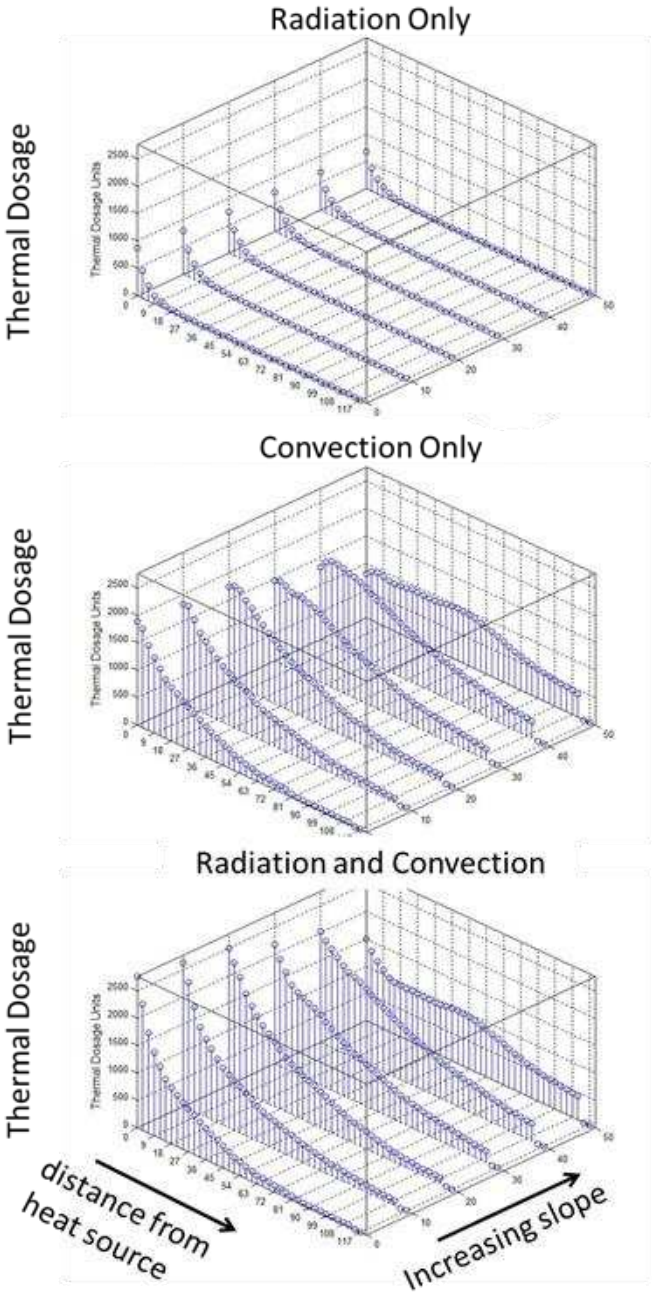

Figure 3. Simulated thermal dosage, a measure of potential burn injury, at different distances from a heat source, and on different slopes for a particular wind speed and set of heat source parameters. Top panel shows radiation, middle shows convection, and bottom shows combined effects.

All three characteristics used to describe the heat source (heat release rate per unit area, depth and duration) significantly impacted the safe separation distance; all three factors interacted with slope and wind as well. In general, Thermal Dosage increased as all three of these factors increased.

Our primary finding, however, was that inclusion of convective heat associated with wind and slope effects could result in burn injuries at distances often several multiples of what would result from radiation alone. Prior rules of thumb used for field personnel in the US, based on radiation alone, for flat ground, with no wind, would characterize safe separation distance as a multiple of four times the

flame length (Butler and Cohen 1998a and b). In contrast, in the most extreme cases we tested, safe separation distance could potentially be nearly an order of magnitude greater, or forty times the flame length.

Discussion

We conducted a series of numerical experiments examining potential thermal exposure at a range of distances from a fixed heat source under a range of wind, slope conditions and with different heat source parameters. We found that safe separation distances may need to be much larger to ensure firefighter safety in wind and slope conditions. This has potentially significant implications for firefighting tactics, design and planning of safety zones, as well as in consideration of escape routes and the safety margins in time needed to ensure safe evacuation (Beighley 1995, Baxter *et al* 2004).

An additional finding of potential consequence was that the characteristics of the heat source were all highly significant to predicting safe separation distance. The intense energy release rates from crown fires are certainly well known but dynamic aspects of convection arising in these intense situations could pose dangers to firefighters. For example, intense jets of superheated air have been observed in crown fire situations (Coen *et al* 2004). Research is needed to better characterize the frequency and magnitude of such events and their potential for firefighter injury. While most interest in fire behaviour emphasizes the active flaming front, our results suggest that heavy fuels and duff, which often burn for long duration and cover large areas, may potentially contribute sufficient energy to affect safe separation distance. We expect that, under some topographic configurations and atmospheric conditions, long burning fuels such as these, contributing energy over often large areas, could potentially result in longer safe separation distances. More research is needed to examine whether this is truly a possibility or not.

It is important to recognize that this work represents a simple early step in investigations along these lines. We expect that future work will provide greater refinement of the concepts we present here. This is a natural and expected course of how scientific knowledge unfolds. Our numerical experiments have a very simple configuration; our use of a non-moving heat source is convenient and tractable for a first approach but is not very representative of a real wildfire; more work must be carried out with moving heat sources. Additional work must be carried out as well to ensure that results such as those presented here are not highly influenced by domain width, domain size, resolution or other potential numerical artifacts. Investigation should examine how vegetation might reduce (or increase) the safe separation distance effects we observed here.

Particularly important, however, is to examine how more complex terrain configurations could influence outcomes. We expect that under many circumstances in real fires these slope/wind multipliers may be less than we observed here, as convective cooling could play a significant role. However there may be cases of particular topographic configurations that could lead to greater distance effects; this could be disastrous. Recent work suggests that particular wind/terrain alignment scenarios can have very significant effects, resulting in rapid changes in fire behavior (Sharples *et al* 2010, Sharples *et al* 2012). More research is needed to link potential burn injury to firefighters, dynamic fire behavior, and atmospheric / topographic interactions such as these.

Using a dynamic, physics-based fire model, we assessed Thermal Dosage arising from radiation alone, convection alone, and both combined. In general, measurement of convective processes can pose significant challenges in the field, typically requiring a great deal of instrumentation and often only permitting a relatively small sample of observations (Kaimal *et al* 1976); inferences made from point observations may result in uncertainties when applied over larger areas (Linn *et al*. 2012). A significant advantage of using a physics-based model, as we did here, is that these quantities, and the dynamic interactions between different influential factors, can be examined in detail, facilitating improved understanding. Such models provide a unique value in that they can provide an experience analogous to laboratory experiments; modeling efforts are uniquely complementary to physical experiments in

laboratories and in larger field campaigns. Fire science benefits from all of these approaches to learning.

Finally, our finding that safe separation distances may need to be much larger to ensure firefighter safety in wind and slope conditions suggests a possible paradigm shift. This shift may already be underway. When we first encountered these results we were somewhat discouraged, as it seemed likely that managers might interpret these results as extremely restrictive, unreasonable, and, in many cases, unattainable, particularly in areas of complex terrain as are common throughout areas within the US and elsewhere where fires often occur. However, in presentations with several groups of managers in the United States, their response has often been quite different; some managers were encouraged that these results could provide them with justification for not sending firefighters into areas from which escape in the event of a blow-up could be very tenuous. We hope that this research, and subsequent work which follows it, may promote the use of more indirect attack tactics and other approaches which limit firefighter risk exposure.

Abstract
Forest fires are a massive source of air pollutants to the atmosphere causing several environmental and human impacts. It is generally accepted that firefighters are potentially exposed to critical levels of air pollution during fire suppression activities (both in direct combat and mop-up), but the concentrations attained in these areas are still scarcely quantified because of the difficulty inherent to the monitoring of air quality close to the fireline. The goal of this work is to provide a better understanding of the spatiotemporal dynamics of the smoke plume, and resulting levels of fine particles, in the proximity of a fire, and how this translates into human safety issues. The experimental study area is located in the mountain range of Lousã, Central Portugal. Ten in-continuum monitoring sensors were positioned at a distance of 5 m (8 sensors) and 10 m (2 sensors) from the top boundary of the burn plot, and at 1.7 m above ground. The concentration of particulate matter with an equivalent aerodynamic diameter smaller than 2.5 µm (PM2.5) was measured during a total period of 50 minutes, capturing the effect of both flaming and smouldering emissions.
The results presented in this work highlight the fact that the concentration of fine particles in the atmosphere close to the fireline is extremely dynamic, with differences between sensors that go up to 540% in terms of average concentrations and 170% in peak values. This is particularly relevant taking into account that these values correspond to sensors at a distance of 10 m. This conclusion suggests that in a single fire crew considerable differences in the exposure of its members can occur depending on their task/position relating the fireline.
For this particular burning plot the time evolution of the observations reveals a dip in PM2.5 concentration that is not explained by the analysis of smoke plume dynamics in video recordings, suggesting that under certain circumstances the visual estimate of fire safety conditions can be misleading due to e.g. reduced visibility. In wildfire suppression operations the safety of the involved personnel should rely also in the use of personal exposure monitoring equipment for the prevention of potentially critical exposure.

Keywords*: real scale fire experiments; smoke emissions; fire safety; smoke exposure.*

Introduction

Forest fires are a massive source of air pollutants to the atmosphere causing several environmental and human impacts. At the operational level, firefighters are confronted with extremely severe environmental conditions, including reduced visibility and toxic atmosphere. In this context, particulate matter, which is abundantly produced during forest fires, has significant effects over the safety and health of personnel in the terrain (e.g., Reinhardt and Ottmar [2004] and Miranda *et al*. [2010, 2012]). In fact, the International Agency for Research on Cancer (IARC) stated that the occupational exposure of a firefighter is possibly carcinogenic [IARC, 2010a]. There are a number of factors that affect the impacts of smoke on firefighter's health, including the concentration of specific air pollutants within the breathing zone, the exposure duration, the exertion levels, and the individual susceptibility (e.g., pre-existing lung or heart diseases) [Reisen and Brown, 2009]. In what relates specifically to smoke particles, the associated health effects not only depend on the chemical and toxic

characteristics but also on their morphological properties, such as size, shape and density [Dost, 1991; Schwela, 2001; Naeher *et al*., 2007].
Despite the research studies carried out in the United States of America [Reinhardt *et al*., 2000; Reinhardt and Ottmar, 2000 and 2004], Australia [McMahon and Bush, 1992; Materna *et al*., 1993; Reisen and Brown, 2009; Reisen *et al*., 2011] and Portugal [Miranda *et al*., 2010 and 2012], the current state of knowledge in this field is still scarce. The difficulty inherent to the monitoring of air quality and personal exposure levels during a fire has largely contributed to this scientific gap.
The complex mixture of smoke constituents induces adverse health effects such as acute and instantaneous eye and respiratory irritation and shortness of breath, that can potentially develop into headache, dizziness and nausea lasting for hours, and mild impairment of lung function for hours to days [Reinhardt *et al*., 2000], while long-term effects are characterized by impaired respiratory function, increased risk of cancer, and cardiovascular disease [Rothman *et al*., 1991]. Special concern is raised by the exposure to respirable particles and potentially toxic compounds adsorbed to them, such as polycyclic aromatic hydrocarbons (PAHs) and semivolatile organic compounds, some of which may be carcinogenic [Le Masters *et al*. 2006; Youakim, 2006; IARC, 2010b].
Aiming to establish cause/effect relationships between exposure to smoke and firefighter's health effects it is fundamental to improve the current understanding about the spatial and temporal dynamics of air pollution levels close to the fireline. It is widely known that the composition of smoke depends on several factors, namely the type of vegetation consumed, the efficiency of combustion, the fuel moisture content, the fire temperature, and the weather conditions [Reisen and Brown, 2009]. However, the extent of the impact of smoke plume dynamics on individual exposure is scarcely documented by field observations. The main goal of this work is to evaluate the spatial and temporal variation of fine particles concentration during a bushfire, and how this potentially translates into human safety issues during firefighting operations.

Fire experiments description

The experimental study area is located in the mountain range of Lousã, Central Portugal (40° 15'N, 8° 10'W), at an elevation of approximately 1,000 m. The fire experiments described in this paper were carried out in May 6, 2010. The characteristics of the burn plot are described in Table 1.

Table 1. Physical characteristics of the burn plot. Fuel moisture was sampled 40 min before the fire ignition.

Area (m^2)	Avg. slope (°)	Fuel cover (%)	Avg. fuel height (m)	Avg. fuel load ($ton.ha^{-1}$)	Avg. fuel moisture (%)	Fuel species
853	16	67	0.31	32.50	Live: 46.6 Dead: 9.0	*Erica umbellata, Erica australis, Ulex minor, Chamaespartium tridentatum*

Average meteorological data acquired during the burn are shown in Table 2.

Table 2. Average meteorological data observed from 10:00 to 10:50.

Wind velocity ($m.s^{-1}$)	Wind direction (-)	Air temperature (ºC)	Air humidity (%)
3.1	East (uphill)	12.8	45.6

As shown in Figure 1, no significant variation of wind velocity and direction was reported in this period.

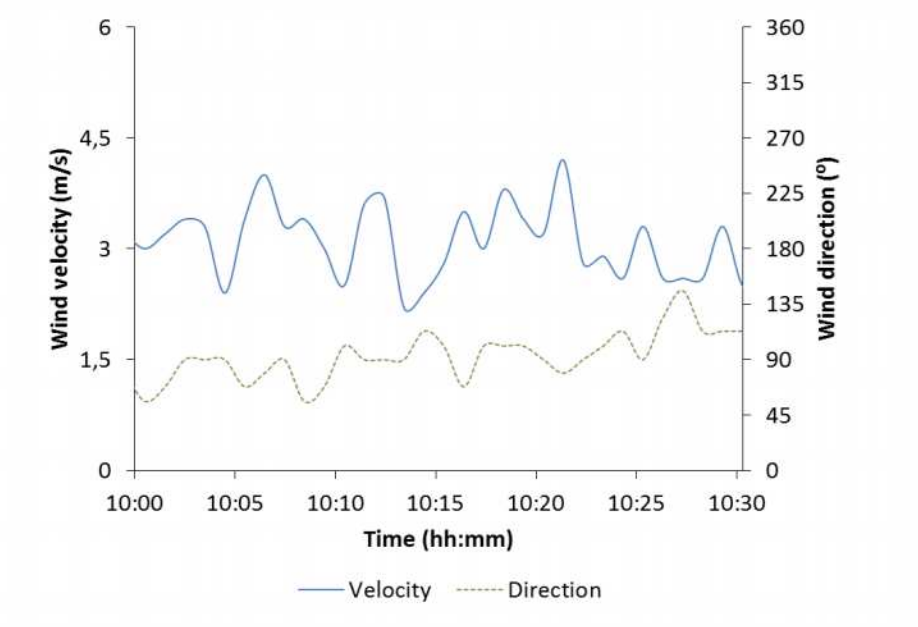

Figure 1. Meteorological data measured during the experiment.

The procedure for the fire ignition is presented in Table 3.

Table 3. Fire ignition (Δt indicates time after ignition).

Fire ignition (hh:mm)	End of flaming stage (hh:mm)	End of smouldering stage (hh:mm)	Fire ignition description
10:00 (Δt=0min)	10:30 (Δt=30min)	10:50 (Δt=50min)	Δt=0min: Linear ignition along the top (West) boundary of the plot starting at the right (North) side; Δt=7min: Linear ignition parallel to the initial one and starting at the left (South) side; Δt=13min: Downhill linear ignition along the right (North) boundary of the plot; Δt=16min: Downhill linear ignition along the left (South) boundary of the plot; Δt=19min: Linear ignition along the bottom (East) boundary of the plot starting at the right (North) side and covering the first 1/3 of the total width; Δt=27min: Linear ignition along the bottom (East) boundary of the plot, covering the remaining 2/3 of the total width.

A snapshot of the plot burning is shown in Figure 2. The effect of the uphill wind is evident in the behaviour of the smoke plume. Also, the effect of the decreased heat release in the smouldering stage is evident in the diminishing of the plume rise in image (d).

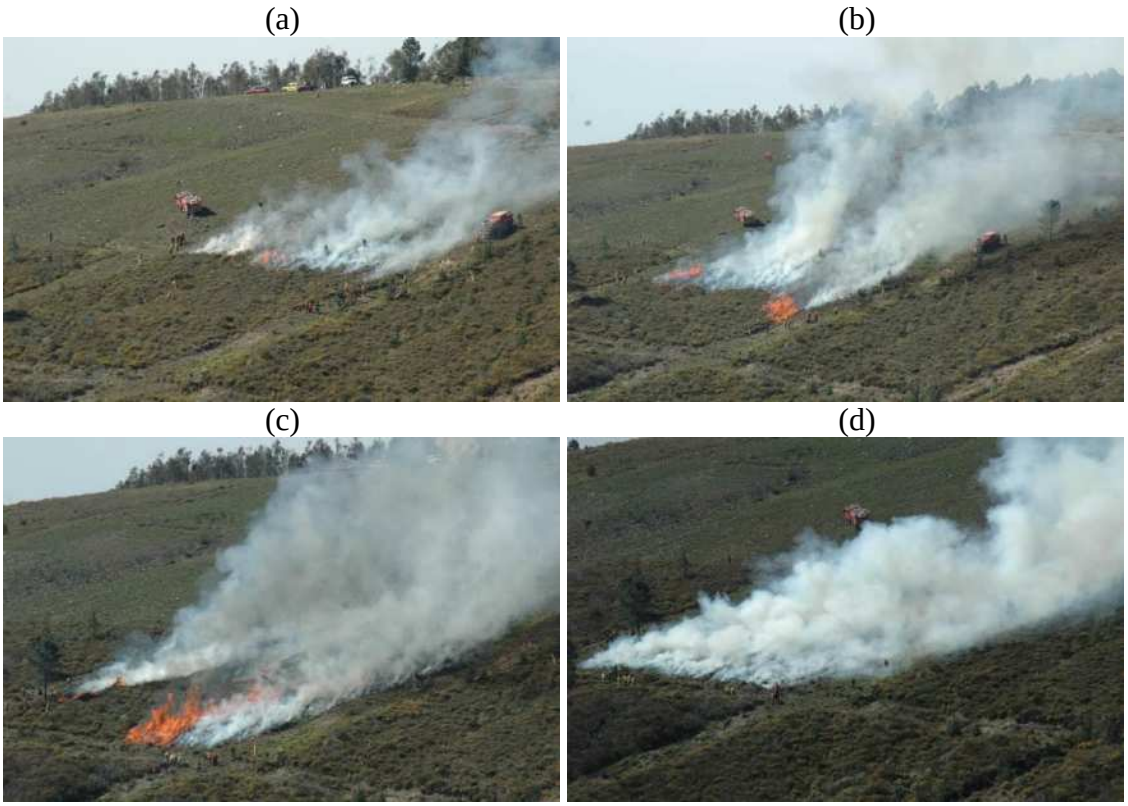

Figure 2. Sequence of photos showing the plot burning at: (a) 10:05 (Δt=5 min), (b) 10:14 (Δt=14 min), (c) 10:22 (Δt=22 min), and (d) 10:32 (Δt=32 min, corresponding to the start of the smouldering stage).

The layout of the sensor grid is schematically shown in Figure 3. Ten in-continuum air quality monitoring sensors were distributed at intervals of 5 m along the top boundary of the plot. The two lines of sensors are, respectively, at 5 m (8 sensors) and 10 m (2 sensors) from the top (West) boundary of the plot. This grid was defined according to the prevailing winds during the burns, with the objective of capturing the smoke plume.

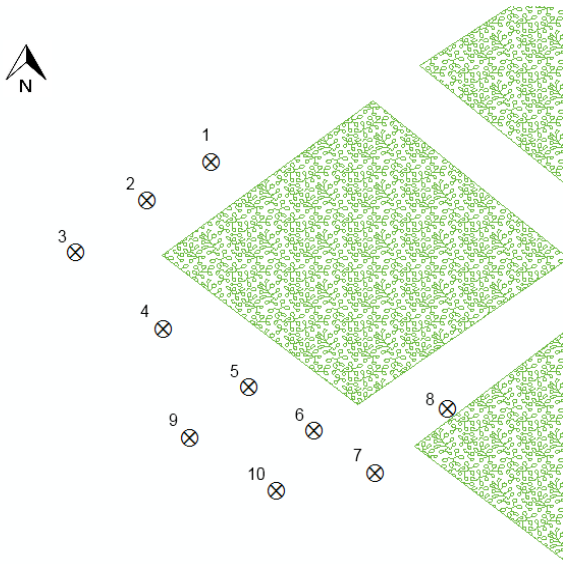

Figure 3. Sensors grid layout.

The equipment used for the measurement of the concentration of particles with an equivalent aerodynamic diameter smaller than 2.5 µm (PM2.5) was a SidePack AM510 (TSI^{TM}) (for more details on the sensors see Miranda *et al*. [2010]). Each sensor was fixed to a mast at a height of approximately 1.7 m above ground, as can be seen in Figure 4.

Figure 4. PM2.5 monitoring sensors indicated by the circles.

3. Experimental data analysis

Figure 5 shows the PM2.5 concentration acquired in each sensor normalized by the global average for all sensors.

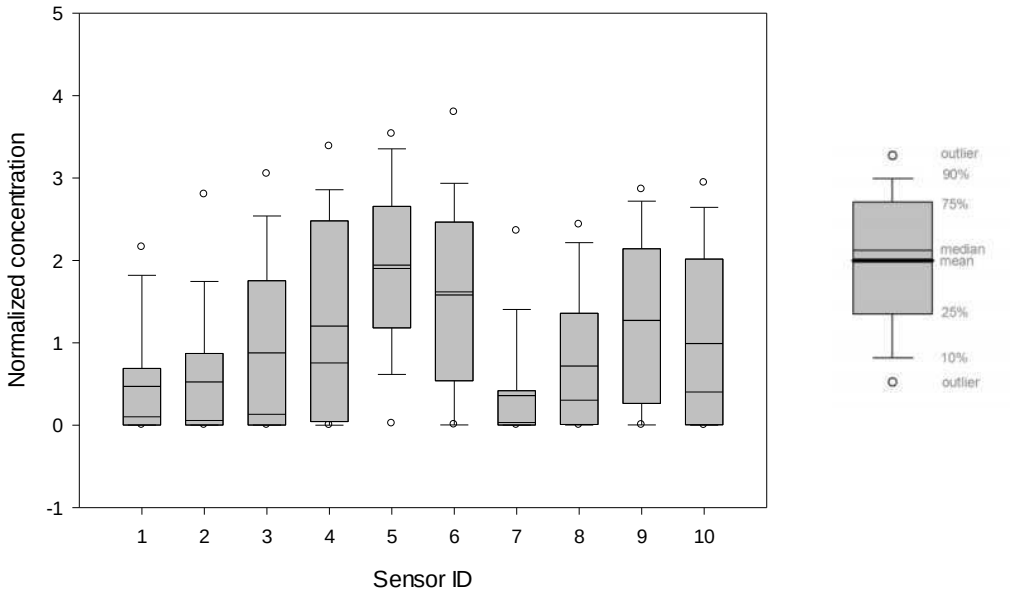

Figure 5. Box plots of normalized 1 min averaged PM2.5 concentration per sensor.

Figure 5 shows a clear discrepancy on the magnitude of the concentrations attained, with sensor 5 hitting an average concentration 5.4 times higher than sensor 7, and 1.7 times higher in the case of peak values, despite the short distance (10 m) between these sensors. Standard deviation is also dependent on sensor location, ranging from 0.6 (sensor 7) to 1.2 (sensor 4). These conclusions are in agreement with previous measurements carried out by the authors [Miranda *et al*., 2010] in similar plots but in which the measuring equipment was used by firefighters (consequently, not representing a specific spot but a given job in the crew).

For an additional understanding of the time evolution of PM2.5 levels, 1 minute averaged normalized values are shown in Figure 6.

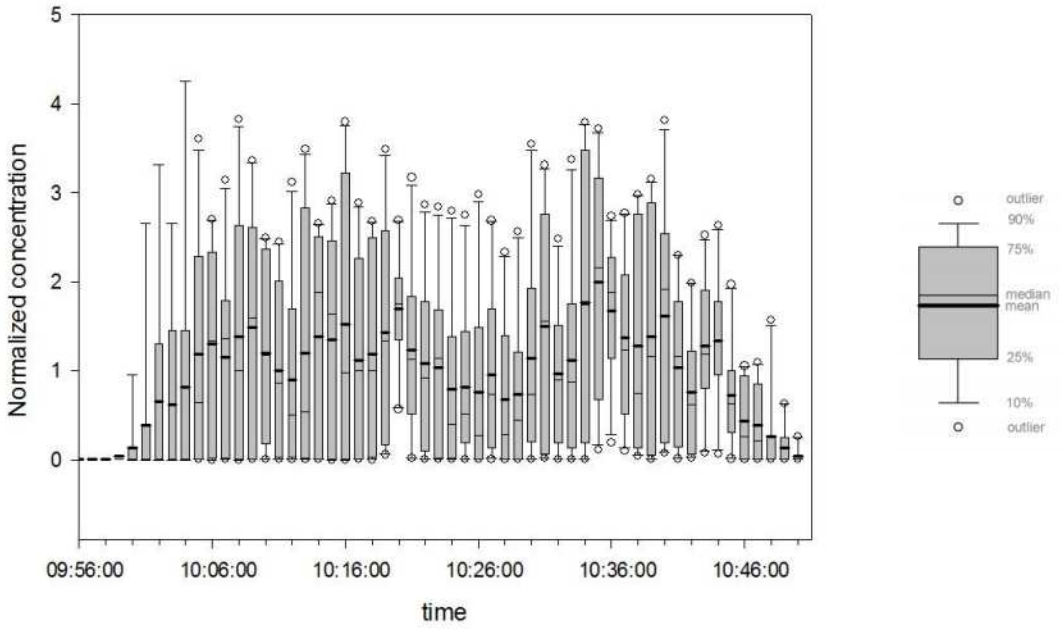

Figure 6. Box plots of normalized 1 min averaged PM2.5 concentration per sensor (a) and per minute (b).

The decrease of concentration around 10:26 shown in Figure 6 corresponds to the end of the flaming stage (at 10:30), thus revealing two distinct fire stages. It is possible to conclude that the PM2.5 levels captured during the first 30 minutes are resulting from a combination of both flaming and smouldering emissions, while the second peak in concentration (around 10:36) is exclusively caused by smouldering emissions, showing the significant contribution of the smouldering phase to the emission of fine particles, again in the agreement with the previous campaign by Miranda *et al*. [2010]. In fact, the (1 minute) average concentration values are higher in this second stage, which is also a consequence of the weakened plume rise (as already observed in the analysis of Figure 2).
Additionally, it is worth to observe in Figure 6 that in the flaming stage a dip in PM2.5 concentration was observed for approximately 6 minutes, starting at 10:10. This effect is not explained by the analysis of smoke plume dynamics in video recordings (at least from the observation point), in which a significant (horizontal or vertical) deviation of the plume was not observed, neither a decrease on fire intensity.

Conclusions

It is generally accepted that firefighters are potentially exposed to critical levels of air pollution during fire suppression activities (both in direct combat and mop-up), but the concentrations attained during these operations are still scarcely quantified. The goal of this work is to give a better understanding of the spatiotemporal dynamics of the smoke plume, and resulting PM2.5 levels, in the close proximity of a fire.
The results presented in this work highlight the fact that the concentration of fine particles in the atmosphere close to the fireline is extremely dynamic, with differences between sensors that go up to 540% in terms of average concentrations and 170% in peak values. This is particularly relevant taking into account that these differences were registered in sensors at a distance of 10 m. This conclusion suggests that in a single fire crew considerable differences in the exposure of its members can occur depending on their task/position in relation to the fire front.
Data analysis suggests also that the visual estimate of fire safety conditions can be misleading, as concluded from the comparison between monitored PM2.5 levels and video footage, as a consequence of e.g. reduced visibility. In wildfire suppression operations the safety of the involved personnel should rely also on the use of personal exposure monitoring equipment for the prevention of potentially critical exposure.
In agreement with previous field measurements [Miranda *et al*., 2010] the smouldering stage can be critical to the security of firefighters in the terrain, because of the higher emission of fine particles (when compared to the flaming phase) and the ‘immersion’ of firefighters in smoke when carrying out mopping operations (due to the decreased fire intensity).

Sources and implications of bias and uncertainty in a century of us wildfire activity data

Karen C. Short

Abstract
Analyses to identify and relate trends in wildfire activity to factors such as climate, population, land use/land cover, and wildland fire policy are increasingly popular in the United States (US). There is a wealth of US wildfire activity data available for such analyses, but users must be aware of inherent reporting biases, inconsistencies, and uncertainty in the data in order to maximize the integrity and utility of their work. Data for analysis are generally acquired from archival summary reports of the federal or interagency fire organizations; incident-level wildfire reporting systems of the federal, state, and local fire services; and, increasingly, remote-sensing programs. This paper provides an overview of each of these sources and the major reporting biases, inconsistencies, and uncertainty within them. Use of the national fire reporting systems of state and local fire organizations has been rising in recent decades, providing an improved set of incident-level data for all-lands analyses of wildfire activity. A recent effort to acquire, standardize, error-check, compile, scrub, and evaluate the completeness of US federal, state, and local wildfire records from 1992-2012 has been completed for the national Fire Program Analysis (FPA) application. The resulting FPA Fire-Occurrence Database (FPA FOD) currently includes nearly 1.7 million records from the 21-year period, 1992-2012, with values for at least the following core data elements: location (fire origin) at least as precise as a Public Land Survey System section (2.6 km^2 grid), discovery date, and final fire size. The FPA FOD is publicly available from the US Forest Service Research Data Archive (http://dx.doi.org/10.2737/RDS-2013-0009.2). While necessarily incomplete in some aspects, the database is intended to facilitate fairly high-resolution geospatial analysis of US wildfire activity over recent decades.

Keywords*: wildfire occurrence, reporting, data, statistics, bias, uncertainty, USA*

Introduction

The statistical analysis of wildfire activity is a critical component of national wildfire planning, operations, and research in the United States (US). Wildfire activity data have been collected in the US for over a century. Yet, to this day, no single, unified system of wildfire record-keeping exists. Data for analysis are generally harvested from archival summary reports of the federal or interagency fire organizations; incident-level wildfire reporting systems of the federal, state, and local fire services; and, increasingly, remote-sensing programs. It is typical for research into wildfire activity patterns for all or part of the last century to require data from several of these sources and perhaps others. That work is complicated by the disunity of the various datasets and potentially compromised by inherent reporting biases, inconsistencies, and errors or uncertainty in the data, as described here.

2. Data sources

Data for analyses of variables like wildfire numbers and area burned in the US are available in various forms from the early 20th century to the present. Figure 1 shows the general temporal coverage of key data sources, grouped into three categories: (1) archival summary reports, (2) documentary fire records, and (3) remotely sensed data.

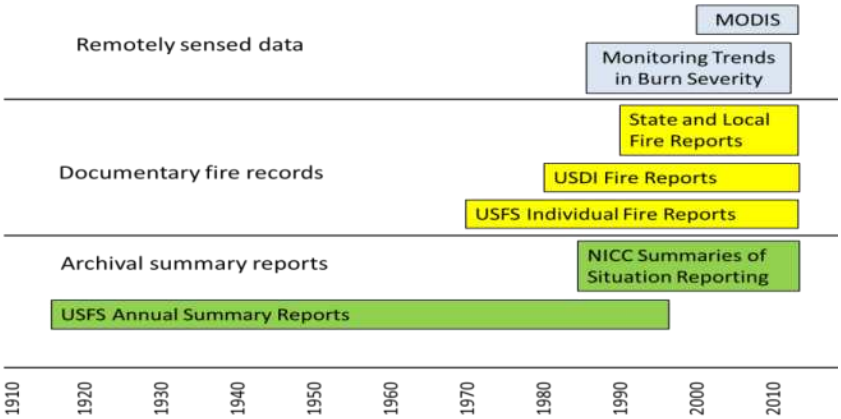

Figure 1. Timeline showing the general temporal spans of the sources of US wildfire activity data discussed in this paper.

The longest time period is covered by the archival summary reports, circa 1916 to 1997, from the US Forest Service (USFS). These reports include annual estimates of wildfire activity on all US lands (forest and non-forest) that qualified for organized wildfire protection in any given year, as per the statutory requirements of the 1911 Weeks Law and subsequent legislation. Figures were reported for each US state and included estimates of wildfire numbers and area burned by land ownership, fire cause, and fire size class. The National Interagency Coordination Center (NICC) began issuing an independently sourced set of similar reports in 1983. The basic fire occurrence information in those annual summaries comes from the NICC's Situation Reporting module, which gets daily activity reports from wildland fire dispatch offices during fire season and weekly reports otherwise. Together, the USFS and NICC archival summary reports provide over a century of wildfire-activity data (Figure 1), and are commonly used to characterize trends in variables like wildfire area burned over lengthy periods at the national level or by interstate region (e.g., Houghton *et al*. 2000, Mouillot and Field 2005, Collins *et al*. 2006, Littel *et al*. 2009).

Documentary fire records, which are created using standard forms issued by the various federal, state, and local fire organizations, are warehoused and readily available in electronic format for several recent decades (Figure 1). These fire reports are intended to capture the basic facts about each individual wildfire occurrence – including point of origin, date, cause, and final fire size – as well as additional information about responses and impacts associated with the incident. The USFS, bureaus of the US Department of Interior (USDI), state fire authorities, and local fire departments use different forms and reporting systems to capture these incident-level data, and their electronic archives span different time periods (approximated by Figure 1). Some states, like California and Alaska have digital archives (including locally mapped perimeters of large fires) that extend over longer historical periods than Figure 1 indicates; but their extensive electronic archives are exceptional cases. The fire-climate analyses of Westerling *et al*. (2003, 2006) are examples of work based on documentary wildfire records.

For recent decades, remotely sensed fire data are also available, including satellite-derived perimeters, or burn scars, of large (i.e., >405 ha) fires dating back to 1984, from the Landsat-based Monitoring Trends in Burn Severity (MTBS) project (Eidenshink *et al*. 2007). The MTBS data have increasingly been used to identify trends in and drivers of large-fire activity in the US (e.g., Riley *et al*. 2013, Dennison *et al*. 2014, Lannom *et al*. 2014). The remote sensing group (Figure 1) also includes satellite fire detection data like the active fire (hotspot) and burned area products that date back to circa 2000 from use of the Moderate Resolution Imaging Spectroradiometer (MODIS) on board the Aqua and Terra satellites (Giglio *et al*. 2003). While other satellite sensors have advanced fire detection capabilities, including the Geostationary Operational Environmental Satellite (GOES) system and the

Visible Infrared Imaging Radiometer Suite (VIIRS), this paper focuses on just the MODIS products due to their widespread use in fire activity analyses in the US and elsewhere over the past decade (Mouillot *et al*. 2014, Schroeder *et al*. 2014; e.g., Urbanski *et al*. 2011, Hawbaker *et al*. 2013, Parks 2014).

Bias and uncertainty

The following sections are intended to provide an overview of the major reporting biases, inconsistencies, and sources of errors and uncertainty in the different types of US wildfire activity datasets (Figure 1). It is beyond the scope of this paper to daylight and detail every issue that may concern a keen analyst. When topics have been covered in more depth elsewhere, readers will be referred to other published work for further information.

Archival summary reports

The USFS annual summary reports cover the longest time period, but are neither complete nor consistent over the ~80 years that they are available, because wildfire activity was tallied from an increasing land area over time. This changing baseline must be taken into account when analyzing and interpreting the data. The reporting area more than triples in size from 1926 to 1983 (Figure 2), which is the time period for which area-reporting figures are included in the USFS annual summaries. The reporting area rises as the land base qualifying for the federal fire protection program that required the reports grows from just the forested and other critical watersheds mandated by law in the earliest years to nearly the total burnable US land area by the early 1980s (Fig 2). (The estimate of total burnable wildland in the US used here is based on data generated by the national LANDFIRE program using circa 2000 satellite imagery [Reeves *et al*. 2006]). Even then, not all of the reporting area was formally protected from wildfire under the program requiring the statistics. Therefore the USFS wildfire activity data are classified as from "protected" and "unprotected" areas, with unprotected areas having no organized fire protection despite their need for it as per the national directive at the time (explained further by Houghton *et al*. [2000]). The total area of protected land estimated in the USFS reports does not reach total US burnable area until the last year it is included in the reports, which is 1990 (Fig 2).

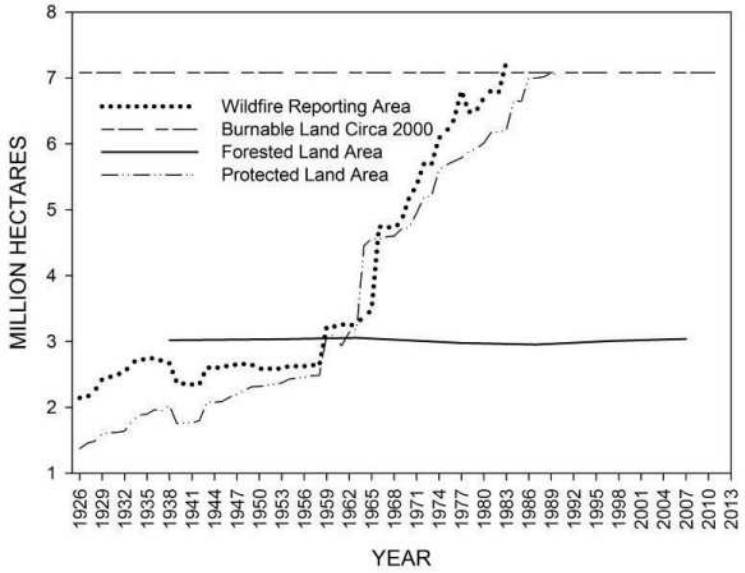

Figure 2. US wildfire reporting area (dotted line), 1926-1983, and protected land area (dot-and-dash), 1926-1990, from the USFS archival summary reports. The upper dashed reference line represents the ~700 million ha of US land, including Alaska, mapped as burnable from circa 2000 satellite imagery by the national LANDFIRE program. The lower horizontal reference line represents approximately 750 million acres of US forested land estimated at various points in time during this period by the national Forest Inventory and Analysis program.

Because the USFS summary reports are broken down by US state, the reporting biases can be examined further at that resolution. Figure 3 shows the percent burnable area reporting, by contiguous US state, as an average within the three decades from 1950 to 1979, which correspond to a collective period of marked increase in land area accounted for in the USFS reports (see Figure 2). By the 1970s, the reporting area begins to reach what could be considered an "all-lands" coverage, but not in all states. Some states, like Alaska and Kansas, are completely unaccounted for in the USFS wildfire activity statistics prior to the 1940s and 1950s; others, like Texas and North Dakota, remain poorly accounted for well into the 1970s.

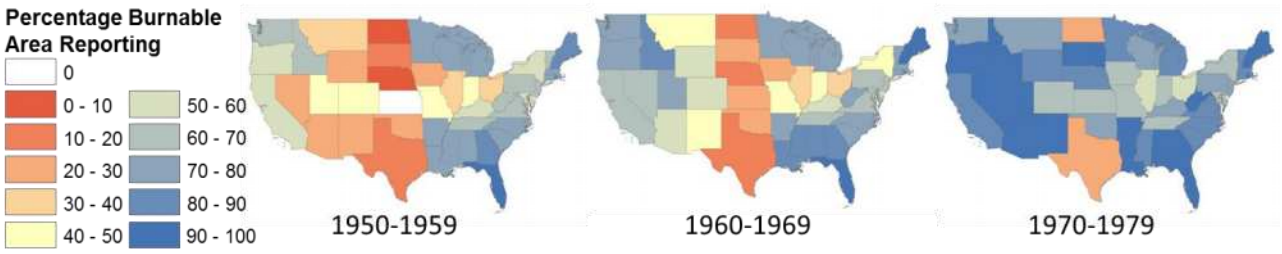

Figure 3. Percent burnable land area accounted for in the USFS annual wildfire summary reports, as an average for each contiguous US state during the three decades from 1950-1979.

One reason for the large increase in land area accounted for in the USFS wildfire summary reports during the 1960s is the inclusion of an additional ~70 million hectares (ha) of western US rangelands administered by the USDI Bureau of Land Management (BLM) (Figure 4). This addition occurred after wildfires burned several hundred thousand acres of BLM lands near Elko, Nevada, in 1964 and brought the BLM fully into the cooperative fire control program for which the USFS reports were generated (Pyne 1982). Estimates of wildfire activity levels on BLM lands in the contiguous US (CONUS) were first included in the 1966 USFS summary reports. Prior to 1966, the USFS statistics accounted for wildfire activity on only about half of the contemporary federal land base in the 11 westernmost states in the CONUS (Figure 4). Littel *et al*. (2009) recognized the reporting bias and, as part of their analyses of fire-climate relationships in the western US, multiplied the USFS-reported wildfire-area-burned (WFAB) estimates "by the ratio of the total area protected in 2003 to the area protected in a given year." Such adjustment assumes that wildfire activity levels are largely equivalent on a per-acre basis between the reporting and non-reporting areas. However, the areas unaccounted for in the early USFS wildfire statistics (e.g., pre-1960s) for the US West should comprise a much greater proportion of non-forested land than the areas reporting, potentially invalidating any assumption of comparable fire-activity levels and possibly contributing to the underperformance of fire-climate models based on WFAB estimates that included the early USFS figures (e.g., pre-1977) versus those that did not (Littel *et al*. 2009).

In addition to the area-reporting bias in the USFS summary reports, analysts should be aware of other inconsistency and uncertainty in the wildfire activity estimates that are included, especially for unprotected areas. Intentional, or controlled burning, was used extensively for vegetation management on nonfederal lands, especially in the southeastern US during the early 20th century. While now used to a lesser extent (but on both federal and nonfederal lands) in the US, intentional burning is not classified in the current reporting systems as "wildfire" unless the controlled burn escapes and requires a suppression response. However, the early USFS wildfire activity summaries do include millions of acres of intentional burning on "unprotected" lands, which, until about the mid-20th century was viewed by the USFS as akin to wildfire, as something that should be prevented and ultimately eradicated (Pyne 1982). Controlled burning became accepted as an acceptable land management practice over time and persists to this day (Melvin 2012); however, statistics regarding its use have not been included in summaries of "wildfire" activity for several decades. Furthermore, the USFS includes with its unprotected area estimates the

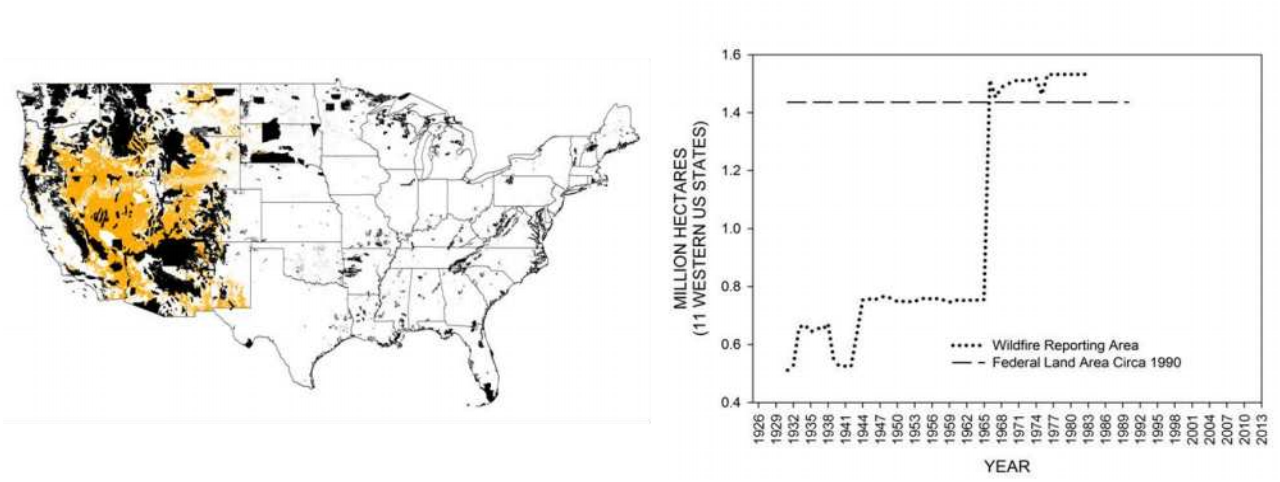

Figure 4. Map of the CONUS showing lands administered by the USDI Bureau of Land Management (BLM) in orange and other federal lands in black. Wildfires on these BLM lands, which include ~70 million ha of largely non-forested area in the western US, are not accounted for in the USFS wildfire summary reports until 1966, after the BLM joined the cooperative fire control program for which the USFS reports were generated. The graph at right shows the spike in reporting area. The dashed reference line represents the ~140 million ha of total federal land in the 11 westernmost states of the CONUS as of the year 1990.

following caveat: "since no field organizations are established in unprotected areas to report fires, the statistics on such unprotected areas are merely the best estimates by local agencies." Although the degree of error in the reported figures cannot be known, egregious errors apparently exist at least in some of the WFAB estimates from unprotected and protected areas. For example, the USFS annual summary reports for 1976-1983 indicated that ~800,000 ha were burned by wildfires in Texas during each of four years within that eight-year period. Those are levels comparable to those witnessed in the state during what have been considered unprecedented fire seasons of 2006 and 2011 – seasons that prompted disaster declarations by the Federal Emergency Management Agency. There are multiple independent sources, including remotely sensed data, that corroborate the 2006 and 2011 estimates; but no records, including media reports, have been found to corroborate the similarly high USFS estimates from 1976-1983. Several authorities within the Texas state fire service have asserted that the USFS estimates must be in error, because the fire service has no recollection of large fires burning in 1976-1983 on par with those in 2006 and 2011; and those recent "outbreak" years were so significant that records of similar years, had they occurred just a few decades prior, would abound, especially in media archives (C. Stripling, T. Spencer, B. Smith: personal communication). If millions of acres did not burn in Texas during each of several years 1976-1983, then any regional or national WFAB estimates based on the USFS summary reports are inflated as well. The total US WFAB reported by the USFS for each of the affected years is 1.6-2 million ha, with 35-50% based on the apparently inflated Texas unprotected-area estimates.

Potential errors in the wildfire activity statistics in the USFS annual summary reports are not limited to Texas, nor are they limited to figures from unprotected areas. Another potentially significant example is found in the USFS report for 1977. In that year, the USFS WFAB figure for protected lands in Alaska is 40,000 ha. However, WFAB estimates for that state in 1977 (~900,000 ha) published by Gabriel and Tande (1983) and several media outlets indicate that the USFS figure is an extreme underestimate.

While the reporting biases and potential errors in the wildfire activity statistics in the USFS annual summary reports should be recognized and addressed in analyses for which they are used, a portion of the data have been made readily available online with no formal citation or any reference to their source. At the time of this writing, the excerpt includes estimates of total wildfire numbers and area burned for the US from 1960-1982, and exists in tabular form on the website of the External Affairs

section of the National Interagency Fire Center (NIFC), which is where the NICC is located. The NIFC webpage with figures for a total span of 1960-2013, http://www.nifc.gov/fireInfo/fireInfo_stats_totalFires.html, is among the first returned in an Internet search for "wildfire statistics" or a similar term. While the estimates are identified as "total wildland fires and acres," at the time of this writing, the figures represent wildfires only, and exclude intentional, or controlled burning, which is a type of wildland fire by definition of the National Wildfire Coordinating Group (NWCG 2014). The figures for 1983-2013 are attributed to the Situation Reporting system that generates the estimates of wildfire numbers and area burned in the NICC annual reports described in Sect. 2 (see also Figure 1). However, the same footnote explains that "prior to 1983, sources of these figures are not known, or cannot be confirmed, and were not derived from the current situation reporting process. As a result the figures prior to 1983 shouldn't be compared to later data." Yet, when the NIFC figures are plotted with the USFS annual summary reports (Figure 5), whether as wildfire numbers or area burned, it is clear that NIFC External Affairs is using USFS estimates for 1960-1982.

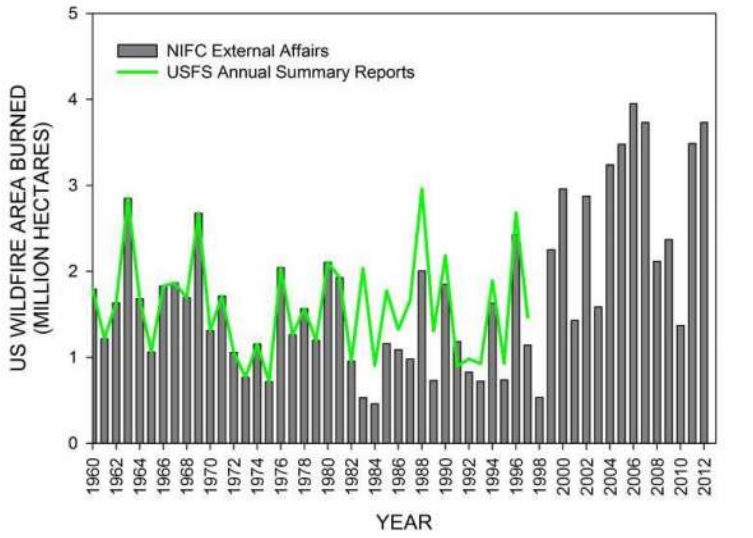

Figure 5. Comparison of US wildfire area burned estimates distributed by NIFC External Affairs for 1960-2012 (bars) compared with estimates for 1960-1997included in the USFS archival summary reports (line). The figures, whether wildfire numbers or wildfire area burned are identical between the sources for 1960-1982, indicating that the USFS summary reports are the source of the NIFC figures. The figures for 1983-2012 differ between the sources, because, as NIFC explains, those estimates are from the NICC summaries of the Situation Reporting data.

When the estimates from the USFS publications and the NIFC estimates sourced from the NICC Situation (SIT) Reporting summaries overlap in 1983-1997, the USFS figures tend to meet or exceed the values in the NICC summaries. As noted above, the USFS estimate for US WFAB for 1983 may be inflated by as much as 800,000 ha. While additional errors may exist in the USFS statistics, the NICC numbers may be biased downward during at least a portion of the period of overlap. Use of the SIT Reporting application, on which the NICC summary reports are based, is required only by agency and local dispatch offices associated with federal lands; it is effectively optional for nonfederal units with wildfire protection responsibility only for nonfederal lands. Voluntary SIT Reporting by nonfederal units may result in considerable underestimation of elements like wildfire numbers and area burned in the NICC annual reports. The magnitude of the discrepancies between the USFS reports and the NICC numbers appears largest in the earliest years of SIT Reporting (circa 1983; Figure 5), when the network of participating units was likely at its smallest

3.2. Documentary fire records

In general, documentary fire records of the federal, state, and local fire organizations are warehoused and available in electronic format only for a relatively recent period of several decades (Figure 1). The numerous US fire organizations have separate wildfire reporting requirements, standards, protocols, and archival systems, and compilation of data from multiple systems is difficult and time consuming (Short 2014). It is therefore typical for wildfire activity analyses based on the documentary fire records to be limited to a single agency, like the USFS, or to federal lands only (e.g., Westerling *et al*. 2003, 2006).

Yet, even within a single fire organization's system of record, the available electronic archive does not necessarily provide a complete or consistent accounting of actual wildfire activity. The USFS digital fire-reporting archive, for example, extends back to 1970. However, records from 1970-1992 were stored on computer tape before they were migrated, in 1992, to the current database archive (Bunton 2000). Bunton (2000) explains that, once the data from that early period were written to tape, no corrections could be made. Moreover, "some fire reports were never added to the tape files, and . . . most of the missing fires were very large fires that were still active (not declared out) until well after the annual report for the year was completed" (Bunton 2000). Once they were migrated from tape to database, records from prior to 1986 remained un-correctable, although Bunton (2000) indicates that some records of missing large fires were added after the current archival system was initiated in 1992. Analysts commonly consider the USDI fire records complete only back to 1980, because the digital archive is erratically populated prior to that year. However, formal and comprehensive fire reporting was not consistently mandated by the USDI bureaus until the mid-1980s, and the USDI archive suffers from many of the data quality and completeness issues as does that of the USFS prior to circa 1992 (S. Larrabee, personal communication).

Each of the fifty US states experiences wildfires that occur outside of the protection responsibility areas of federal government, and each maintains records of those events in non-federal reporting systems. While the period of record in the digital archives differs among the various non-federal fire organizations, the degree and quality of formal fire reporting has generally risen over time (Thomas and Butry 2012, Short 2014). For analyses of wildfire activity that include figures from states like Texas, for which wildfire protection and reporting is almost entirely the responsibility of the state or local service (see Artley 2009), it will be crucial to recognize and account for any nonfederal reporting idiosyncrasies within the domain of interest; they can be substantial (Short 2014).

The content, quality, and completeness of the available data can vary considerably among organizations and over time. For example, in the federal systems, the spatial resolution, or precision, of a fire's reported point of origin has generally improved over time from a legal description – township, range, and section – to actual point coordinates in latitude and longitude. However, most local fire department records can be spatially resolved to county or zip code at best – often referencing the zip code of a responding fire station. Location information from the state reporting systems can span the whole spectrum from a latitude-longitude point of origin to a nominal state designation only. Fire cause and final fire size are other basic occurrence-related elements that tend to range in both specificity and accuracy, if reported at all (Prestemon *et al*. 2013). Estimates of fire size from locally (e.g., manually) mapped and satellite-derived fire perimeters (polygons) may differ from that included in the incident reports; and all may overestimate area burned by including unburned islands within the fire perimeter (Kolden and Weisberg 2007).

3.3. Remotely sensed data

The use of satellite-derived fire detection and mapping products in wildland fire science has been expanding in the US and across the globe in recent decades (Mouillot *et al*. 2014). These remotely sensed datasets have proven particularly valuable where ground data are lacking or otherwise incomplete (Mouillot *et al*. 2014). In the US, areas of limited ground-based documentary wildfire data

may include lands for which fire protection is the responsibility of a local fire service that does not submit fire activity information to the (voluntary) national fire department reporting system. Millions of burnable hectares, including large fire-prone areas within several states in the south-central US (e.g., Kansas, Oklahoma, and Texas) may fall into this category in any given year (Short 2014). However, the MODIS active fire and burned area products have a relatively short history among the US wildfire activity datasets, dating back only to circa 2000 (Figure 1). To benefit from the enhanced fire detection capability of dual sensors (Hawbaker *et al*. 2008), analyses of MODIS products must be restricted to post-2003, which is the first full year that instruments were in use on both the Aqua and Terra satellites. The current MTBS large-fire perimeter (and burn severity) dataset nominally spans a lengthier period, 1984-2012, although it does not account for the majority of large fires in Alaska prior to 1999.

At present, the 30 m resolution MTBS burn scar dataset affords a consistently generated geospatial archive of large fire occurrence for nearly 30 years across most of the US. Fires are mapped regardless of land ownership or agency affiliation, and therefore the MTBS dataset can be used for all-lands analyses of spatially explicit large fire activity in recent decades. Yet, although it is intended to represent all fires greater than 404 ha in the western US and those greater than 202 ha in the eastern US, the MTBS dataset does miss some fires. Landsat scene selection in the MTBS mapping process is directed by reports of large fires in a compilation of documentary fire records from federal and state wildland fire reporting systems (Eidenshink *et al*. 2007). Fires missing from the MTBS compilation of documentary records – and fires with records lacking adequate temporal or spatial information to point to a specific Landsat scene – are unlikely to be included in the MTBS perimeter dataset, unless the burn scars are discovered by chance in the process of mapping other fires. Fires may likewise be missed or incompletely mapped due to poor scene quality (e.g., clouds, smoke, shadows), obstructive tree canopy over surface fire scars, patchy burning within pixels, mismatches in pre- and post-fire imagery related to sun angle and phenology, or rapid (<1 year) post-fire vegetation recovery (e.g., in some grassland and sprouting-shrub systems) (Kolden and Weisberg 2007, Kolden *et al*. 2012).

While the MTBS data suite includes pixel-level severity estimates for mapped fires, the identified unburned areas are not excised by rote from fire perimeters included in the polygon-based MTBS product. The unburned portions within the MTBS (and other) mapped perimeters can be substantial. Kolden *et al*. (2012) reported a total of 14-35% unburned area within fire perimeters from three national parks in the western US, 1984-2009, mapped using the MTBS protocol. Kasischke and Hoy (2012) found a similar average of 20% unburned within fire perimeters from Alaska forest fires in 2004 and 2006-2008. However, the unburned fraction can vary greatly among fires, and has been found to be inversely related to factors like fire size and severity (Kolden *et al*. 2012). If the size and severity of wildfires, for example, increase over time, the unburned portions within fire polygons may decrease. Kolden and Weisberg (2007) describe in further detail the challenges and associated sources of error in the mapping and measuring of wildfire area burned, both locally and remotely via the MTBS protocol, and readers are referred to that publication for more on these topics.

The MTBS dataset identifies prescribed (or controlled) burns separately from wildfires. This "fire type" attribute is useful for screening out the intentional, controlled burns for an analysis of wildfire activity. However, prior to the 2014 release, fires mapped by MTBS defaulted to a fire-type label of "wildfire," and that default label was updated to another type (e.g., prescribed fire) only when the associated fire report specified accordingly. For this reason, all fires mapped without the aid of documentary records (e.g., fires discovered in the process of mapping others) were all identified as wildfires. In the 2014 release, this issue was remedied to some degree by relabeling any fires of uncertain fire type to "unknown." Of the ~23,000 fire polygons in the 2014 MTBS product release, 4,500 (20%) are now labeled as unknown fire type. Analysts must determine the appropriate use of these uncertain types. Many of the fires of unknown type map within the Flint Hills region of Kansas and northern Oklahoma, where ~700,000 ha are intentionally burned each spring for rangeland improvement (KDHE 2010, Melvin 2012). Fires of unknown type in that region are prime candidates for exclusion from MTBS-based analyses of wildfire activity.

Improvements in spaceborne sensors over the past couple of decades have expanded the available set of data products characterizing fire activity and associated burned area (Mouillot *et al*. 2014). Products derived from MODIS sensors are increasingly used for analyses of wildland fire activity, as the instruments employ what are considered to be the most useful channels (spectral bands) for fire monitoring and mapping – at spatial resolutions of 500 m (burned area) to 1 km (active fire). The MODIS active fire product (Giglio *et al*. 2003) is based on detection of thermal anomalies; and while strictly a fire detection product, it has been used to estimate burned area in the US (e.g., Wiedinmyer *et al*. 2011, Hawbaker *et al*. 2013). Temporal sampling by the MODIS sensors (on two Earth Observation Satellites) is relatively limited: a total of four satellite overpasses comprise a midday pair and a nighttime pair. Thus the sensors will not always overpass as burning occurs, and clouds (or smoke) may preclude active fire detection during the limited overpasses (Giglio *et al*. 2006, Hawbaker *et al*. 2008, Urbanski *et al*. 2009). In general, the MODIS active fire product is subject to high omission errors with regard to fires of small size, short duration, or low-intensity and may underestimate area burned by large, rapidly moving fires that travel across multiple MODIS pixels between overpasses (Hawbaker *et al*. 2008). The MODIS sensors are generally considered to have a lower fire-size detection threshold of ~100 m^2 under the most favorable conditions (Giglio *et al*. 2003). But above that size threshold, omission errors can be quite high and tend to be much greater in grasslands and open shrublands than in forested areas (Hawbaker *et al*. 2008, Urbanski *et al*. 2009, Mouillot *et al*. 2014). According to Urbanski *et al*. (2009), "even large rangeland fires (>2000 ha) may completely evade MODIS detection." Within a given vegetation type, however, active-fire omission errors tend to decrease with increasing fire size (Hawbaker *et al*. 2008, Urbanski *et al*. 2009).

Errors of commission in the MODIS active fire product may result from confusion of highly reflective non-fire surfaces with true fires, or, due to its contextual algorithm, from sharp radiometric contrasts between adjacent non-fire elements, like certain vegetation and soils (Hawbaker *et al*. 2008). More importantly and despite omission errors, burned areas derived from MODIS active detection products tend to overestimate the true burned area because the sensor's detection threshold of ~100 m^2 is much lower than the product's 1 km pixel resolution (Giglio *et al*. 2006). Thus, while MODIS active fire product may capture the majority of certain types of large fire events (e.g., forest fires), the corresponding burned area estimates are highly error prone. Adjustments to initial burned area estimates, including scaling by fraction of vegetation cover or a combination of vegetation cover and fire-pixel clustering, may improve burned area estimates derived from the active-fire product (Giglio *et al*. 2006, Wiedinmyer *et al*. 2011).

Aside from the thermal-based active-fire product, several 500-m resolution MODIS burned area products based on surface reflectance (burn scars) have been generated (Mouillot *et al*. 2014). Roy *et al*. (2005) and Giglio *et al*. (2009) identify burn scars based on changes in surface reflectance, while Urbanski *et al*. (2009) developed an algorithm to produce near-real-time burn scar data using a single observation of surface reflectance. The burn scar algorithm of Roy *et al*. (2005) is employed in the standard, monthly MODIS burned area product distributed by the US National Aeronautics and Space Administration. Both Giglio *et al*. (2009) and Urbanski *et al*. (2009) leverage the active fire detections in their algorithms to confirm burn scars and reduce uncertainty in burned area estimates; using a version of this method (and MTBS burned pixels rather than NICC burned area estimates as "ground-truth" data) Urbanski *et al*. (2011) were able to reduce the apparent upward bias in MODIS burned area estimates for the western US, 2003-2008, to 7% and estimated uncertainty in their annual estimates of area burned by wildland fire to $\leq$5%.

From a *wildfire* activity standpoint, another important source of uncertainty in the MODIS-based products is the conflation of wildfire and intentional, controlled (or prescribed) burning in both wildland and agricultural areas. All of the controlled burning must be screened from remote sensing fire products for any analyses of wildfire activity, *per se*. According to estimates from the NICC, an average 800,000 ha of wildlands have been intentionally burned (with prescribed fire) in the US annually since the NICC began keeping records in 1998. However, that figure is a conservative

estimate, because much controlled burning on private lands, including commercial timberlands, is not reported to the NICC. An independent survey of controlled burning levels for the year 2011 by the National Association of State Foresters and the Coalition of Prescribed Fire Councils, suggests that the total area deliberately burned in the US during that year was 8 million ha, or *ten times* the NICC estimate (Melvin 2012). Of that total, 39% (3.1 million ha) was reported as controlled burning on forested lands, predominantly in the southeastern US; while the remainder was considered agricultural burning, largely in western and central plains states (Melvin 2012). Assuming the 2011 controlled burning figures are typical, which Melvin (2012) suggests, and given that the average annual area burned by wildfire over the past 20 years is estimated (from several sources) as ~2.3 million ha (Short 2014), then the vast majority of area burned annually in the US is not from wildfire, but from intentional burning for agricultural or other land management purposes. Moreover, the contemporary annual area burned by wildfire in the US appears likely to be less than that burned deliberately for forestry objectives. Therefore, even if MODIS detection rates from agricultural areas are expected to be relatively low (Hawbaker *et al*. 2008) and even if remotely sensed landcover maps can be used to exclude detections in pixels mapped as developed or agriculture/cropland (McCarty *et al*. 2007, Urbanski *et al*. 2011, Hawbaker *et al*. 2013), additional efforts must be made to exclude controlled burning in forested areas. Otherwise, "wildfire" activity levels would likely be greatly overestimated from MODIS products, especially if the southeastern US is included in the analysis.

Mouillot *et al*. (2014) expand on many of the points made here with regard to potential limitations of the MODIS (and other satellite-based) products and discuss them specifically in light of potential uses of the data, including for hazard assessment, mobilization of firefighting resources, and emissions modeling; readers seeking more information on these topics are encouraged to consult that publication. With growing interest in MODIS-based active fire count and burned area datasets there is increasing pressure to improve the accuracy, resolution, and temporal specificity of the products (Mouillot *et al*. 2014, Schroeder *et al*. 2014). Any changes in detection capabilities or processing algorithms that result in such improvements must be taken into account in any multiannual analysis to potentially mitigate influences of temporal instability in the datasets.

Summary and Conclusion

There is a wealth of US wildfire activity data available for analyses today, but analysts must be aware of inherent reporting biases, inconsistencies, and uncertainty in the data in order to maximize the integrity and utility of their work. Users of data from archival summary reports should recognize that the estimates come from an increasing land area over time, and even the most recent annual wildfire summary reports from the NICC do not account for all wildfire activity (especially fire numbers) in the US, due in part to limited wildfire reporting by local fire departments (Thomas and Butry 2012). Moreover, all estimates are just that, and area-burned estimates are inherently uncertain. Burned area estimates based on fire perimeters, which often include significant unburned portions, are typically biased high (~15-30%). Analysts attempting to assess MODIS burned area products have, for example, adjusted the NICC reference figures of area burned by a factor of 0.72 to account for a perceived overestimation of 28% (Urbanski *et al*. 2009). Unadjusted, area burned figures based solely on the MODIS active fire product tend to be overestimates, due to the ability of the sensors to detect fires smaller than the products' pixel sizes. Algorithms that use the active fire detections to confirm burn scars can generate MODIS burned area products that align well with those estimated from MTBS burn scars (with unburned islands excluded).

All remotely sensed datasets intended for analyses of wildfire activity, per se, must be carefully screened to remove areas burned intentionally for in both agricultural areas and wildlands, which may account for 80% of the total area burned in the US in any given year. Millions of ha of intentional burning in the southeastern US are included as part of the annual estimates of wildfire activity on unprotected lands for several early decades of the USFS annual summary reports. It is inappropriate

to compare, for example, the early total area burned estimates, which factor in "prescribed fire," to the statistics in later USFS reports, which omit it, or to compare them to figures post-1998 in the NICC reports, which greatly underestimate levels of intentional burning in the US.

Documentary fire records from the digital archives of federal wildfire reporting may not fully represent total wildfire activity levels in years prior to 1992, but it is unclear how much data is missing. Use of the national fire reporting systems of state and local fire organizations has been rising in recent decades, providing an improved set of incident-level data for all-lands analyses of wildfire activity. Short (2014) expanded on earlier efforts of Schmidt *et al* (2003) to compile federal and nonfederal wildfire data from the various reporting systems for the national Fire Program Analysis system. The resulting FPA Fire-Occurrence Database (FPA FOD) currently includes nearly 1.7 million records from the 21-year period, 1992-2012, with values for at least the following core data elements: location (fire origin) at least as precise as a Public Land Survey System section (2.6 km^2 grid), discovery date, and final fire size. The FPA FOD is publicly available from the USFS Research Data Archive (http://dx.doi.org/10.2737/RDS-2013-0009.2). While necessarily incomplete in some aspects (Short 2014), the database is intended to facilitate fairly high-resolution geospatial analysis of US wildfire activity over recent decades. Additional elements added to the original fire records, including the unique MTBS perimeter identifiers, effectively provide a "bridge" between the ground- and satellite-based datasets, and the MTBS perimeters can be used in conjunction with the FPA FOD to expand upon geospatial analyses possible with point-of-origin information in the original fire reports (Short 2014).

Suppression capability of foams used fighting against forest fires with the test of weight rate remained on the crown surface R-10A Method - weight effectiveness experiment

Agoston Restas

National University of Public Service, Budapest, Hungary, Restas.Agoston@uni-nke.hu

Abstract
Introduction: The effectiveness of the foams used in fighting against forest fire depends on common effect of some coefficients. Cooling and isolation effects as main extinguishing effects as well as side extinguishing effects, like evaporation, blanket and separation effects are also included. Under the same conditions, the more extinguisher remains on the surface, the more extinguishing effect it has. Methods: A product for the test was randomly chosen out of the ones on the market. Spruce was chosen for the test due to its high flammability. The goal was to determine the amount of extinguisher at the end of the branches in the foliage. Groups of the same size were created in the selected foliage. To start with, the weight of the untreated foliage was measured, followed by the groups of foliage dipped in water and foaming agents. Results and discussion: According to the findings of research, the amount of foam remaining on the foliage is remarkably higher than that of water. Its rate is 3.36-3.76 compared to water. The research also revealed that this rate does not significantly depend on expansion rate. As a result, the fire intensity which can be extinguished by using foams expands as well.

Keywords: suppression capability, foam, weight effectiveness experiment, R-10A method

Introduction

The effectiveness of the foams used in fighting against forest fire depends on common effect of some coefficients. Cooling and isolation effects as main extinguishing effects as well as side extinguishing effects, like evaporation, blanket and separation effects are also included (Kuncz, 1972). The efficiency of isolation effect certainly depends on the amount of extinguishing agent measured in unit area of surface, which in the case of not horizontal surfaces is in correlation with the adhesion of the extinguisher that is the rate of remaining on the surface. Under the same conditions, the more extinguisher remains on the surface, the more extinguishing effect it has.
Since the quantity of the extinguisher has a great impact on the firefighting techniques applied as well as the effectiveness of the techniques applied (Bleszity, 1990), it is recommended to review the various factors not only because of their importance but also because of the safety of the intervention crew (Pantya, 2011). Several studies are dealing with the effectiveness of extinguishers and separate measurement methods were created (Batista, 2011; Morris, 2011). However, researches aimed at the extinguisher remaining on the foliage may be scarce, according to the author. The paper wishes to present a unique approach to this topic, comparing water and foam as extinguishers with different structures and their ability to remain on the surface. This procedure following the below assumptions got a fantasy name and was called R-10A method.

Methods

The method was developed in order to measure the rate of foam remained on the vegetation surface (spruce) to determine the extinguishing potential of foam blanket. This problem can have not just one aspect. In case of using very “light” foam – meaning that the expansion rate of foam is large, with other words the density is low – it will remain on the top of the crown, therefore it is unable to protect

the bulk from the radiation heat or it can be blown over by the wind. In other case, when using very "heavy" foam – meaning that the expansion rate is low or the density is high – it takes the features as Newtonian fluid and will drip to ground resulting that the larger part of foam will not remain in the area of the burning cell. Both case causes useless waste. Even if the ideal expanditure rate of foam can be different depending on the situation or the type of vegetation but author's experience say it must be higher than 6 but below 13. As a series in this research author used foams expanditure rate of 6 – 9 – 12.

The other aspect is that, what is the difference between the weights of the extinguisher materials remaining on the surface (crown).

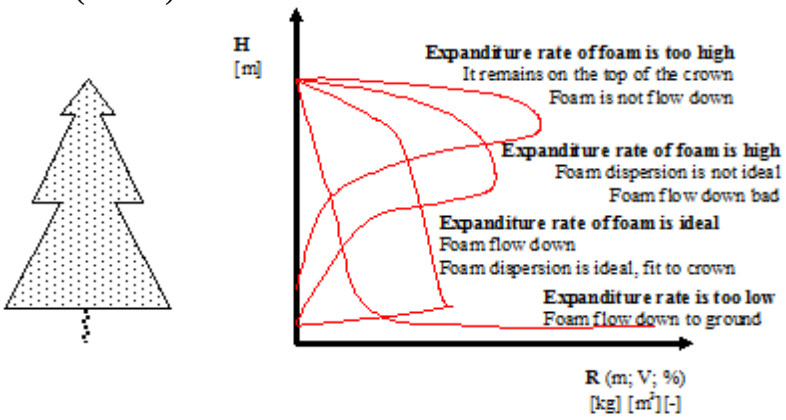

Figure 1. Structure of foam remaining on the crown depending on the rate of expanditure

Prepare the process

During the research the goal has been formulated to develop a simple, easily reproducible method used for both illustration and teaching which proves the differences in the extinguishers' adhesion and presents its consequences. The author opted for analysing the mass/volume of extinguisher left on the surface. A product was randomly chosen out of the ones on the Hungarian market. It is named Light Water, what is used in Hungary as common foam concentrate, even in case of serious forest fire, however this type of foam not typical at the international practice (or at forest fire). Using this foam is acceptable, because the aim of the test is not to determine the efficiency of the extinguisher, but to demonstrate its application.

Spruce was chosen for the test due to its high flammability. The goal was to determine the amount of extinguisher at the end of the branches in the foliage. Groups of the same size were created in the selected foliage. To start with, the weight of the untreated foliage was measured, followed by the groups of foliage dipped in water and foaming agents. In the case of the latter groups, the weight of the foliage itself was subtracted from the total weight, giving us the maximum amount of the extinguisher remaining on the foliage. During the experiment 6 – 9 – 12 expansion rated foams were applied.

Below is declared the main important things for preparing the test, and some basic process for being ready to measure the mass/volume foam left on the surface. Means required for the process:

1. Choosing samples: The highly flammable spruce was chosen as a sample. Twigs of 100-150 mm were cut down (4x10pcs= 40pcs). Thus, that part of the spruce was examined which has the greatest role both in fire spread and keeping the extinguisher.
2. Preparing the samples: the twigs are dried in sun for 4 hours in 30°C. Thus, the surface becomes totally dry similarly to the typical conditions of intense fire periods.
3. Preparing the matrix holding the samples: a matrix was created according to the set of measurements. It included the boxes (altogether 4x10 pcs) to keep water and the foams of 6 – 9 – 12 expanditure (Hk = 6 – 9 – 12).

4. Preparing the extinguishers to be examined: normal tap water and foam-forming substance was used in the experiment. The foam-forming substance was Light Water, which is generally used in Hungary.
5. The preparation of the extinguishers: Water was 20°C, normal temperature, 15 ^{0}dH (water hardness in German degrees). Preparing a foam solution in measuring bottles: the foam-forming substance is Light Water, out of which foams of different expanditure were created, using a mixture of 3%. These were in three different bottles: Hk = 6; Hk = 9; Hk = 12.

Figure 2. Preparing the spruce twigs for measurement

2.2. Measured data of different treated samples1

The measurements clearly show that water and foam remain on the surface of the foliage in completely different shapes (Figure 3). Water is not evenly distributed, but it sticks to the surface in drops, separately, while the foam surrounds the twig in a homogenous mass. In spite of the conspicuous difference, we do not know if the difference in structure causes any significant difference in the extinguishers' ability to remain on the surface. If so, then the extinguisher which has more quantity on surface possesses more heat capacity proportionately.

Figure 3. Different treated samples – foam and water

1 Author made this measurement in 8th May, 2013, Szendro, Hungary

The findings of the measurements carried out and the values obtained from the data can be found in Table 1.

Table 1—Measured data

R-10A	**Measured weight** (gram)			
Weight of untreated samples (n=10) (avarage:34,17)	33,48	34,26	35,33	33,60
1. Sample group				
Weight of samples treated by water (net)	50,52	-	-	-
Weight of water	17,04	-	-	-
Rate of extinguisher (water) to max. water on surface	1	-	-	-
2. Sample group				
Weight of samples treated by foam, Hk=6 (net)	-	98,33	-	-
Weight of foam, Hk=6	-	64,07	-	-
Rate of ext. (foam, Hk=6) to max. water on surface	-	3,76	-	-
3. Sample group				
Weight of samples treated by foam, Hk=9 (net)	-	-	94,84	-
Weight of foam, Hk=9	-	-	59,51	-
Rate of ext. (foam, Hk=9) to max. water on surface	-	-	3,49	-
4. Sample group				
Weight of samples treated by foam, Hk=12 (net)	-	-	-	90,81
Weight of foam, Hk=12	-	-	-	57,21
Rate of ext. (foam, Hk=12) to max. water on surface	-	-	-	3,36

2.3. Calculations

The following calculations were made to assess the findings. To start with, the author specified the average weight of the samples from each sample group, and then calculated the weight of the individual sample by averaging.

Secondly, by dipping the samples into water, the author specified the maximum value of water saturation. Thus the water retention capacity of the samples can be determined, by considering the differences in weight.

Thirdly, foams of different expanditure and their ability to remain on the surface were examined. The samples were dipped into foam (it results also the maximum weight on surface), weighed and then the relevant data were calculated by averaging.

The ability of the extinguisher to remain on the surface was determined by subtracting the weight of the untreated samples from the values measured. Then we get the values of the foam by comparing these data to the data of the samples treated with water. The calculations produce the following results:

1. Average weight of the individual samples of the 4 sample groups

$$\overline{m}_{P\_Nature} = \frac{\sum_{i=1}^{n} m_{P\_Nature\_n}}{n} = \frac{33{,}48g}{10} = 3{,}348g$$

$$\overline{m}_{P\_Nature} = \frac{\sum_{i=1}^{n} m_{P\_Nature\_n}}{n} = \frac{34{,}26g}{10} = 3{,}426g$$

$$\overline{m}_{P\_Nature} = \frac{\sum_{i=1}^{n} m_{P\_Nature\_n}}{n} = \frac{35{,}33g}{10} = 3{,}533g$$

$$\overline{m}_{P\_Nature} = \frac{\sum_{i=1}^{n} m_{P\_Nature\_n}}{n} = \frac{33{,}60g}{10} = 3{,}360g$$

2. Average of the average samples of the sample groups

$$\overline{m}_{P\_Nature} = \frac{\sum_{i=1}^{4} m_{P\_Nature\_n}}{n} = \frac{3{,}348g + 3{,}426g + 3{,}533g + 3{,}360g}{4} = 3{,}417g$$

3. The average weight of the spruce sample dipped into water

$$\overline{m}_{P\_H_2O} = \frac{\sum_{i=1}^{n} m_{P\_H_2O\_n}}{n} = \frac{50{,}52g}{10} = 5{,}052g$$

4. The average weight of the spruce sample treated with foam of expanditure Hk

$$\overline{m}_{P\_Foam\_H_K=6} = \frac{\sum_{i=1}^{n} m_{P\_FoamH_K\_n}}{n} = \frac{98{,}33g}{10} = 9{,}833g$$

$$\overline{m}_{P\_Foam\_H_K=9} = \frac{\sum_{i=1}^{n} m_{P\_FoamH_K\_n}}{n} = \frac{94{,}84g}{10} = 9{,}484g$$

$$\overline{m}_{P\_Foam\_H_K=12} = \frac{\sum_{i=1}^{n} m_{P\_FoamH_K\_n}}{n} = \frac{90{,}81g}{10} = 9{,}081g$$

5. The average weight of the water on the spruce sample

$$\overline{m}_{H_2O} = \overline{m}_{P\_H_2O} - \overline{m}_{P\_Nature} = 5{,}052g - 3{,}348g = 1{,}704g$$

6. The average weight of the foam of expanditure H_K on the spruce sample

$$\overline{m}_{Foam\_H_K=6} = \overline{m}_{P\_Foam\_H_K} - \overline{m}_{P\_Nature} = 9{,}833g - 3{,}426g = 6{,}407$$

$$\overline{m}_{Foam\_H_K=9} = \overline{m}_{P\_Foam\_H_K} - \overline{m}_{P\_Nature} = 9{,}484g - 3{,}533g = 5{,}951$$

$$\overline{m}_{Foam\_H_K=12} = \overline{m}_{P\_Foam\_H_K} - \overline{m}_{P\_Nature} = 9{,}081g - 3{,}360g = 5{,}721$$

7. The rate of foam of expanditure H_K and water on the spruce samples

$$R_\gamma = \frac{\overline{m}_{Foam\_H_K=6}}{\overline{m}_{H_2O}} = \frac{6{,}407g}{1{,}704g} = 3{,}76$$

$$R_\gamma = \frac{\overline{m}_{Foam\_H_K=9}}{\overline{m}_{H_2O}} = \frac{5{,}951g}{1{,}704g} = 3{,}49$$

$$R_\gamma = \frac{\overline{m}_{Foam\_H_K=12}}{\overline{m}_{H_2O}} = \frac{5{,}721g}{1{,}704g} = 3{,}36$$

Results

According to the findings of research, the amount of foam remaining on the foliage is remarkably higher than that of water. Its rate is 3.36-3.76 compared to water. The research also revealed that this rate does not significantly depend on expansion rate. The surface of the foliage in a full-grown forest is able to hold 4-5 kgm^{-1} water, which is enough to control a fire of about 3400 kWm^{-1} fire intensity. We can come to the conclusion that if fire intensity is so high that the cooling capability of water is not enough to extinguish the fire, applying foam can extend the range of extinguishing possibilities to dimension where extinguishing with water is not possible for objective reasons. Its reason is that by applying foam, the mass remaining on the surface, thus the cooling capability of the extinguisher, can be tripled. As a result, the fire intensity which can be extinguished expands as well.
We have to add that in addition to the foam's weight effectiveness increase, insulation effects can be noticed, too, resulting in additional extinguishing effects. Weight effectiveness and insulation effects do not add up but multiply, which is yet another proof of the advantages of foams.
The above results show that the factor of weight effectiveness of the foams is significant, which offers the opportunity of increasing the amount of extinguisher on one unit of surface. The unsatisfactory extinguisher effect of water can be improved and extinguisher solutions have become available which have been impossible so far.

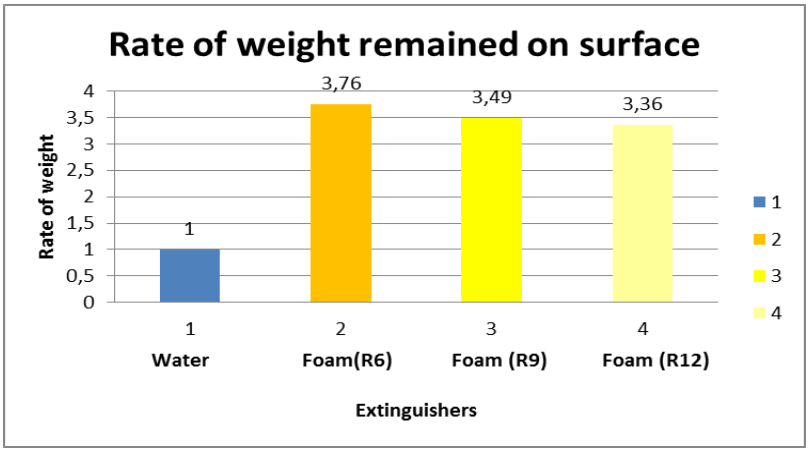

Figure 4. Rate of weight remained on surface depending on the expanditure rate of foams

Appendix A – Notation

1. m_{P_Nature} = the weight of the individual twig (sample), untreated;

2. $\overline{m}_{P\_Nature}$ = the average weight of the untreated samples;
3. $m_{P\_H_2O}$ = the weight of the individual samples treated with water;
4. $\overline{m}_{P\_H_2O}$ = the average weight of the samples treated with water;
5. $m_{P\_Foam\_K_k}$ = the weight of the individual samples treated with foam of H_K expanditure;
6. $\overline{m}_{P\_Foam\_K_k}$ = the average weight of the samples treated with foam of H_K expanditure;
7. $\overline{m}_{H_2O}$ = the average weight of the water remaining on the samples;
8. $\overline{m}_{Foam\_H_K}$ = the average weight of the foam of H_K expanditure remaining on the samples;
9. R_γ = the weight of the foam of H_K expanditure and water remaining on the samples;
10. $m_{\max H_2O\_m^2}$ = the weight of the water remaining on one unit of surface (constant) = 5kg;
11. $m_{\max FoamH_K\_m^2}$ = the weight of the foam of H_K expanditure remaining on one unit of surface.

Appendix B – Mathematical formulas used for calculations

1. The average weight of the untreated spruce sample

$$\overline{m}_{P\_Nature} = \frac{\sum_{i=1}^{n} m_{P\_Nature\_n}}{n}$$

2. The average weight of the spruce sample dipped into water

$$\overline{m}_{P\_H_2O} = \frac{\sum_{i=1}^{n} m_{P\_H_2O\_n}}{n}$$

3. The average weight of the spruce sample dipped into foam of H_K expanditure

$$\overline{m}_{P\_Foam\_H_K} = \frac{\sum_{i=1}^{n} m_{P\_FoamH_K\_n}}{n}$$

4. The average weight of the water remaining on the spruce sample

$$\overline{m}_{H_2O} = \overline{m}_{P\_H_2O} - \overline{m}_{P\_Nature}$$

5. The average weight of the foam of H_K expanditure remaining on the spruce sample

$$\overline{m}_{Foam\_H_K} = \overline{m}_{P\_Foam\_H_K} - \overline{m}_{P\_Nature}$$

6. The rate of the average foam of H_K expanditure and water remaining on the samples

$$R_\gamma = \frac{\overline{m}_{Foam\_H_K}}{\overline{m}_{H_2O}}$$

7. The amount of water effectively remaining on one unit of surface

$$m_{\max H_2O\_m^2} = const = 5kg$$

8. The amount of foam of H_K expanditure remaining on one unit of surface

$$m_{\max FoamH_K\_m^2} = m_{\max H_2O\_m^2} R_\gamma$$

Abstract

Fires are a common, disastrous phenomenon (hazard) that constitutes a serious threat for many years. Due to their speed of propagation and intensity they often lead to property damages, personal injuries and loss of human lives. The probability of forest fire eruption in the Wildland-Urban Interface (WUI) is steadily increasing due to the climate change and human activities. WUI refers to all types of areas where forests, water bodies, and rural lands interface with homes, other buildings and infrastructures, including first and secondary home areas, industrial areas and tourist developments.

The Sensor Web Fire Shield (SWeFS) research project designs, develops and demonstrates an integrated system of sensors, networking and computing infrastructure aimed to detecting, monitoring, predicting and assisting in natural hazards such as forest fires at the WUI zones. Its goal is to deliver: (i) a methodology for developing a novel Sensor Web platform for dynamic data-driven assimilation (DDDAS) for securing the WUI zones against environmental risks, and, (ii) a prototype DDDAS system specifically optimized/tuned for addressing the serious threat of forest fires in Greece. SWeFS pushes the state-of-the-art by combining and using technologies derived from multidisciplinary research in the areas of sensor networks, distributed vision systems, remote sensing, geographical information systems (GIS), data stream fusion, space-time predictive modeling and control systems.

Keywords*: fire detection and monitoring, active sensing, wireless sensor networks, dynamic data driven assimilation, data fusion, space-time predictive modelling, closed-loop architecture*

Introduction

Countries in the Mediterranean basin suffer from 50.000 fires annually with damaged land that covers 600.000 hectares. The cost of fire prevention and fire fighting in the Southern European countries scales up to 1 billion USD. The cost of the destructive fires of 2007 in Greece has been estimated to 1 billion euros. The land impacted by fires annually in the same region is equivalent to the surface of Crete or Corsica while the fires in Spain, Portugal, France, Italy and Greece have quadrupled since the 1960's. The rapid development of WUI areas is the outcome of pollution and overpopulation of city centers that grew in the ‘70s. Settlements were built without efficient road networks while homes and other buildings were developed in or near areas that form the flood plain of water catchments.

To minimize the aforementioned damages, early detection of environmental hazards like forest fires is critical. It is also very important to have early and accurate information about the exact origin(s) of the fire and its course as it spreads. Great technological effort has been invested on the design of systems for fire detection and monitoring. From an engineering perspective, machineries can be designed and used to help with detection or prediction of the disastrous events. One technology that enables (near) real-time detection of such events is the so-called Wireless Sensor Networks (WSNs). WSNs typically consist of a large number of small, low-cost sensor nodes distributed over a large area. The sensor nodes are integrated with sensing, processing and wireless communication capabilities. A simple WSN could be based only on a network of multi-sensor field devices that are able to detect increases in the temperature and/or decreases in the humidity percentage. However, the most promising approach for the early forest fire detection in WUI zones is the combination of various

heterogeneous sensors. Typical temperature and humidity sensors can be combined with video-capable wireless sensors, optimally placed in an area of interest, to better observe the outbreaks of various hazardous phenomena. The prediction accuracy of such an approach could be enhanced through the exploitation of remote sensing products such as satellite monitoring (another source of information interfaced to the systems). Of course, one of the requirements that have to be addressed is the optimal placement of the available sensor infrastructure in order to maximize the coverage of the monitored area. WSN systems can reach, at a reasonable cost, the density of physical parameter measurements needed for an accurate and timely fire detection, localization and progress monitoring.

During the past years, a lot of research has been conducted in the area of forest fire detection. The study from Elmas et. al. (2011) discusses a Forest Fire Decision Support System (FOFDESS) model, which is a multi-agent Decision Support System for Forest Fire. Depending on the existing meteorological state and environmental observations, FOFDESS does the fire danger rating by predicting the forest fire and it can also approximate fire spread speed and quickly detect a started fire. The considered model adopts data fusion algorithms such as Artificial Neural Network (ANN), Naive Bayes Classifier (NBC), Fuzzy Switching (FS) and image processing. The SFEDONA project (co-funded by ESA) deals with a complete end-to-end fire detection and alerting application which makes use of state-of-the-art fire detection technologies based on terrestrial optical cameras and sensors, data fusion, satellite and wireless communications as well as modern IT technologies. The SFEDONA project adopts a terrestrial wireless network for the interconnection of various components installed on-field such as optical and panoramic PTZ cameras, weather monitoring stations and wireless environmental sensors, as well as of a SatCom (satellite) network for the interconnection of the end user's premises with local field. The SatCom connection is used for delivering alarms on fire events to the core control center. The model presented by Li et. al. (2005) discusses a hybrid contextual fire detection algorithm for airborne and satellite thermal images. This model essentially treats fire pixels as anomalies in images and can be considered a special case of the more general clutter or background suppression problem. The system from Lloret et. al. (2009) deploys wireless IP multi-sensors able to sense fire by infrared radiation and smoke. The system sends an alarm to the control system if the combination of physical sensors reports a fire event. When a fire is detected, the sensor alarm is sent through the wireless network to the control center. The center selects the closest wireless IP cameras to the sensor and sends them a signal in order to receive real-time images from the affected zone. Regarding the cases where the fire detection algorithms use satellite remote sensing capabilities, most of them are based on a single sensor approach and are using basic signal processing techniques. Specifically for MSG/SEVIRI data, the different approaches rely on variations of EUMETSAT's (the international organization managing the Meteosat series of geostationary meteorological satellites) proposed classification methodology. Sifakis et. al. (2011) from ISARS/NOA and Carvalheiro et. al. (2010), among others, have adopted a similar approach for identifying hotspots. It should be noted that the method presented by Calle et. al. (2006) was applied in the framework of SAFER (EC/GMES) project with noticeable omission errors for Greece, mainly attributed to insufficient customization for the geographic area's special characteristics in terms of vegetation species and underlying land cover. Finally, in the context of the EU project SCIER (Sensor and Computing Infrastructure for Environmental Risks management) as described from Sekkas et. al. (2010), a scalable system architecture that integrates private and public sensor and camera networks in a hierarchy has been developed and tested. The system was designed to protect WUI areas by adopting a scalable and modular approach for early detection and effective fire management. In addition to the sensory system (WSNs), SCIER provided the capability of performing parallel simulation (using Grid computing) of multiple fire scenarios corresponding to different environmental conditions (e.g. wind direction and speed). This unique capability was an innovation offered for the first time by SCIER. However, SCIER and the rest of the aforementioned approaches did not attempt to integrate WSN sensing and predictive modeling with remote sensing and GIS into a *closed-loop active sensing system* and implement a DDDAS scheme for fire detection and management. This unique innovative approach is pursued in

SWeFS. Moreover, SWeFS deals with multiple parameters and trade-offs, hence, considers and aims both for energy-efficiency and early-detection. The Sensor Web Fire Shield (SWeFS) research project aims at delivering: (i) a methodology for developing a novel Sensor Web platform as a Dynamic Data-Driven Assimilation System (DDDAS) for securing the WUI zones against environmental risks, and, (ii) a prototype DDDAS specifically optimized/tuned for addressing the serious threat of forest fires at national and international level.

SWeFS High Level Architecture

SWeFS adopts a combination of heterogeneous sensors including remote sensing and predictive risk propagation models in a *single closed loop active sensing system*. The first step towards the completion of SWeFS architecture (Figure 1) is the *efficient collection and processing of data streams* that is provided from the various subsystems of the Input Block (IB) (i.e., network of sensors, cameras, remote sensing and unmanned air vehicles).

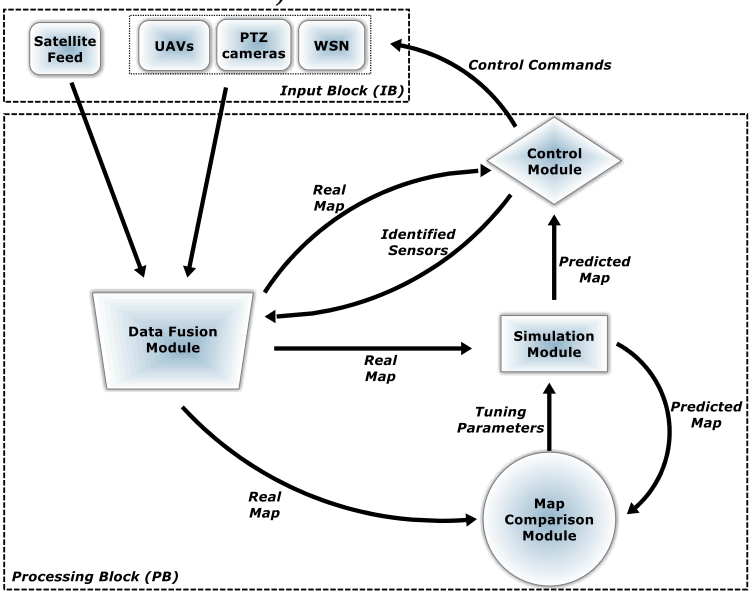

Figure 1- Interconnection of SWeFS components

The remote sensing methodologies employed in SWeFS greatly facilitate the early detection and monitoring of wildfires while the active sensing techniques give an identification mechanism for the type and combination of sensors that provide the most useful measurements from the field. In addition, the ability provided by SWeFS to simulate multiple scenarios in parallel is important from a management point of view since it enables "what if" type queries and worst case scenario identification in real-time. Of course, the prediction mechanism is equally important for the encapsulation of the DDDAS scheme in SWeFS. The processing of the streaming data derived from the IB is operated by the components of the Processing Block (PB), in a closed loop approach, in order to provide accurate information regarding the exact origin(s) of the fire and its course as it spreads. The outcome is the visualization of hazard maps for the monitored phenomenon on a map based graphical user interface (GUI). To the best of our knowledge, SWeFS is pioneer to its domain with respect to the adoption of a closed loop approach in order to detect and monitor the evolution of a hazardous phenomenon such as forest fires at the WUI zones.

Another important element of innovation in SWeFS is the simultaneous implementation of both asynchronous and synchronous communication, which is defined according to the type of functionalities and the information handled: in the former case (asynchronous), new information or information updates are either published from the components of the IB or consumed from the components of the PB as soon as they become available, while in the latter one (synchronous), access

to the needed data (i.e., spatial data for available sensors, fuel data, etc.) and functionalities (i.e., control of the sensory infrastructure) happen "on request". This architecture is achieved through the utilization of a Message Oriented Middleware (MOM) to act as the communication infrastructure for the interconnection of the SWeFS structural components. Publisher and Subscriber entities are present in the various modules belonging either in the IB or the PB to respectively publish and consume information of interest through the MOM.

Input Block

The Input Block (IB) of SWeFS consists of a heterogeneous infrastructure of sensors that provides the means for the optimal collection of measurements related to a fire incident in the monitored area. Currently, the following categories of sensors are integrated:

- In-field sensors able to measure temperature, humidity and gas concentrations,
- Weather stations that provide additional information about rain rate, wind speed and wind direction
- Out-of-field sensors like:
    - Pan-Tilt-Zoom (PTZ) and Fixed Cameras
    - Unmanned Air Vehicles (UAVs) equipped with cameras
- Remote sensing and processing facilities

Figure 2-SWeFS Sensory Infrastructure

Raw data stemming from in-field sensors provide on-the-run information about the actual progress of the phenomenon to experts. On the other hand, the data coming from the satellite feed and the available camera network constitute pre-processed streams that provide an estimation (i.e., probability values) regarding the occurrence of a fire incident in the area that falls in their supervision. The processing stage of such feeds is based on widely accepted image processing techniques from the research community. These operations are either performed locally on the nodes, through the exploitation of Field-Programmable Gate Arrays (FPGAs) (i.e., camera feed processing) or centrally on the back-end infrastructure of the system (i.e., process satellite feed).

Due to the heterogeneity of the sensor sources, the description of the sensed information must be homogenized. Since the main idea in SWeFS is to take advantage and reuse open standards that secure the inbound interoperability, we have adopted the Open Geospatial Consortium (OGC) Sensor Observation Service (SOS) in order to provide access to sensor descriptions and observations. The SOS specification leverages the Observations and Measurements (O&M) specification to encode observations and the Sensor Model Language (SensorML) specification to encode sensor descriptions. Both of these formats are based on the Extensible Markup Language (XML). The SOS standard defines a Web-based interface (Web service) that allows querying observations, sensor metadata or representations of observed features. Further, this standard provides means to register new sensors or remove existing ones. It also defines operations to insert new sensor observations. The SOS operations follow the general pattern of other OGC Web Services and inherit or re-use, when needed, elements defined previously. For every available sensor category we developed the corresponding proxies that ensure the robust communication of the sensory infrastructure with the rest architecture. The role of

each proxy is twofold since the sensors supporting SWeFS, apart from providing their sensing capabilities, can be also externally controlled in order to optimize the capabilities of the system. This broader meaning assigned to the sensing devices is illustrated in Figure 3.

Figure 3. Sensor Entity of SWeFS

A proxy that lies upon a sensing element, on the one hand transforms/encapsulates the sensed values in SOS compliant messages which are subsequently forwarded to the MOM. On the other hand, these proxies act as controllers that translate and forward the consumed control commands and inform the rest system for the result. However, a fundamental issue is the way to process and combine the collected data streams and subsequently control the identified sensors of interest in order to reach to a meaningful decision related to the fire phenomenon. In SWeFS, the components of the PB undertake this task.

Processing Block

The building components of the PB are interconnected in a way to achieve the smart closed loop integration approach. The designed workflow is triggered by information derived from the elements of the IB. The processing task of the collected sensor data streams is assigned to the Data Fusion Module (DFM) while the Control Module (CM), the Map Comparison Module (MCM) and the Simulation Module (SM) enhance the active sensing capabilities and the DDDAS nature of SWeFS. As depicted inFigure Figure 1, an inner/smaller closed loop is shaped between these components. The DFM is the entry point for the sensor measurements in this circle while the CM is the component that broadcasts the result of the processing chain to the sensory infrastructure in the form of control commands. A description regarding each one of these modules follows.

Data Fusion Module (DFM): The DFM facilitates the integration and interpretation of different types of sensor data. In addition to the statistical advantage gained by combining same-source data (e.g., obtaining an improved estimate of a physical phenomenon via redundant observations), the use of multiple types of sensors increases the accuracy with which a quantity can be observed, interpreted and used for an event recognition in the context of SWeFS. The most fundamental mechanism of the DFM involves (i) the detection of pre-defined events, (ii) the decision or inference regarding the characteristics of an observed entity and (iii) an interpretation of the observed entity in the context of a surrounding environment and relationships to other entities.

The SWeFS sensor infrastructure provides an indication of the spatiotemporal evolution of the fire front. Such input can be highly localized (e.g., an alarm originating at a certain ground sensor) or of broader spatial scope (e.g., a sizeable ground segment of the observed terrain). The DFM processes data streams received from the available infrastructure in order to detect possible changes in their typical (no-event) distribution. Both types of input (coarse- and fine-grained) are taken into account for establishing the actual fire front (i.e., a time-invariant polygon that is approximated by the real feed; ground sensors, visual and satellite observations).

DFM architecture is partially based on the contextor's theory presented by Coutaz et. al. (2002) and leverages the SOS standard for the interoperable integration of sensor data. A typical contextor is a software abstraction that models a relation between variables of an Observed System Context which is the composition of situations as observed by the system. A contextor does not exist as an isolated entity but rather as a part of a connected directional graph, produced by connecting Data-In channels with compliant Data-Out. The core principle of the DFM design is that each contextor encapsulates the functionality provided by a specific algorithm (e.g. Bayesian Network, Cumulative Sum, Linear

Opinion Pool, etc.) or operator (e.g., minimum, maximum, average, threshold, etc.). The DFM provides the necessary middleware services which will allow contextors to acquire data, execute the encapsulated algorithms, exchange information with each other, and finally produce the desired output. From an operational perspective, the DFM can be characterized as an event based system, which can run specific fusion applications. A fusion application comprises from a directional acyclic graph (DAG) of contextors with defined external inputs and defined outputs. Each input is a data flow coming from the network (i.e., sensory infrastructure), while each output is another data flow dispatched in specific format using a specific protocol adapter. What accounts as an event is a new value produced by an input data flow, both in macroscopic and microscopic level. So, in macroscopic level, this means that a new value coming from the network (e.g., a sensor) will trigger the engine by forcing the specific contextor which receives the corresponding data flow in its Data-In channel to execute. But, also, microscopically seen, inside the DFM, each output produced by a specific contextor, flows through its Data-out channel, to its connected contextor's Data-In channel, producing a corresponding event. This sequence of events results to the output of the DFM application which can be delivered in various formats using a variety of transport protocols such as http, email, etc. Both formatters and protocol adapters are pluggable modules which means that new implementations of both can be added at any time to the engine. DFM applications are modeled using a specific xml-based language, the Application Description Language (ADL). An XML parsing subcomponent inside the DMF is responsible to simply transform the static information of a script to Fusion Engine directives, used to build the application context inside the DFM.

The definition of the detected events depends upon the specific application under consideration. In a very simple scenario, the event detection mechanism in DFM could be based on certain pre-defined thresholds for evaluating the occurrence of an event. However, the combination of multiple sensor data sources and the implementation of advanced detection and fusion algorithms could achieve satisfactory detection levels in a variety of operating conditions. The output of the DFM can be an improved estimate on an event occurrence. The aforementioned capitalize on the dual nature of the DFM in the SWeFS context. On the one hand, through the exploitation of a simple fusion application script based on thresholding operators over the available sensor streams, the DFM can operate in a *detection mode*. In this case, the localization of the incident in the monitored area is pursued. On the other hand, by taking advantage of the detection mode's outcomes and the active sensing approach adopted in SWeFS, the DFM can also operate in a *monitoring mode*. The results of this mode are continuously improved through the periodic deployment of more sophisticated and near-to-real application scripts with respect to the selected data sources that participate in the process. These scripts are created dynamically in compliance with the outcomes of the active sensing process. Through the DDDAS approach and the active sensing scheme, the information of the sensor sources that should participate in each round is constantly refined and consequently, the fusion scripts are refined as well. This results in more accurate estimations regarding the current state of the monitored fire front. The output of the DFM in SWeFS is provided in the form of ASCII Raster files that describe the estimated probability maps (probabilistic and binary) for the monitored area.

Simulation Module (SM): Due to the dynamic nature of the wind, which is the most influential fire simulation parameter, the SM was developed around the notion of *Multiple Simulation Scenarios* (MSS). Multiple wind direction and speed scenarios are generated as perturbations around an expected average scenario and executed in parallel. When combined, the MSS simulation results give rise to a map of burn probabilities that can be visualized as a fire hazard map. The capability to simulate multiple scenarios in parallel is also important from a management stand point since it allows the Tactical Commanders to pose "what if" type queries in the field and identify worst case scenarios faster than real-time. Furthermore, it greatly facilitates dynamic sensor selection (active sensing) and accurate fire course predictive modeling.

The SM is based on *fireLib* by Bevins (1996), and it stems from a previous work on the Fire Logic Animator (*FLogA)* interactive wildfire simulator by Bogdos et. al. (2013). However, instead of using

fireLib's default fire propagation algorithm (which exploits only 8 possible fire propagation directions) the SM utilizes a more flexible 16-neighbors scheme. Consequently, the fire front's propagation is less biased and the resulting propagation distortion is not noticeable under spatially heterogeneous conditions. Furthermore, the SM is designed to take advantage of CPUs with multiple processor cores in order to take advantage of parallelism and reduce execution time, i.e. the different simulation scenarios are executed in parallel by adopting a Master-Workers processing pattern.
As suggested by the interaction of the various SWeFS modules depicted in Figure , the SM is triggered each time the DFM produces estimations for the current state of an ongoing fire. Just before generating and executing the MSS, the SM consumes the up-to-date weather data from the MOM and uses the current wind parameter values to define the mean of the sampling ranges to be used for the MSS generation. Moreover, the relative air moisture value is used to calculate the 10hr dead fuel moisture content value reduction (10-H timelag) as in Vasilakos *et al*. (2007).

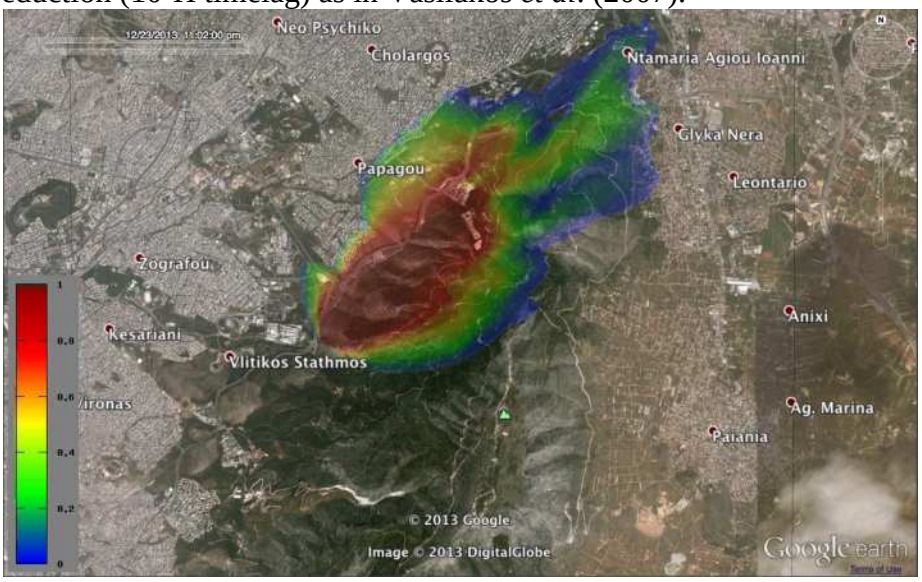

Figure 4: Visualization of a fire hazard map considering an MSS with 64 scenarios and equidistant (deterministic) parameters sampling around the expected wind direction and speed values.

The SM generates an MSS by performing deterministic or random sampling in a configurable wind speed and direction parameters range. Subsequently, the SM simulates the generated multiple scenarios as a combinatorial experiment, which means that it executes a wildfire simulation for each possible parameter values combination. The results are combined to produce KML visualization files using ground overlay images produced automatically by Gnuplot (2014) for the flame length of each scenario as well as the combined hazard map of the whole MSS. Figure 4 provides an example of a fire hazard map visualization based on a 8x8=64 scenarios MSS ignited at the northern end of the NKUA campus, in Athens. The prediction window was 2 hours while the ranges of the wind speed and direction parameters were 5m/s - 7m/s and 200º - 250º respectively (remaining constant throughout the simulation time). Moreover, equidistant (deterministic) parameters sampling was used.

Map Comparison Module (MCM): The DFM and the SM provide an estimation for the real map that describes the current state of the monitored fire front and a prediction for the phenomenon's possible evolution respectively. One of the objectives of the DDDAS approach is the continuous recalibration of the various components of a system in order to produce results as close as possible to the real situation. Hence, the actual fire front can be compared against the estimated (predicted) one derived through simulations in order to establish model accuracy metrics by taking into account the uncertainty in parts of the forest where data is not confirmatory of the real fire status. Such metrics (e.g., percent overlap between the estimated and the observed fire front) can be used for deciding on the recalibration

of the model (simulator). A refined simulation outcome will result in a refined product from the CM's procedures as well, thus, the overall quality of the produced results is improved. This important task for the realization of the DDDAS approach in SWeFS is undertaken by the MCM.
The MCM receives at each *processing round* of the closed-loop the estimated real map from the DFM along with the prediction of the SM for the phenomenon's evolution. The input from the SM is multidimensional since parallel processing is performed and several simulation scenarios are produced in every simulation step from the engine. The MCM, by taking into account the spatial characteristics of the affected area, compares every received estimated map with the real one from the DFM. To eliminate possible map alignment issues the same coordinate system is utilized for the produced probability maps from DFM and SM. The metrics provided for the calculation of the overlap percent among the maps are the Jensen-Shannon Divergence, the Pearson Correlation Coefficient, the Kullback-Leibler Divergence and the Similarity Score. From these metrics, although the simplest one, the Similarity Score seems to outperform the other ones for map comparisons with respect to calculation accuracy and processing time in SWeFS.
Through the processing circle of the MCM an evaluation of the simulation results is performed by ranking the multiple simulation results (that refer to the same time horizon) based on the achieved score. This ranking is subsequently forwarded to the SM which in turn evaluates it and recalibrates, if need be, the appropriate internal tuning parameters. Should the MCM outcomes indicate that the simulation presents large deviation from the actual evolution of the phenomenon (i.e., quite low scores in terms of coverage percent), the SM restarts the simulation procedure by considering as ignition area the currently estimated real map from the DFM.

Control Module (CM): Through the existence of the CM, the active sensing aspect is implemented. Active sensing techniques are capable of identifying the type and combination of sensors that provide the most useful measurements (e.g., because they are placed close to the observed phenomenon). The CM receives the products of the DFM and SM, i.e., actual and predicted probability maps respectively, correlates them with the deployed sensor infrastructure and the spatial characteristics of the monitored region (e.g., elevation, slope, etc.) and identifies the sensor nodes that should be controlled. The algorithm that is used as the core of this internal procedure is based on the so called Cognitive-based Adaptive Optimization (CAO) approach presented by Kosmatopoulos et. al. (2009). CAO transforms the energy efficiency and the coverage problem into an optimization one where in every processing round the goal is to optimize the sensing capabilities of the available sensor resources so to meet the objective of the monitored area's optimal coverage with respect to energy efficiency. For instance, the CM can alter the sampling frequency and/or the strength of the transmitted signal for the in-field sensors, steer the available PTZ cameras by providing a new triplet of pan, tilt and zoom control directives and transmit a new waypoint for the available UAVs. This dynamic management of the infrastructure has a positive impact on the optimal monitoring of the affected area and the energy consumption of the nodes.
The CM outcomes are equally important for the recalibration of the results derived from the fusion processing. Since forest fires is a rapidly growing phenomenon as time evolves and the output of the DFM is highly correlated with the quality of the accounted data streams, is of paramount importance to know, at each iteration of SWeFS closed-loop processing, the combination of sensor sources that can monitor the phenomenon's evolution optimally. The CM is able to identify with accuracy these sensors. This information is forwarded via the MOM to the DFM in order to recalibrate its operation by dynamically configuring and deploying timely and accurate fusion application scripts. Through this procedure is assured that the produced result of the DFM is aligned with the evolution of the fire front and one aspect of the DDDAS nature of SWeFS is materialized.

DDDAS Approach

Unsurprisingly, a lot of praise has been given to the Dynamic Data-Driven Assimilation Systems (DDDAS) concept following its introduction from Darema (2004). In the classic simulation approach the applications are using a static input dataset. An inherent disadvantage of such applications is that they are not able to adjust the model parameters in case of significant simulation drift. Conversely, the DDDAS paradigm entails the ability to receive and respond to online data and measurements, thus recalibrating the simulation and allowing for more accurate predictions. The benefits of adopting a sound DDDAS strategy are indisputable for numerous environmental applications. For example Douglas (2005) mentions that before DDDAS it was more probable for meteorologists to fail in predicting the path and the scale of storms while the Forest Services were more likely to ignite controlled burns that would eventually become proper wildfires.

SWeFS aims to not only assimilate online measurements but also utilize them to improve the quality of the monitoring process (active sensing). To do this effectively, the SM needs to provide an accurate fire evolution prediction, so as to offer valuable data for the CM to steer the sensory infrastructure effectively based on the near future fire evolution predictions. This is why it is crucial for the SM to also conform to the DDDAS principles in order to provide as accurate predictions to the CM as possible.

One important point in taking a decision to calibrate the SM is to be able to discover how much the simulation has drifted from reality, by effectively comparing the simulation predictions and the field measurements. We approached the problem of comparing the predicted and real fire maps by borrowing some ideas from the image-processing field. Specifically, we observed that a fire hazard map in the form of a burn probability distribution shares many properties with a saliency map. We experimented extensively with various map comparison metrics reported in the literature and found that the simplistic Similarity Score by Judd et. al. (2012) is the most advantageous. Specifically, when comparing two burn probability maps (in the MCM) generated by two different MSSs, this comparison metric has the following desirable attributes:

1. The returned similarity scores reflect consistently the difference in the weather parameter values between the two MSS
2. The similarity scores remain unaffected by the size of the fire fronts
3. The calculation performance for the metric meets our real time constraints

Each time the SM is triggered by the DFM, it utilizes the comparison results from the MCM to obtain the Total Similarity Value (TSV) for the simulated MSS against the estimation of the real fire map (DFM outcome) and the Scenario Similarity Value (SSV), which is an indication for the accuracy of each scenario. Our DDDAS approach for the next step is to use two predefined threshold values thresh1 and thresh2, with thresh1 > thresh2, as follows:

1. If the *TSV > thresh1* then the simulation drift is considered *insignificant* and the SM continues with the same/previous settings.
2. If thresh2 < TSV < thresh1 then the simulation drift is considered *moderate* and the SM uses the SSV of each scenario to modify its weight coefficient used to compute the burn probability distribution of the MSS. More specifically, the weight of each scenario is modified as: $w_i = \frac{SSV_i}{\sum_1^n SSV_i}$, where n is the number of simulation scenarios in the MSS. In this case the results of the individual scenarios do not change, as the MSS parameters remain unaltered. What changes is how these individual results are combined to produce the burn probability distribution of the MSS.
3. If TSV < thresh2 the simulation drift is considered *significant* and the SM adopts the wind speed and direction values of the best scenario (highest SSV) as the posterior mean wind speed and wind direction values to be used for the MSS redefinition at the next time step.

The CM consumes the updated prediction of the burn probability distribution raster file instantly and the latest fire hazard maps are updated automatically in the provided GUI.

Conclusions

In this paper we have discussed the SWeFS approach that delivers an integrated solution able to detect, monitor, predict and assist in the management of natural hazards at WUI areas. SWeFS enables several desired features of monitoring and surveillance systems, such as fusion of sensor data streams, remote sensing, forest fire simulation and closed-loop integration. The paper presents the overall system architecture describing the design approaches followed during the development phase as well as certain implementation details.
Through the flow of information within the SWeFS architecture, data assimilation is also accomplished to better observe a detected phenomenon. Consequently, SWeFS can be characterized as a DDDAS which constitutes a unique innovative approach in forest fire monitoring.
The presented sensor web based closed loop fire shielding system provides:

1. *Real-time data stream processing* for the estimation of parameters that affect the fire spreading models.
2. *Fast simulation of multiple fire scenarios* for predicting fire evolution and provisioning of dynamic (time varying) probabilistic hazard maps for a given area.
3. *Intelligent closed-loop control mechanism* acting on the basis of available measurements and estimating the most important sensors for optimized active sensing.

Future work includes the improvement of the existing sensor data fusion mechanism by implementing and integrating new data aggregation algorithms. Finally, we are planning to develop optical detection algorithms that can be deployed in the cameras located in the available UAVs targeting at the localization of a forest fire front. The latter will take into consideration data related to the current position, height and angle of the UAV.

The effectiveness of suppression resources in large fire management in the US; A Review

David Calkin[a], Hari Katuwahl[b], Michael Hand[a], and Tom Holmes[c]

Abstract
Wildfire management currently represents nearly 50 percent of the US Forest Service's total budget. In both 2012 and 2013 large fire suppression exceeded the Agency's budget allocations by over $400 million (US$). Despite the scale of this investment relatively little is understood about how suppression actions influence large wildfire spread and those conditions that ultimately lead to containment. There is considerable uncertainty in managing large wildfires including the quality of weather forecasts, complex environmental conditions, variation in the type and quality of suppression resources, and whether or not requested suppression resources will be assigned.
In this presentation we review several recent studies that attempt to understand how suppression actions influence fire progression of large wildland fires in the US. Finney et al. (2009) who established the critical importance of quiescent fire growth periods in achieving final fire containment. Holmes and Calkin (2013) used econometric analyses including Cobb-Douglas production functions and production possibility frontiers to examine the effect of different suppression resources and fire characteristics on daily reported fire containment. We extend the Holmes and Calkin (2013) analysis by focusing on geospatially delineated fire progression maps to identify how suppression resources and fire characteristics influenced the amount of fire perimeter that held on a given day. Additionally we review a small sample of large fires where field based data collection allows us to better understand the types of mission and relative efficiency and effectiveness of field based crews.
Despite these recent efforts, there remains limited understanding of suppression effectiveness. These results suggest that modelling large fire containment as a production process of fireline construction similar to traditional initial attack models is inappropriate. Improved understanding of large fire management effectiveness and efficiency will require spatially tracking individual resource assignments, activities, and tactics within the broader suite of fire management objectives and strategies.

Keywords*: wildfire management, suppression effectiveness*

Introduction

Wildfire management currently represents nearly 50 percent of the US Forest Service's (USFS) total budget. Suppression of large wildland fires represents the single largest outlay within wildfire management; currently the USFS consistently exceeds $1 billion (US) annually in large fire suppression costs alone. In both 2012 and 2013 the Agency exceeded its large fire suppression budg*et al*location by over $400 million. A majority of wildfire ignitions (96-98 percent) are captured during initial attack, or the first burning period with only a small percentage exceeding initial attack capability. Although these escaped fires constitute a small portion of the total number of fires, they account for the majority of the suppression expenditures of all wildfire management activities (Calkin *et al*. 2005). Despite the scale of the investment in large wildfire suppression, relatively little is understood about how suppression actions influence large wildfire spread and those conditions that ultimately lead to containment (Finney *et al*., 2009). Wildfire containment under initial attack (IA) has typically been

modelled by evaluating the elliptical rate of spread of an ignition under identified fuel and weather conditions compared with the productive capacity and arrival time of IA resources (see for example Fried and Fried, 1996). However, the large fire environment presents additional complexity and it has not been demonstrated if the IA containment approach is relevant to large wildfire suppression.

There is considerable uncertainty in managing large wildfires including the quality of weather forecasts, complex environmental conditions, variation in the type and quality of suppression resources, and whether or not requested suppression resources will be assigned (Thompson and Calkin, 2011). Additionally, many resources are engaged in non-line building activities such as point protection, contingency line development and mop-up. Further, given that the wildfire escaped IA it is likely that the characteristics of wildfire growth are such that line building efforts may not be feasible or effective.

Data necessary to understand suppression effectiveness within the US can be difficult to obtain. Some recent studies have relied on primary reporting systems such as the ICS-209 Situation report. However, these data do not provide spatial characteristics of the fire environment and rely on self-reporting by the incident team responsible for managing the events. In particular some of the most relevant data for suppression modelling contained within the ICS 209; specifically percentage of the wildfire contained, growth potential, and reported values at risk are subjective and may not be accurately reported (Holmes and Calkin, 2013). Despite these challenges several authors have examined the 209 data to model suppression effectiveness

Finney *et al* (2009) modelled the probability that on a given day a large fire would be declared fully contained by examining wildfire suppression resource assignment, daily fire growth, fuel model and other reported data within the 209 reports. The most significant finding to achieving wildfire containment was the critical importance of quiescent periods during the fire. That is, the most important factors in determining if a wildfire was fully contained were the number of low growth fire days and the number of previous intervals of low growth. Containment probability was negatively related to the presence of timber fuel types. No significant relationship was found between likelihood of containment and fire size or number of personnel assigned.

Holmes and Calkin (2013) utilized similar data from the ICS 209 to examine the relative efficiency of suppression resources by comparing published resource line building production rates published by Broyles (2011) with daily line built estimated from reported fire size and percentage containment. The results indicated that the actual production rates of suppression resources on a set of large wildland fires in 2009 were between 14 to 93% of the reported standard production rates. Further, the econometric models indicated that the marginal productivity of all inputs increased as total resources assigned increased. This result may indicate economies of scale in fire suppression or, alternatively, that fire managers learn how resources may be deployed more productively over the course of a fire.

In this paper we evaluate recent efforts to better understand the effectiveness of suppression resources in containing large fires. Given results from recent and current studies we identify potential opportunities for future research efforts that will allow us to better understand the implications of the existing research and improve the effectiveness of future large wildfire management.

2. Methods

We examine fireline productivity and suppression effectiveness for large wildland fire suppression activities as fire progresses using geospatial perimeter data. We estimate suppression effectiveness using stochastic frontier analysis. We modelled wildfire containment as a production process where crews are resources are assigned to build fireline until the amount of built fireline along the final fire perimeter equals the current fire perimeter. Production of controlled fireline on a particular fire day is the final output of the daily production operation. A mixture of resources are engaged in a large wildland fire suppression operation, and the production of controlled fireline depends on combination

of these major inputs (e.g. crews, dozer, engines, helicopter and air tanker). The ability of a production unit to transform inputs into corresponding outputs is affected not only by the combination of major inputs but also by exogenous environmental factors. We include these weather and landscape related variables on the right hand side of the frontier production function as the inefficiency effects component of our model to capture effect of these characteristics on productivity and suppression effectiveness.

Results

The coefficient of all suppression resource input variables are significant and as of the expected direction of a priori assumptions with the exception of a negative and significant coefficient for ground crew resources. That is the presence of additional ground crews results in a reduction in held fireline for that day. Estimates from the inefficiency effect model provide the direction of the influence of the corresponding variables to efficiency. However, these coefficients do not provide magnitude of the effect and cannot be interpreted reasonably.
Results from the marginal effects of inefficiency model indicate that efficiency increases if firelines are built along the natural break see table 1. However, marginal effects are fairly small. Previous fires seem to play a significant role in increasing efficiency of controllable fireline production. Again, marginal effects are fairly small. Relative day seems to be one of the strongest factors that influence efficiency. Every one day increase fire days increases the efficiency by about 7 percentage points suggesting that contained fireline increases over time possibly due to learning how best to engage the fire with improved suppression strategies and tactics. Efficiency gain is highest on those fires where full suppression is identified as the preferred strategy.

Table 1. Marginal Effect of specified variables on daily fireline produced.

Variable	Marginal Effect
max_gust_	0.04556
max_rh_lag	-0.05212
timber	1.021
rivers	0.1074
roads	0.01456
full_suppress	2.646
previous _fire	0.07543
relative_days	7.151

Most interesting, our results indicated that the number of assigned crews is not significantly related to the amount of permanently controlled fireline. This is most likely related to our definition of the objective of suppression efforts. Our definition of the suppression objective is to produce controlled fireline on a given day that ultimately is along the final fire perimeter. It should be noted that it does not include any fireline that may have been produced, but ultimately burned over, nor any built fireline such as contingency lines that never engage the fire. Further, on many fires strategies may include significant effort on burn out operations. In these circumstance significant resource effort is assigned to construct indirect line over several days that is ultimately burned out. This results in all of the effects of the effort being recognized on a single operational day when the burnout was conducted. Additionally, on many fires significant suppression effort is assigned to assure that controlled fireline along already burned areas does not reignite by “mopping up” any burning material within the fire’s interior.

In a related effort we collected field based data for a small set of individual large fires that provide the ability to link the specific assignment of all ground suppression crews assigned to the fire. Results from this small sample of large fires demonstrate that only 22 percent of all ground crew assignments were related to direct line building missions whereas approximately 60 percent of all assignments were related to indirect line building, holding, or mopping up a fire.

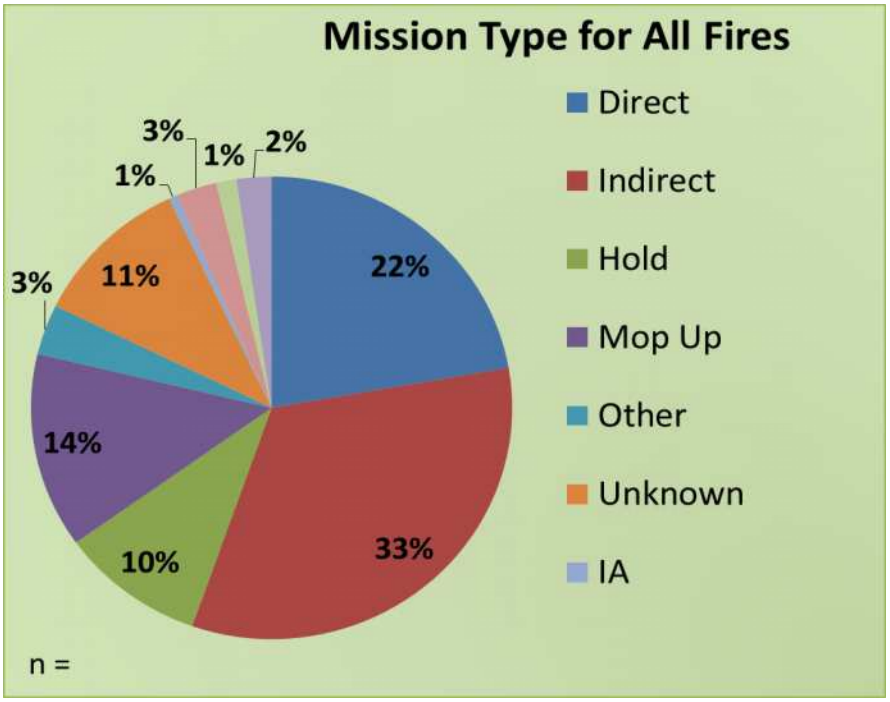

Figure 1. Ground crew mission type for 5 large US Forest Service Fires

The fire environment is the most important factor that can determine the success or failure of suppression effort. Obviously, fire managers have no control over topographic or weather elements. There could be several other variables that influence fire behaviour and efficiency of fireline production but are not included in our analysis. With these caveats in mind, our results suggest that production of controllable fire line is more efficient if they are built along the natural lines such as rivers and roads. However, these effects are only marginally significant and fairly small. Similarly, if there are areas that were burnt by previous fires, it is more efficient to construct the controllable fireline. Thus, efficiency analysis provides useful information in that it identifies the circumstances under which the suppression effort (as defined in this analysis) is more efficient

Discussion

These results collectively call for a re-evaluation of how we model the effectiveness of wildfire suppression actions and the productivity of individual resource categories assigned to large wildland fires. Uncertainty around fire progression, weather, and individual resource effectiveness make developing wildfire suppression strategies extremely challenging. Improving our understanding of how resources contribute to reducing wildfire related losses is critical to improving the safety, effectiveness, and efficiency of large wildfire management.

Abstract
The ODS3F project (funded in the framework of the EC Civil Protection Financial Instrument) is devoted to the development of a common understanding of the capabilities of vision (optical or thermal) and detection systems on which a fire remote detection network can be based.
This paper illustrates the project results.

Keywords*: camera, fire, performances, comparison*

Introduction

The ODS3F project (funded in the framework of the EC Civil Protection Financial Instrument) is devoted to the development of a common understanding of the capabilities of vision (optical or thermal) and detection systems on which a fire remote detection network can be based. The main objective of such project is the technical assessment and operational comparison between remote visual systems devoted to monitor wooded areas or areas of particular environmental, touristic and/or cultural interest. In particular, apart from the definition of an optimal way to obtain the information needed to detect a fire at the early stage, the project aims at evaluating the possibility of exploiting such information for simulating the fire propagation behavior. Furthermore, the project has the objective to promote the cooperation in spreading and sharing objectively recognized successful practices in reducing the incidence of forest fires or improving the reaction time allowing an enhanced distribution of the human and means resources on the ground
The project originates from the evidence that several surveillance systems devoted to monitor vegetated areas are available in Europe. In particular, the activity of the project relies on the availability of a system based on visible cameras operated in Italy, France and Greece and a system based on thermal cameras operated in Spain. Therefore, this project aims at: - evaluating, through an agreed evaluation scheme, the performances of the already available monitoring systems based on visible or thermal camera already available in the project partners countries; - comparing the results taking into account the different characteristics of the monitored area and the observation system; - assessing the possibility of complementing the monitoring network with a system capable to simulate the fire behaviour providing the most probable, time dependent, propagation conditions by taking into account the meteorological conditions, the orography and fuel (vegetation) type and status; - defining agreed criteria capable to guide the decision about the adoption of situation reports devices based upon remote observation system, in terms of convenience and/or basic characteristics (visible or thermal camera).
The paper is devoted to illustrate the project results.

Methods

The ODS3F project contemplates two levels of analysis:
- one devoted to evaluate the performances of the camera based surveillance systems in terms of omission and/or commission errors by comparing the events detected by such system with the events reported by other sources (watchtowers, satellite sensors, fire brigade or forest corps reports);
- the second one devoted to define the basic elements to be taken into account for a correct comparative evaluation of the different systems performances.

The first level of analysis (system performances) has been addressed by comparing the alarms (omission errors) provided by the system with the events detected by satellite systems (MODIS, SEVIRI) or reported by Forest Corps or Fire Brigades. Also the number of false alarms (commission errors) is taken into account.
The comparison among systems has been carried out taking into account:
- the land characteristics (as topography, vegetation type),
- main weather conditions in which each system operates,
- the landscape characteristics that could affect the contrast approach.

We assume that an analysis aimed at characterizing the ground/weather/contrast of each area of interest could be carried out, with more or less success depending mainly on the availability of accurate weather data.

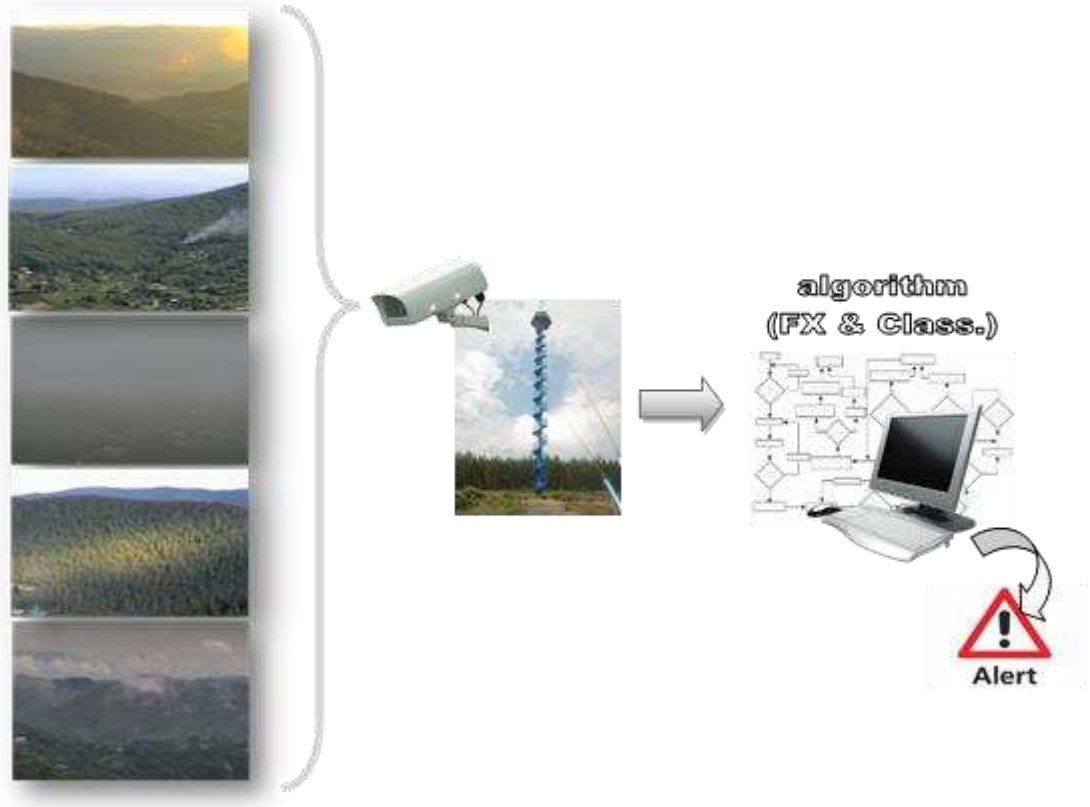

Figure 1. Fire monitoring/detection system.

Furthermore, we proceed by introducing an analysis of the algorithms on which the fire detection is based. Considering an outline of a monitoring/detection system architecture (Fig.1), beyond the above mentioned inherent complexity related to a landscape characterization due to its high dynamism, and leaving out a technical characterization of the cameras installed within the consortium, we intend to address the problem of how each system analyzes the information acquired by the cameras.

Smoke detection and feature extraction processing is a topic developed in many studies, focusing on different approaches (as wavelet decompositions, histogram-based smoke segmentations, colour space transformations, multi-temporal differences, area growth variable and smoke growth rate, spatial characteristics of smoke column, fractal self-similarity properties, RGB space thresholds, texture analysis with gray level co-occurrence matrix, irregular boundaries and background subtraction, neural network and support vector machine classifications).
Then we intend to give as an input in each system an imagery dataset including a number of different context situations (illumination, sunrises and sunsets, foggy and other extreme weather conditions, etc.) in order to evaluate the performance of each classification algorithm in several contrast circumstances.

Results

This paragraph is devoted to describe more in detail the results of the camera systems performances analysis (Figure 2 and Figure 3) and the strategy adopted for comparing the different systems in a way that will take into account the different conditions in which such systems are operating.

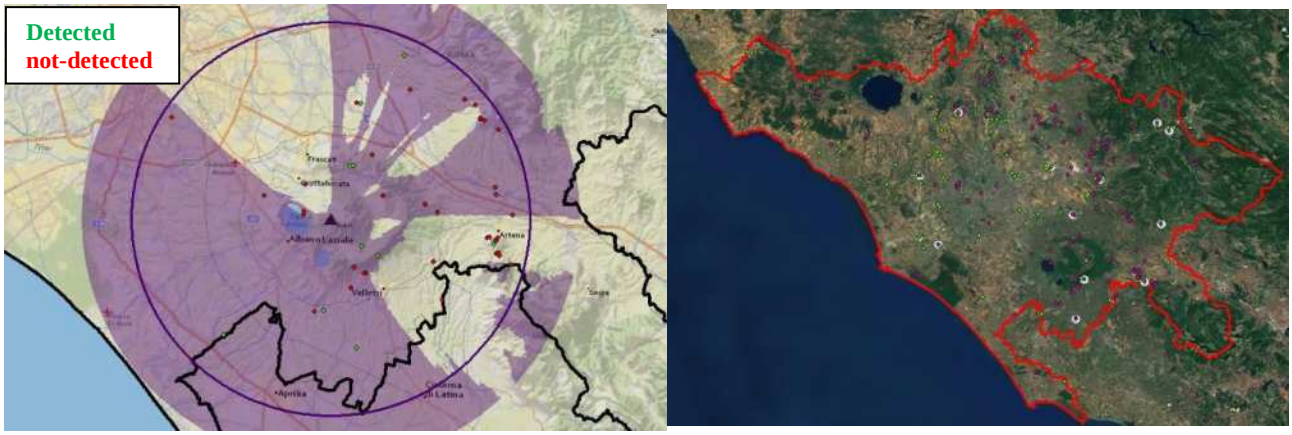

Figure 2. (left) CICLOPE system (Province of Rome) performances analysis. Comparison between camera system reported events (a single camera has been considered) and those provided by Italian Forest Corps, the camera visibility is shown in violet, the fires not detected by CICLOPE are given in red whereas those detected are shown in green. (right) Comparison between Forest Corps events (violet) and MODIS sensor based hot spot (green), the coincident events are highlighted with a cyan circle for the whole Province of Rome.

Figure 2 refers to the system available in the Lazio region (Italy) based on visible camera. Regarding the system based on thermal cameras operating in the Castilla y Leon region (Spain), some results of the analysis of the performances of the detection system are shown in Figure 3. The system is operational since 2006, even if, the number of cameras has increased with time. Figure 3 shows the increasing trend of the effectiveness of the system, reaching an average efficiency of 32%, from the date (2006) of commissioning to 2013.
Table 1 shows, more in details the results concerning the years 2012 and 2013. The year 2012 had a number of fires over the average of the decade. But, only 24 of them exceeded one hectare of burned area. However, to evaluate the full performance of the detection systems in 2012, all the occurred fires were considered, even in farmland.
2013 was one of the best years of the last decade in terms of the number of fires and burned surface in Soria province. 40% fewer fires than the average of the decade. This low incidence of fire in 2013 not facilitates to test the efficiency of the cameras and be able to provide data representative of actual performance. So we also considered all the occurred fires.

These data indicate an effectiveness in **viewed area** of **26,9%** and an effectiveness in all detection range (8km buffer) of 16,3% .

Table 1. Comparison of the surveillance system performances for years 2012 and 2013

	2012	2013
Nº Total fires in the year throughout the province	**207**	**76**
Forest fires	**156**	**47**
Fires between June and October	**110**	**67**
Fires in detection buffer (all the year)	**46**	**20**
Fires in detection buffer and in period of detection	**27**	**16**
Fires in viewed area	**28**	**10**
Fires in viewed area and in period of detection	**17**	**9**
Fires Detected	**4**	**3**
Monitored Fires	**35**	**10**

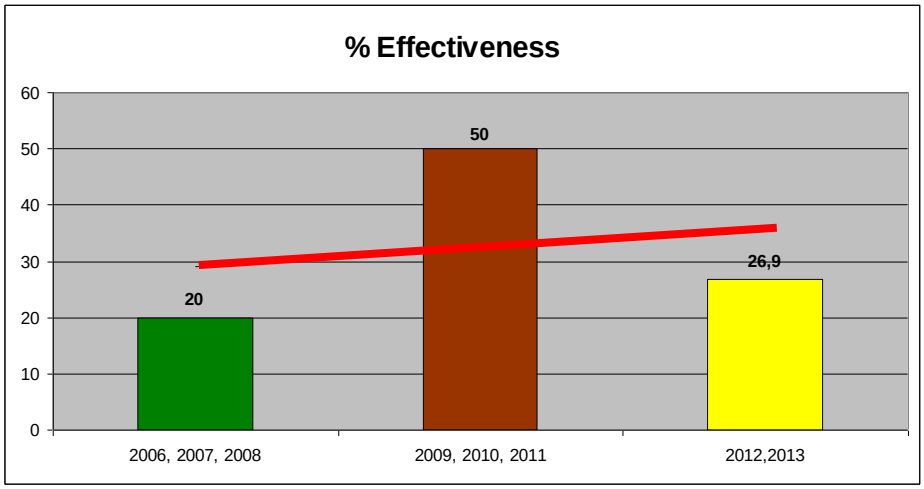

Figure 3. Trend of the effectiveness of the thermal system in Castilla y Leon.

The main causes of this, still low efficiency are:

- A high number of systems failures.
- Short operating time during the year.
- Low rotation speed of some systems.
- Bad calibration for fire detection under adult trees.
- High occurrence of small fire and fast extinction.
- Low visual coverage.
- Absence of qualified personnel throughout all the operation time.

From such analysis we come out with the idea that, besides trying to correct the technical failures and extend the system operating time during the year, it will be necessary to make changes in the operations protocol and mostly important to proceed with a new **calibration of the cameras.**

With reference to the definition of the parameters characterizing the operational 'environment' of the cameras we have identified:

- **terrain characteristics**. The topography of the area monitored by cameras can be characterized by introducing the:

- TPI (topographic Position Index) that gives an estimate of the landform type (Figure 4);

- Aspect, that identifies the downslope direction of the maximum rate of change in value from each cell to its neighbors (Figure 5 left);
- Illumination, which put into evidence different hillshades depending on different hours of the day, providing relative measures of solar illumination (Figure 5 right), which potentially define contrast values with previous Aspect direction;
- Binary Viewshed analysis, which gives the possibility to quantify the amount of covered area seen at surface level, especially useful for thermal cameras (Figure 6 left) and Minimum Smoke Height maps (Figure 6 right), which evidence the Minimum Smoke Height that a smoke column need to reach in order to be seen by the camera.

- **weather conditions** capable to produce fog that can impact the detection capabilities of the system.
  - The frequency of fog conditions can be evaluated introducing the FSI (Fog. Stability Index) based on the knowledge of meteorological data (Figure 7 left);
  - The impact on visibility can be approximated from FSI values by a comprehensive statistical analysis (Figure 7 right).

- **land cover/fuel type**. The vegetation type and status (dryness), potentially, define the amount and 'color' of the smoke, that should be taken into account for detection.

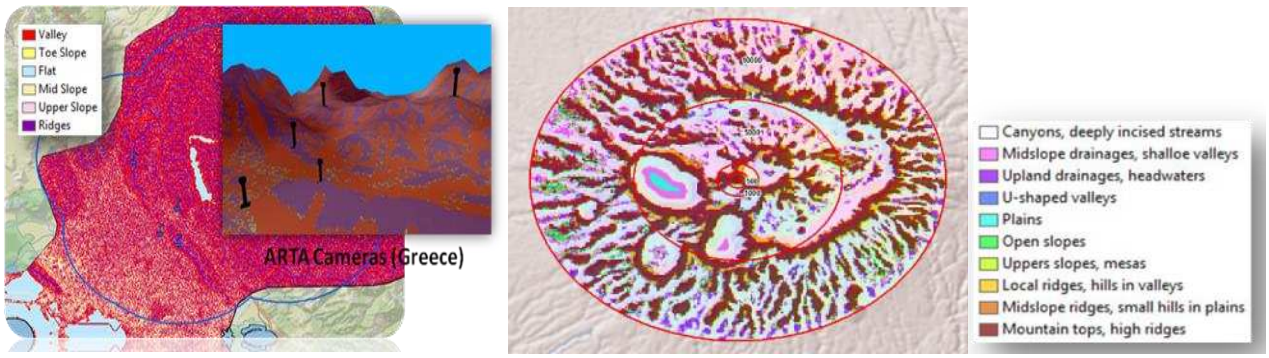

Figure 4. Topographic analysis of the Greek's system in Arta region (right), Provence Region (right)

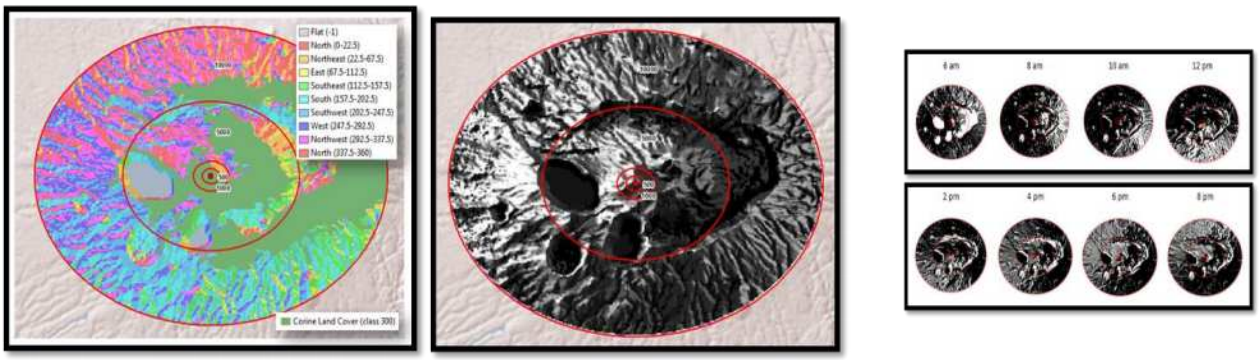

Figure 5. Aspect (left) & Illuminations products (right)

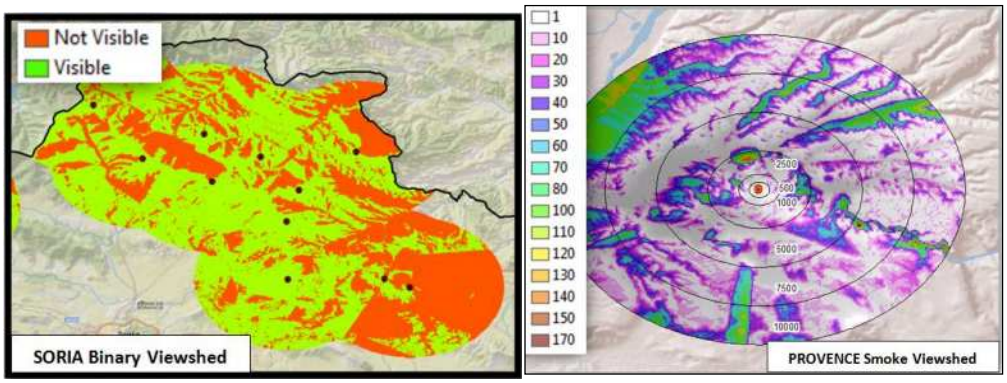

Figure 6. Example of Binary Viewshed analysis of Soria (left), and Minimum Smoke Heights maps of Provence (right).

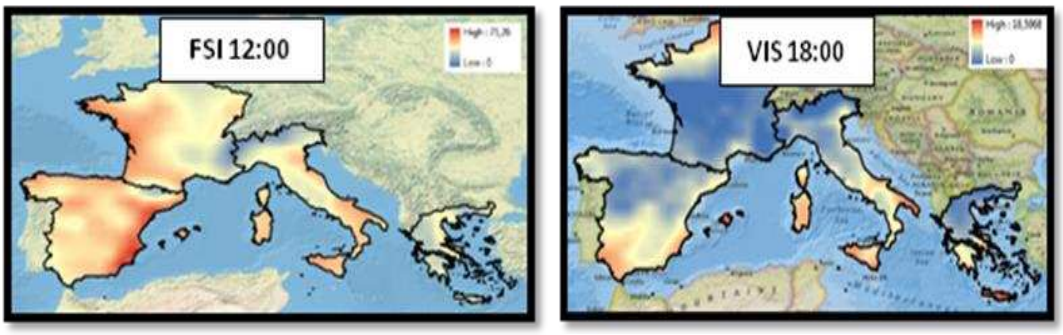

Figure 7. Examples of assessment of the FSI (left) and the visibility (right) for ODS3F countries.

From the different parameters and classes extracted and described above the potential weight that each parameter has can be measured to better understand principal omission and commission errors, and in a further work the potential influences of the territory on each fire monitoring system (Figure 8).

If from a side, as explained above, we are trying to define the 'environmental' parameters which can affect the effectiveness of the camera based surveillance system, on the other side, for comparing the different systems, it is also necessary to set certain common criteria related to the events analyzed.
In fact, during the summer 2014 a campaign covering the summer season will be carried. During such campaign, for each alarm provided by the fire detection systems under study, a template containing a minimum set of variables that could vary according to the detection type systems (heat or smoke) opportunely identified, will be filled:

- Type of detection: thermal or smoke, Kind of sensor and algorithm used.
- Detection range: maximum distance that can detect a fire. (radius).
- Nº Forest Fires in detection range: Official data of the fires that have occurred in the detection range of each system along the period of study.
- Fire forest in detection range and in operational time: Official data of the fires that have occurred in the detection range of each system and in its working time.
- Fire forest in detection range, operational time and in viewed area: Official data from fires that should have been detected by the system
- Fire Forest detected: Number of automatic real detections of fire
- Fire forest Monitoring: Number of fires not detected by the system but monitored
- % Effectiveness of detection: fires detected divided between those who should have detected

Other variables taken into account are:

Operability:

- Work time day / year: how many days the systems work during the year.
- Work time hour / day: how many hours the systems works during the day.

False Alarms:

- Type 1 (Technical): generated by the system when there is some kind of technical failure.
- Type 2 (Natural): are originated by natural causes, such as sunrise and sunset, reflections, clouds, etc.
- Type 3 (Realistic): any other cause giving rise to a hot spot or a column of smoke but no actual case of a wildfire. Such equipment, barbecue, fireplaces, agricultural practices.

Other:

- Installation cost: The cost of systems, excluding tower infrastructure.
- Maintenance cost: cost of commissioning, calibration and annual maintenance (€ / year / system).
- Lifetime of each system: estimated duration that each system can have with correct operation.

Product	Class 1	Class 2	Class 3	Class 4	Class 5	Class 6

Conclusions

The ODS3F project objectives originate from the circumstance that even if the systems based on (visible and thermal) cameras devoted to monitor/detect fires are spreading all over Europe a comprehensive study, of such systems and their limits compared with the environment where they operate is not available yet.
Through the comparisons of different systems ODS3F aims at defining an optimized system, a standardized set of information, a common method of using the situational reports for enhancing the correct, effective and efficient utilization of the available data in facing emergencies (as wildfires are) and in reducing their consequences. Finally, a guidelines document describing the elements to be taken into account for selecting the most suitable surveillance system for monitoring, protecting a given area of interest and for optimizing the exploitation of the produced information will be issued.

Thematic division and tactical analysis of the UAS application supporting forest fire management

Agoston Restas

National University of Public Service, Budapest, Hungary, Restas.Agoston@uni-nke.hu

Abstract
Introduction: This paper describes many initiatives and shows also practical examples which have happened using Unmanned Aerial Systems to support fire managers in different ways. Since the operation of manned aircraft at forest fires is usually expensive, in many cases managers miss the aerial activity even for reconnaissance however that would be required for the effective intervention. Today more and more experts say Unmanned Aerial Systems can give real alternatives for aerial reconnaissance even if this application is far from manager's mentality yet. Methods: Author used thematic division of Unmanned Aerial Systems applications; it is based on two key elements, one of them is the time flow of fighting forest fires, the other is its tactical requirements. Research used mainly author's own experiences in this field, accompanied by function analysis, practical experiments, economic analysis and also expert estimation. Results and discussion: Logically Unmanned Aerial Systems can be used before fire for hot spot detection, before starting the intervention for fire reconnaissance, during the intervention for intervention monitoring and after suppression for post fire monitoring. The method of prescribed fire can also be in the focus of Unmanned Aerial Systems use as a special application for fire prevention.

***Keywords**: Unmanned Aerial Systems (UAS), tactical analysis, forest fire management, fire detection, fire monitoring, prescribed fire*

Introduction

The operation of manned aircraft at forest fires is usually expensive, therefore in many cases managers miss the aerial activity even for reconnaissance or supporting decision making, even if that would be required for the effective intervention. Today's experiences say Unmanned Aerial Systems[1] (UAS) can give real alternatives of manned aircraft's operation not just for aerial reconnaissance but even other activities. This paper describes many initiatives and shows also practical examples which have happened using UAS to support fire managers in different ways.
UAS activities regarding forest fire is not new. We can reel off activities using UAS to fight against forest fire in the United States (Ambrosia and Hinkley, 2009), in Croatia (Hucaljuk, 2004; Restas, 2013), in Spain (Ollero, 2004; Pastor, 2008). In Hungary the Szendro Fire Department carried out many activities helping fire management using UAS (Restas, 2004).
This paper gives an approach for thematic division of using UAS at forest fires; it is based on the tactical differences. Logically UAS can be used *before fire* for hot spot detection, *during the intervention* helping fire management and *after suppression* for post fire monitoring. The method of prescribed fire can be also in the focus of UAS use as a *special application* for fire prevention. (Restas, 2011)
The paper uses the chronological flow of fighting forest fire for thematic divisions, although the last part of this paper, the *UAS generated prescribed fire* can be disputed; it could have been also the first part. As a latest development of this application author found it as the latest place for the best.

[1] There are other abreviations like UAV (Unmanned Aerial Vehicle) or RPAS (Remotely Piloted Aircraft Systems) meaning the similar technology as UAS. „Drone" is also used for this technology.

Aerial patrol for hot spot detection

Aerial patrol with manned aircraft is a commonly used procedure for detecting hot spot. Many countries such as Australia, Canada, France, Russia, Spain, and United States regularly use this procedure while others such as Germany and Poland used to apply it but today not.

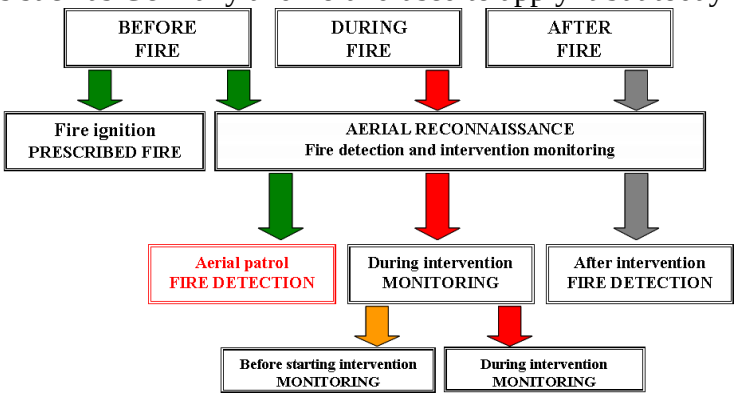

Figure 1. Aerial patrol for hot spot detection in the structure of thematic division of UAS use

Detecting hot spots by aerials earlier than reporting it by civilians obviously helps fire managers limit the damages fires cause. Unfortunately, the main reason why this method is not always used is the huge costs of aerials. If the procedure made by UAS is cheaper than the traditional one (manned aircraft), it means that the option of UAS use is the better solution. Naturally this case assumes the similar professional efficiency of different methods.

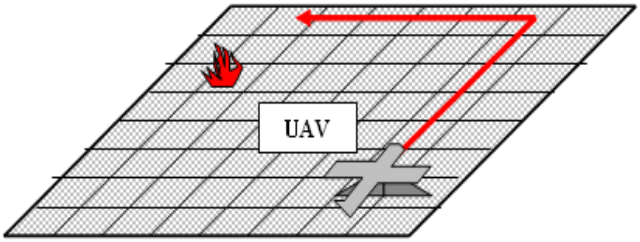

Figure 2. Planning UAS mission for hot spot detection

During this task UAS makes a patrol following the pre-programmed flight path and based on the real time video supply the staff in the control station can detect and check any hot spots. In case of real danger staff reports it to the fire service.

Figure 3. UAS mission in the United States. Ikhana strategic UAS

Figure 4. UAS based hot spot detections: in Croatia (2011) and the first one in Hungary (2004)

No doubt, aerial patrol by UAS can detect hot spots very quickly and it is able to give the first fire report to fire brigades. It can reduce the time of first attack but study says that based on economic calculations, this application can be effective just under special conditions such as at extremely high Fire Weather Index and at geographically high articulated area. Detailed criteria must be developed in the future for optimizing the effectiveness of UAS applications.
For effective hot spot detection different type of UAS can be used. Depending on the area staff responsible for both strategic and operational UAS can be effective tool for the early hot spot detection. In the United States the high altitude long endurance (HALE) Ikhana was used for both early detection and intervention monitoring. In Croatia and Hungary tactical UAS were also used for hot spot detection.

Aerial reconnaissance before starting intervention

When starting intervention the main problem is the lack of objective information regarding the affected area, fire intensity, etc. (Bleszity, 1989). Operational used UAS could help in this case; below just a few minutes it can be ready for launch and 2-3 minutes later it transmits the real time pictures about the fire and their circumstances.

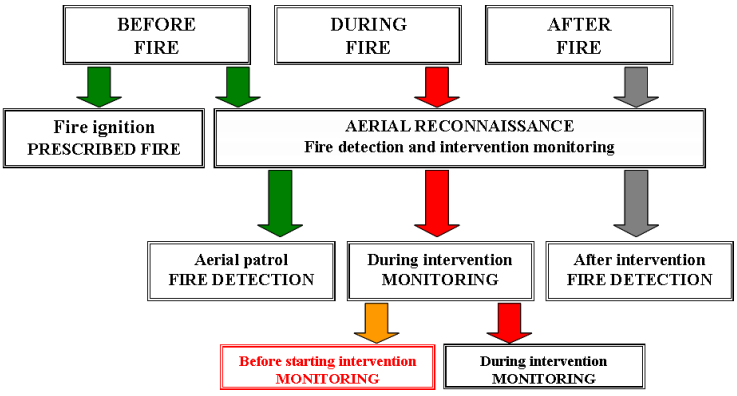

Figure 5. Aerial reconnaissance before starting intervention in the structure of thematic division of UAS use

For aerial patrol aimed at hot spot detection the reasonable type of UAS belongs to the category of high altitude, long endurance or medium altitude long endurance (HALE, MALE) band. In this case a special UAS service can also be used effectively. In case of aerial reconnaissance before starting

intervention the situation is totally different. Fire managers require some basic information about fires immediately and for this task a highly qualified UAS service is not applicable.
In case of aerial reconnaissance the quick access to the information is much more important than the quality (e.g. resolution of the video, photos) of that. Therefore the simple but *immediately ready for start* UAS is required for this type of task. Capability of this type of UAS is limited. Fire manager needs objective information about the fire characteristic, fire intensity, speed of spreading fire, smoke emission, wind direction, etc. but very quickly. For this task a hand launch, by electric engine powered UAS is considered the best solution.

Figure 6. Launch of fix wing UAS (Fenix) for fire reconnaissance before starting intervention. Rotary wings UAS (Bee) hovering at forest fire. Source: 6DOF (Croatia) and R-Fire Ltd. (Hungary)

The simple criterion for economic effectiveness is that all costs of UAS use must remain below the value of the forest saved by this process.

Figure 7. Differences between fire fronts can be seen face to face or from the air after arriving. UAS supported intervention in Hungary (DRAVIS II, 2011)

Aerial reconnaissance during intervention

During intervention, where aerial reconnaissance is required but manned aircraft is above price, UAS could give also a cost effective solution. If the commander of fire-fighting operations is at the scene, he is too close to the fire to be able to manage it along with its environment. Quite literally, he cannot see the forest for the trees! As the extinction of forest fires is a protracted process in time, and since during that time the fire will continue to spread, the ability to manage a fire together with its environment is an indispensable precondition for the efficient extinguishing of a fire.
Manned aircraft is used on several occasions to assist with the reconnaissance of forest fires. However, these fires cover very large areas and putting them out takes several days, and the fire-fighting action

is managed at higher levels of the organisation, usually at executive staff level. These experiences indicate that air reconnaissance is effective.

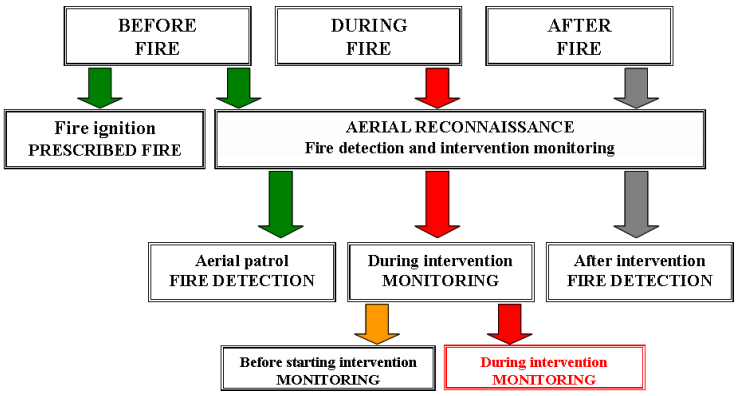

Figure 8. Aerial monitoring during intervention in the structure of thematic division of UAS use

During intervention the UAS use can be very effective because obtaining an overview of several hundred or even thousand hectares of forest allows intervention measures to be co-ordinated. Without air reconnaissance, co-ordination of measures can only be based on the information circulating between the commanders of individual units at various locations. But the assessment of the scope of their individual situations by commanders located at various sites may be completely subjective and not made in relation to the other sites. Air reconnaissance helps to eliminate subjectivity in such judgements and to rank the individual sites in relation to the others.

Figure 9. Typical fire forms: spot fire and linear fire spread. Photos made by UAS in Croatia (2011)

At huge fires using manned aircraft for bombing water or just to support the reconnaissance with information is a normal procedure. On the other hand, small fires don't require aerial support; these are managed by traditional equipment. Between these extremes, logically, there is a sector, where fire size is larger than management could suppress successfully just with traditional equipment, but not large enough to ask manned aircraft for help. In this case the manned aircraft is economically, obviously, not effective, but a solution such as UAS - which is cheaper than the use of manned aircraft – can already be.

If the UAS based aerial reconnaissance satisfies the minimum criteria of the professional requirements of the effective reconnaissance, it means that this solution can be even economically effective.

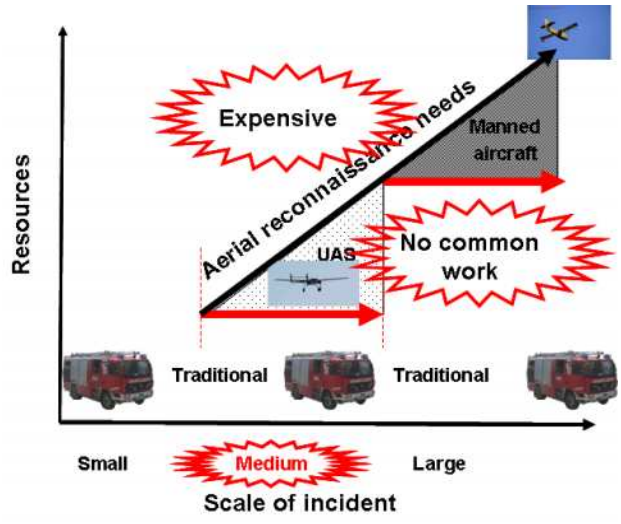

Figure 10. Efficiency of UAS application depends on fire size

We can demonstrate the effectiveness of UAS based aerial reconnaissance also by the *damage – time function.* This kind of applications is not just reducing the damages caused by the fire but even reducing the time of the intervention. Shorter intervention is reducing also the risk posed to citizens caused by the lack of fire fighters who are ready for alarm in case of accident, house fire, etc. Unfortunately this kind of risk is usually assessed much lower than the reality requires.

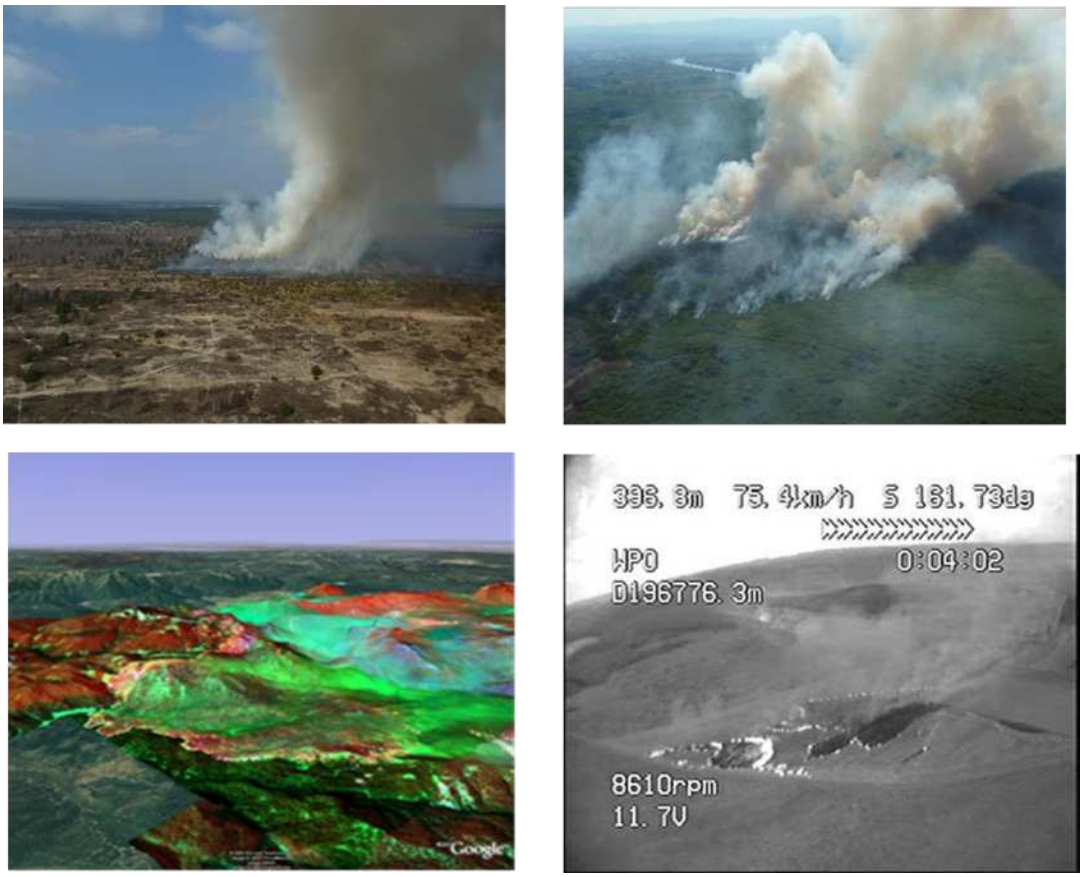

Figure 11. Intervention supported by UAS: forest fires in coloured (Bee, Germany, 2010, and Phoenix, Croatia, 2011), artificial coloured (Ikhana, US, 2007) and black and white photos (Hungary, 2004)

Post-fire monitoring

After suppressions, many times, area surveillance is required to prevent starting fire again by remained cinder. UAS equipped with IR camera can detect the critical points easily and with a small team can manage hot spots while let fire fighters leave the area.

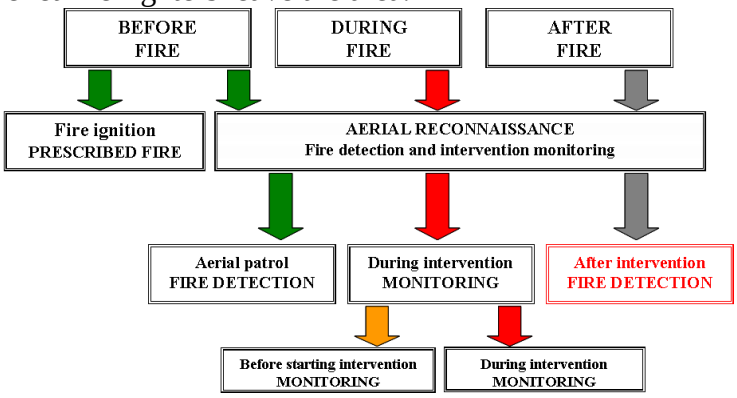

Figure 12. Post-fire monitoring in the structure of thematic division of UAS use

Burnt area monitoring besides the tactically advantages gives also other options. Since many cases UAS use is optimal when it is in the hand of fire service, the post fire monitoring is ideal for training recruit. After the intervention, there is no stress regarding success, no pressure from media or residents. But post fire monitoring is a real task while its environment means a reality. It means hot spots, remained cinder what also requires responsible management.

Figure 13. Thermo cam is installed on UAS board and able to detect the remained cinder

Planning the post-fire monitoring UAS must fly around the extinguished fire front instead of monitoring the whole area (hot spot detection). For this task a simple but with IR equipped UAS is required.

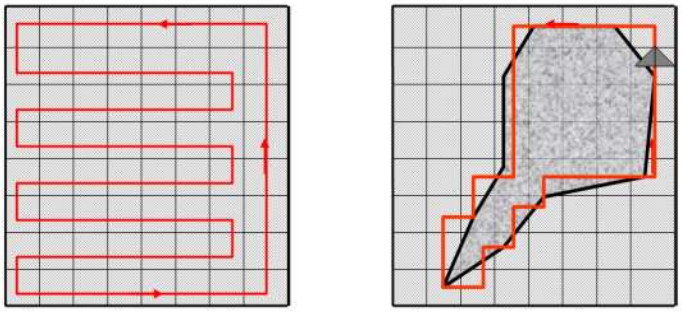

Figure 14. Differences between planning UAS mission for early fire detection and remained cinder detection

Prescribed fire – made by UAS

There are other initiatives such as making prescribed fires with using medium size UAS. The special equipment filled with fire eggs or pastilles weighs less than the payload capacity of UAS. It means UAS can provide also this task, giving more possibilities for managers using prescribed fires method with limited costs.

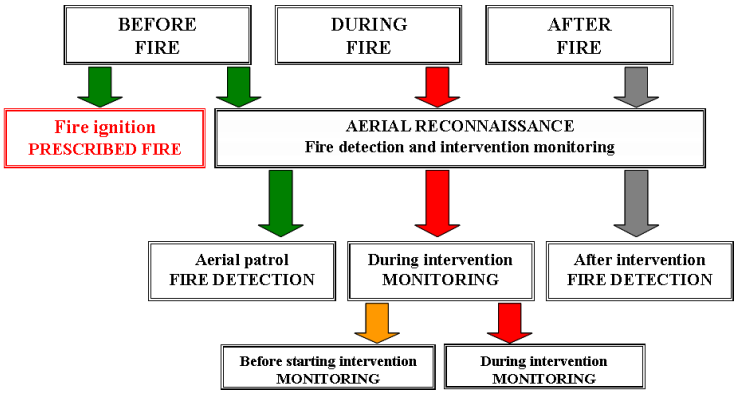

Figure 15. UAS generated prescribed fire in the structure of thematic division of UAS use

No doubt, prescribed fire is a very effective management tool for avoiding the serious fires in critical seasons. In this process fire managers burn areas with controlled fire reducing the fuel load of the territories. Less fuel load means less fire intensity and damage. There are different ways from hand tools (drip torch) till aerial means making this process.
For the sake of better efficiency today managers can use special equipment for this task such as fire eggs and pastilles. These equipment weighs about 20 kg. This method means that a light helicopter carries these 20 kg weight machines for dropping the eggs or pastilles. Since both fix wing and rotary wings UAS are able to carry this machine, we can supply this task also with UAS.
Professionally there is no difference in effectiveness between manned aircraft or UAS. There are other tactical advantages of using UAS for generating controlled fire. UAS can fly not just in day mission but also at night widening the term when control fire can be made. It means the possibilities of UAS generated fire is more than just giving an alternative solution.

Figure 16. Example for the special equipment generating prescribed fire and a real application

As usual we can demonstrate the effectiveness of UAS generated control fire also by the damage – time function. Since the prescribed fire reduced the fuel load in case of not intended fire the fire intensity will remain at low level. Low level fire intensity means reduced fire spread, more time for intervention and limited severity.

Figure 17. Method of UAS generated prescribed fire and an example of UAS ready for doing it

7. Results

Based on the above examples UAS can be a very effective tool in the hand of fire managers. After launch the UAS can supply real time data continuously, therefore within in the first few minutes it can provide effective support for the decisions of the commander. One such element of decision support is that even before the UAS returns, it will be possible to establish the extent of the burning area and to request the assistance of further units. This will save a significant amount of time.
Another example of decision support: if commanders are able to manage the entire area in a complex way, it may be the case that protecting the area where the fire is currently most intense is the most important task. It is possible that our forces need to be concentrated in a location other than that furnished by the initial assessment.
While firefighting is in progress, the fire continues to spread in the areas where no countermeasures are taken, and indeed it may meet natural obstacles or barriers. A river, a wider road or glade may stop the fire as a natural barrier, so beginning fire-fighting measures at a distance of 100 or 200 metres from such a natural barrier can only be considered efficient if we have plenty of resources.
On the other hand, it is also possible that in a direction which currently has low parameters for spread and is thus assessed as lower priority, there lies a much more valuable area, such as a highly protected plant community, a habitat of protected animals, or perhaps an area of vegetation with higher parameters for spread.
The above examples show that the most efficient intervention is not necessarily the same as intervention at the point where the fire is the most intense. In order to make the best decision, the area of the fire must be managed in a complex manner, together with its environment.
The tactical UAS, which has proven effective, can be made available to even the smallest fire brigades. Traditional reconnaissance no longer provides information of a quality and quantity sufficient for today's applications. Increasing the efficiency of reconnaissance will result in increasingly efficient interventional measures. This will increase the area of forests saved while reducing the areas destroyed. The workload of fire-fighters may be reduced; in many instances there may be no need to mount a response at all. The elimination of unnecessary responses will reduce the level of risk to citizens, resulting in a higher level of fire safety.

Abstract
Advances in electronics, sensor technologies, embedded hardware and software are boosting the application scenarios of wireless sensor networks. Specifically, the incorporation of visual capabilities into the nodes means a milestone, and a challenge, in terms of the amount of information sensed and processed by these networks. The scarcity of resources – power, processing and memory – imposes strong restrictions on the vision hardware and algorithms suitable for implementation at the nodes. Both, hardware and algorithms must be adapted to the particular characteristics of the targeted application. This permits to achieve the required performance at lower energy and computational cost. We have followed this approach when addressing the detection of forest fires by means of wireless visual sensor networks. From the development of a smoke detection algorithm down to the design of a low-power smart imager, every step along the way has been influenced by the objective of reducing power consumption and computational resources as much as possible. Of course, reliability and robustness against false alarms have also been crucial requirements demanded by this specific application. All in all, we summarize in this paper our experience in this topic. In addition to a prototype vision system based on a full-custom smart imager, we also report results from a vision system based on ultra-low-power low-cost commercial imagers with a resolution of 30×30 pixels. Even for this small number of pixels, we have been able to detect smoke at around 100 meters away without false alarms. For such tiny images, smoke is simply a moving grey stain within a blurry scene, but it features a particular spatio-temporal dynamics. As described in the manuscript, the key point to succeed with so low resolution thus falls on the adequate encoding of that dynamics at algorithm level.

Keywords*: forest fires, surveillance systems, wireless sensor networks, automatic early detection, artificial vision, low-power sensors, vision algorithms.*

Introduction

Wireless Sensor Networks (WSNs) (Akyildiz *et al*. 2002) constitute an enabling technology for the paradigm of *pervasive computing* (Weiser 1991). One of the most representative application frameworks of this paradigm is *environmental monitoring*. Typical scenarios are precision agriculture (McCulloch *et al*. 2008), forest canopy analysis (Tolle *et al*. 2005), volcanic studies (Werner-Allen *et al*. 2006), meteorological station networks (Barrenetxea *et al*. 2008) etc. In all these cases, the network nodes incorporate particular sensing capabilities according to the requirements of the application considered. These capabilities share a common feature: they provide scalar measurements, e.g. temperature, humidity or wind speed. Moreover, the data sampling rate is usually low or moderate at most, leading to a reduced amount of information to be handled locally by the nodes. These conditions significantly change when it comes to the in-node implementation of multimedia sensing (Akyildiz *et al*. 2007). Specifically, the implementation of vision hardware at WSN nodes is not a trivial issue at all since the visual stimulus implies to deal with a massive flow of multidimensional information. Taking into account the very strict power budgets allocated to the nodes, the mere capture and digitization of an image sequence could represent a significant percentage of their energy consumption.

But the critical point arises just afterwards. On the one hand, the sequence could simply be transmitted for remote processing, affecting dramatically the scalability and bandwidth of the network. On the other hand, the node itself could deal with the image sequence by taking advantage of its processing capabilities. In this case, the nature of such processing is greatly influenced by the energy constraints, demanding new strategies which permit to reach the targeted result with the minimum possible power cost.

Most WSN applications take a new dimension when imaging is added to the catalogue of in-node sensing capabilities. A clear example is wildfire monitoring. Image processing permits not only to monitor a certain area from the perspective of environmental conditions (Hefeeda 2007, Aslan *et al.* 2012), but also to carry out visual inspection in order to perform early detection of smoke or flames (Fernández-Berni *et al.* 2012, Jakovcevic *et al.* 2013). At the moment, two fundamental intertwined challenges are hindering the commercial exploitation of vision-enabled WSNs performing fine-grain detection of forest fires: node cost and battery life. A scalable deployment of sensors across typical regions of interest for fine-grain detection, e.g. Wild-land Urban Interfaces (WUIs), demands a competitive cost per node, what in turn demands the use of standard technologies and reduced form factors. Maintenance also plays a key role in terms of system cost when hundreds of vision-enabled nodes are to be deployed. Frequent change of batteries directly impacts the commercial viability of the network. Rechargeable batteries making use of solar panels or other energy-scavenging devices could be a solution, but they significantly increase the node form factor and the cost. They also strongly influence the locations of the sensors, which must be adequate for the particular physical process collecting energy. These considerations again point to ultra-low power consumption as the primary requirement of vision-enabled WSNs, a fact that is emphasized for the specific application of forest fire detection.

All in all, we summarize in this paper our contribution to the power-efficient implementation of vision hardware on wireless sensor network nodes targeting early detection of forest fires. This contribution is the result of long-term research. The tasks carried out range from devising a robust vision algorithm for smoke detection to the design and physical implementation of a power-efficient smart imager tailored to the characteristics of such an algorithm. By integrating this smart imager with a commercial wireless platform, we endowed the resulting system with vision capabilities and radio communication. Numerous tests were arranged in different natural scenarios in order to progressively tune all the parameters involved in the autonomous operation of this prototype node. We have also studied the performance of another platform based on commercial components, the so-called *Silicam IGO* (Silicam 2014). This smart camera includes two low-cost image sensors with a resolution of only 30×30 pixels. Reliable smoke detection is still possible in real scenarios even for such a small amount of visual information. Indeed, the low resolution itself can be a helpful mechanism to filter out spurious data. Experimental results are presented for both systems.

Methodology

The methodology followed to address early forest fire detection by vision-enabled WSNs comprises: i) the development of a reliable vision algorithm for smoke detection suitable for embedded systems, that is, featuring low computational load and undemanding memory requirements; ii) the recording of meaningful footage for algorithm parameter tuning and off-line tests; iii) the implementation of the algorithm on a commercial system for preliminary field tests; iv) the design and implementation of a vision-enabled WSN node based on a full-custom smart imager; v) field tests in real scenarios; and vi) exploration of a new low-cost platform aiming at increasing power efficiency while preserving system reliability and robustness against false alarms.

Vision algorithm for smoke detection

The general conditions in which the visual inspection of a vegetation area will take place for the targeted system must be specified before addressing the design of a vision algorithm for smoke detection. The requirements for camera systems surveying extensive areas from very tall towers – the most usual scenario for automatic detection of forest fires – are very different to those of vision-enabled nodes in a WSN. In our case, we are pursuing an arrangement of watching devices like the one depicted in Figure 1. This arrangement presents several advantages when compared to current automatic ground systems (Fernández-Berni *et al.* 2008). Basically, the objective is to exploit the low-cost and low-power features of the nodes in order to increase the surveillance grain, what in principle should lead to a faster, more reliable and more robust detection. We therefore devised a vision algorithm assuming that each vision sensor surveys a small vegetation area located around it within a limited range (typically 1km).

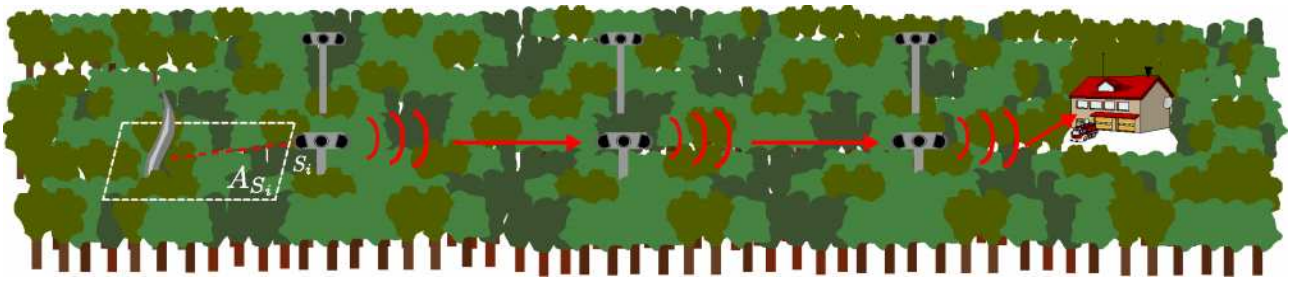

Figure 1. Proposed arrangement for visual detection of smoke.

Most of the details of the algorithm were described in (Fernández-Berni *et al.* 2012). However, we have introduced some minor modifications that were applied for the tests realized after that publication. They have resulted in higher robustness against false alarms. The modifications consisted in: i) setting a longer time interval for the maximum detection period and for the confirmation phase, now encoded by $T_{D_{MAX}} = 60\text{s}$ and $T_C = 12\text{s}$; ii) making the transition between the detection phase and the confirmation phase more flexible by not updating the background model as soon as the number of candidate bins goes below the corresponding threshold, as was the case for the previous version. The new flowchart of the algorithm is represented in Figure 2. These modifications are really interrelated since it is the larger values of $T_{D_{MAX}}$ and T_C what allows for accommodating a wider spectrum of smoke dynamics without triggering false alarms.

Parameter tuning and off-line tests

The discriminative power of the proposed algorithm is fundamentally supported by an adequate setting of the thresholds associated to its parameters. Such setting was performed by a thorough analysis of different sequences recorded in a natural environment, using commercial pyrotechnic material as smoke generator. We also recorded additional footage useful as a testbench and took a number of photographs in the variety of real scenarios we visited during all the field tests arranged the last few years. Most of this material is available for download at http://www.imse-cnm.csic.es/vmote (accessed 21 May 2014).

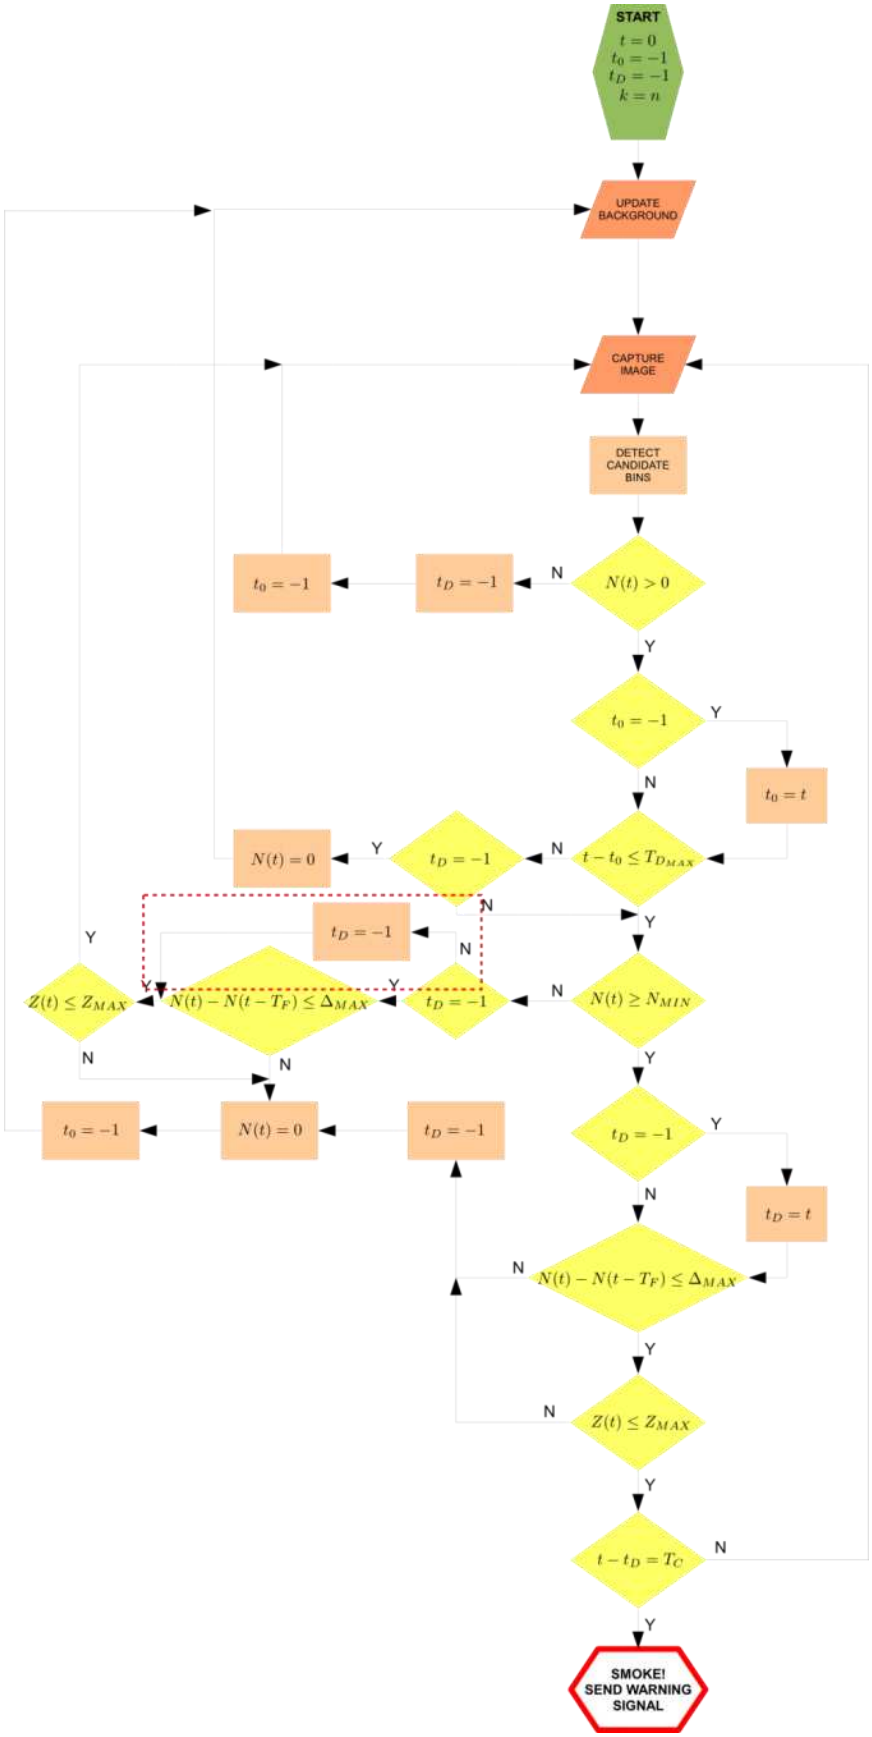

Figure 2. Flowchart of the algorithm. The modification related to the transition between the detection phase and the confirmation phase is highlighted by a red dashed rectangle.

2.3. Field tests with a commercial system

Once the algorithm was tuned for smoke detection, we programmed it into the *EyeRIS v1.2*, a commercial autonomous vision system built by AnaFocus Ltd (Seville, Spain, http://www.anafocus.com, accessed 22 May 2014). After a setup stage in the laboratory, two controlled burns of forest debris were surveyed by this system in order to test the algorithm in a real scenario. This test was also useful to learn and cope with typical operational problems of field experiments, permitting a better arrangement in following trials. All the details about these burns can be found in (Fernández-Berni *et al.* 2012). As a summary, smoke was detected without false alarms in both cases. In the first, the alarm was triggered at 2min 50s from ignition, whereas in the second, the alarm was delivered after 57 s. The most remarkable aspect about the results was the algorithm´s ability to filter motion other than smoke.

2.4. Design and implementation of a vision-enabled WSN node

The successful tests with the *EyeRIS* system demonstrated the viability of reliable forest fire smoke detection with low-power low-resolution autonomous vision systems in a scenario like that of Figure 1. But we wanted to go further concerning power efficiency and also to incorporate wireless communication to the sensor node. Based on our expertise on microelectronics, and specifically on vision sensor chips, we addressed the design and implementation of an ultra-low-power smart imager embedding different processing capabilities (Fernández-Berni *et al.* 2011-1). This chip met several academic purposes, one of which was to play a key role in the prototype vision-enabled WSN node we built, the so-called *Wi-FLIP* system (Fernández-Berni *et al.* 2011-2), shown in Figure 3. This system resulted from the integration of our smart imager and Imote2, a commercial WSN platform from MEMSIC Corporation (Andover, MA, www.memsic.com, accessed 22 May 2014). This platform is built around a microprocessor that can operate in a low-voltage low-frequency mode, hence allowing low-power operation. A ZigBee-compliant radio is also integrated into the Imote2 system.

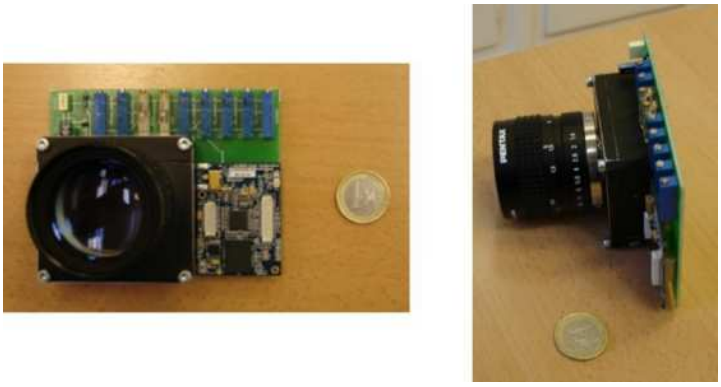

Figure 3. Wi-FLIP, a vision-enabled WSN node based on a focal-plane low-power image processor.

2.5. Field tests in real scenarios

As for the *EyeRIS* system, we also arranged for some preliminary tests with the *Wi-FLIP* system after the corresponding setup in the laboratory. Such tests took place in the same public park where we recorded the smoke sequences enabling the algorithm parameter setting. Once the whole system was tuned during these preliminary trials, additional tests involving controlled burns of vegetation areas were carried out in collaboration with the Andalusian Forest Fire Suppression and Prevention Service (INFOCA). These tests, whose results will be described in the next section, generated alarm signals as an outcome. The alarms were wirelessly sent to a base station located within a range of 30m. Also images were sparsely broadcast from *Wi-FLIP* since an alarm signal was triggered. This would permit

further visual checking from personnel supervising the network. Some of the scenarios where the field tests took place are depicted in Figure 4.

Figure 4. Some of the scenarios where our field tests took place.

2.6. Exploration of a new ultra-low-power low-cost vision platform

As stated in Section 1, node cost and battery life are currently hindering the commercial exploitation of vision-enabled WSNs for fine-grain detection of forest fires. The performance of the *Wi-FLIP* system has been remarkable as a first prototype, providing autonomous operation for ~10h powered by small commercial batteries. However, further steps must be given to reach much better performance figures at lower cost. In this context, we have had the possibility of running the algorithm on the images provided by the platform *Silicam IGO* (Silicam 2014). This is the first version of a commercial embedded vision system including, among other components, two grayscale 30×30-px image sensors and a radio module with 64 channels whose cost does not go beyond a few dollars. Indeed, the imagers are high-performance optical mouse sensors. A really competitive network node in economic terms can be built up from these extremely cheap modules. But the first step is to evaluate how the algorithm performs when being fed by so coarse images. This is what we have done during the realization of new field tests by making use of the *Silicam IGO* platform. A couple of snapshots of this system are shown in Figure 5.

Figure 5. Silicam IGO platform capturing images for on-site smoke detection.

Results

This section reports the experimental results achieved from both the *Wi-FLIP* and the *Silicam* systems. Concerning *Wi-FLIP*, some results were already described in (Fernández-Berni *et al.* 2012) but we are gathering here those results together with the new ones obtained after that publication. A complete perspective of the *Wi-FLIP* performance is thus provided.

Wi-FLIP

As mentioned in Section 2.5, the operation of *Wi-FLIP* was first tuned in the same public park where the video sequences for the algorithm settings were recorded. The setting up of these tests was complicated due to strong gusts of wind. Nevertheless, no false alarm was triggered during eight sequences of smoke generation and detection was successful in five of them. Smoke was not successfully detected in the others because, owing to the wind, the pyrotechnic material burnt out before it had entered the field of view of *Wi-FLIP* sufficiently to be registered.

The next test consisted in surveying the prescribed burning of a 95×20-m^2 area of vegetation in a public forest in collaboration with INFOCA. This area was mechanically divided into three zones of similar sizes according to the density of vegetation. *Wi-FLIP* was placed ~80m away and monitored all the activity occurring in it for over 2h. The first zone presented very sparse vegetation, generating very thin smoke that was not detected by *Wi-FLIP*. However, successful detection took place for the second and third zones. A first alarm was triggered 5min 28s after ignition for the second zone whereas it took 3min 29s to trigger an alarm for the third zone. No false positives were triggered either before or after the prescribed burn, despite the fact that many people and vehicles were moving around.

Finally, a new test similar to the just described was arranged in a different location of the same public forest. In this case, the operation conditions were harder. To start with, the wireless vision system was placed ~200m away from the prescribed burning. Fast cloud motion was constantly changing the illumination conditions. The motion of people and vehicles was even more intense than for the previous test. The surveillance period was ~2h. Two false alarms were triggered during this interval. The first one was caused by clouds that entered the field of view of *Wi-FLIP* rapidly. The second one was generated by a sudden change of illumination. Despite these false alarms, the algorithm was capable of filtering out most of the constant activity taking place in the scene other than smoke. Detection was successful for the three zones of the prescribed area progressively burnt. The detection time from ignition was always below 8min: 3min 40s for the first zone, 5min 4s for the second one and 7min 26s for the last zone. The background model just before starting to survey the third controlled burn along with the foreground segmentation of smoke at the detection instant and the first image sent via radio are depicted in Figure 6. It can be seen that some false candidate bins were segmented at the

detection instant. However, it did not prevent the fire from being detected. We have summarized the experimental results achieved with *Wi-FLIP* in Table I.

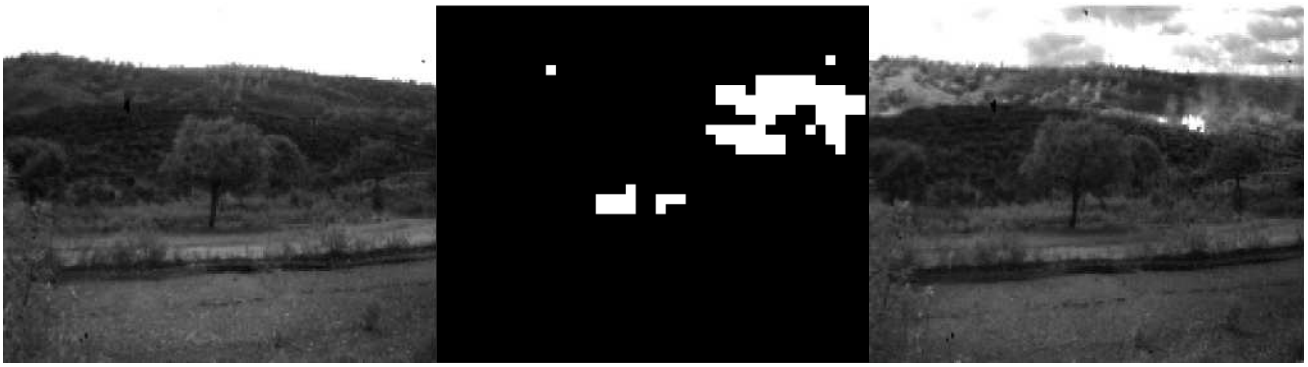

Figure 6. Initial background (left), foreground segmentation (center) and image sent via radio by Wi-FLIP (right) during one of the field tests carried out.

Table I – Summary of the experimental results achieved with Wi-FLIP.

Test#-Location	Smoke source	Surveillance period	True positives	False positives	False negatives	Detection time (distance)
#1-Public park	Pyrotechnic	~20m	5	0	3	43s max (~100m)
#2-Public forest	Controlled burns	~2h 30m	2	0	1	5m 28s max (~80m)
#3-Public forest	Controlled burns	~2h	3	2	0	7m 26s max (~200m)

3.2. Silicam

We also arranged for a first set of field trials with *Silicam* in a public park. Pyrotechnic material was again used as smoke source. It was burnt out within distances between ~50m and ~100m with respect to the vision system. Only one of the imagers of *Silicam* was used. No false alarm was triggered during the seven smoke sequences analysed at four different locations. There was only one false negative due to lack of contrast of the generated smoke against the background. Successful detection was achieved for the other six sequences. The background model at the detection instant along with the captured image and foreground segmentation at that same moment for one of these sequences are depicted in Figure 7.

A controlled burn in a public forest could be surveyed with *Silicam* too. However, the arrangements for this test were far from ideal. First of all, the vegetation to be burnt was sparse and relatively damp, generating thin smoke. The characteristics of the surroundings were not suitable either for adequate surveillance: tall trees prevent the thin smoke arising from the burn from being detected from higher locations. The trees also caused high illumination contrast in the visual scene, making the detection more challenging. We had to place *Silicam* very close to the ignition points, what at least permitted to confirm once again the robustness of the algorithm against false alarms: there was only one throughout the over 2h of visual inspection. Detection was successful in three of the sequences analysed. Concerning false negatives, we consider that the smoke was thick enough to have being detected in other three sequences. One of the successful detections is shown in Figure 8. A couple of photographs taken during the realization of this test are included in Figure 9. The results achieved with *Silicam* are summarized in Table II.

Figure 7. Background model (left), captured image (center) and foreground segmentation (right) just at the detection instant of smoke from pyrotechnic material with Silicam.

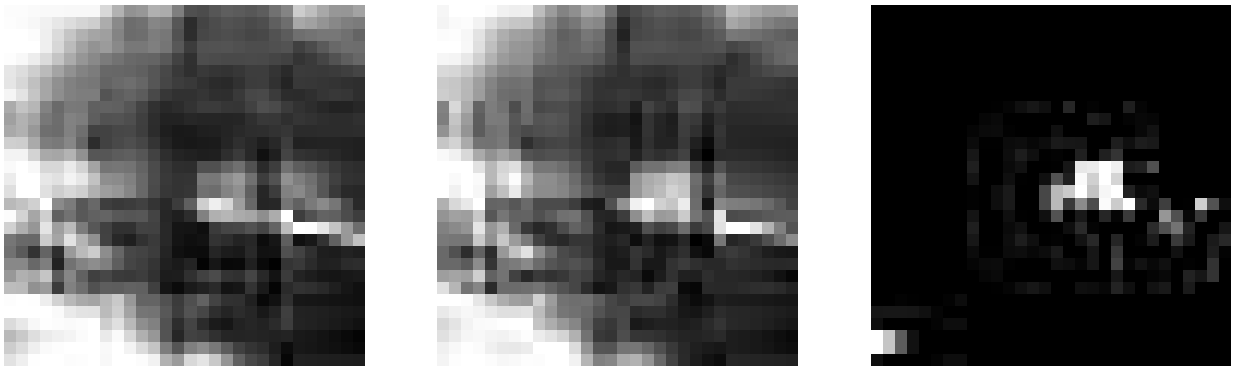

Figure 8. Background model (left), captured image (center) and foreground segmentation (right) just at the detection instant of smoke from controlled burn with Silicam.

Figure 9. Snapshots taken during the controlled burn surveyed by Silicam.

Table II – Summary of the experimental results achieved with Silicam.

Test#-Location	Smoke source	Surveillance period	True positives	False positives	False negatives	Detection time (distance)
#1-Public park	Pyrotechnic	~45m	6	0	1	51s max (~100m)
#2-Public forest	Controlled burns	~2h 15m	3	1	3	4m 7s max (~30m)

Conclusions

Fine-grain detection of forest fires is technologically possible nowadays. State-of-the-art vision-enabled WSN nodes can be deployed throughout a region of interest to locally survey small vegetation areas and wirelessly send alarm messages by multi-hopping. However, operational costs still seem to be very high for a dense deployment. Node cost and battery life demand new strategies that permit to reduce the former while increasing the latter. In this paper, we have described our contribution to achieve such objective. Tight integration of the different system components arises as a major requirement. Among these components, the vision algorithm for detection stands out as the primary demander of computational power and hence of power consumption. The algorithm proposed in this manuscript features low computational load and can also cope with very low resolution images. The results from the numerous field tests presented suggest pushing in this direction by further algorithm tuning. To this end, the feedback provided by real deployments in different locations and circumstances is mandatory, according to our experience. Ultra-low power consumption and miniaturization should ultimately lead to the seamless integration of vision within the catalogue of sensing capabilities available for WSNs.

Acknowledgments

The authors express their deep gratitude to Mr Salvador Benítez Moscoso, Mr Manuel Larios de la Carrera and Mr Francisco Senra Rivero of INFOCA for arranging the burns. This work has been funded by the Spanish Government through projects TEC2012-38921-C02 MINECO (European Region Development Fund, ERDF/FEDER), IPT-2011-1625-430000 MINECO and IPC-20111009 CDTI (ERDF/FEDER), by Junta de Andalucía through project TIC 2338-2013 CEICE, by the Office of Naval Research (USA) through grant N000141410355 and by Ghent University through its BOF program for visiting foreign researchers.

Abstract
While deforestation represents an obvious ecosystem change, forest degradation is often more difficult to discern or quantify, but it impacts a number of ecosystem functions which are vital for biodiversity and climate feedbacks. In the Brazilian Amazon, land-use changes increase fire occurrence, especially in fragmented forests close to managed land. We used remote sensing imagery to estimate the extent and impact of forest fires in degraded tropical rain-forest in the Brazilian Legal Amazon between 2007 and 2010 and examined land-use establishing in degraded areas. The trends in degraded area vs. burned area were different. Even though degradation increased one year after a high fire year, there was no spatial overlap, which points to other causes for degradation. Up to 11% of the degraded area was burned in the same year, playing escaping fires from managed and deforested lands a significant role in degradation by fire. Eighty-four percent of 2007s degraded area remained forest one year later, whereas the rest was identified as deforestation, secondary vegetation or pasture. Three years after degradation, 80% remained forest, the proportion of deforested area decreased and areas in regeneration after being deforested increased. Monitoring of forest degradation across tropical forests is critical for developing land management policies and for carbon stocks/emissions estimation.

Keywords*: forest degradation, logging, forest fires, land-use, Brazilian Amazon.*

Introduction

In Brazilian Amazonia, the extent of canopy and subcanopy disturbance has been underestimated and often exceeds the total area deforested (Peres *et al.*, 2006; Souza Jr. *et al.*, 2013). Deforestation in the region is superimposed upon synergistic processes of anthropogenic forest degradation (events when, unlike in deforestation processes, the forest canopy cover is only partially or temporarily removed), which implies the reduction in the overall capacity of a forest to supply goods and services (Simula, 2009). Several aspects of the forest may be affected by degradation including productive capacity, protective capacity, biodiversity and health and carbon storage (Parrotta *et al.*, 2012). The proximate drivers of forest degradation include unsustainable and illegal logging, human-induced fires, over-harvest of fuelwood and non-timber forest products, overgrazing and poor management of shifting cultivation (Chazdon, 2008; Kissinger *et al.*, 2012). In addition to these adverse impacts of land-use change and human-induced forest degradation, climate change poses an increasing threat to tropical forest ecosystems increasing the frequency of severe droughts (Malhi, 2012).
In the Brazilian Amazon humans have substantially altered forest fire regimes and fires have increased in extent and frequency as a result of forest fragmentation, the expansion of managed lands and logging (Asner *et al.*, 2005; Morton *et al.*, 2008; Armenteras *et al.*, 2012), thus contributing to forest degradation and reducing forest resilience (Barlow and Peres, 2008; Nepstad *et al.*, 2008). Moreover, forest fire can increase susceptibility to further burning in a positive feedback by killing trees, opening the canopy and

increasing solar penetration to the forest floor (Cochrane and Laurance, 2008; Alencar *et al.*, 2011). Anthropogenic forest disturbance from fires produces long lasting changes in forest structure and biomass but the changes are sometimes hard to detect in satellite imagery and are quickly obscured by the regenerating forest canopy (Matricardi *et al.*, 2010), which makes it difficult to properly assess forest degradation by fire.

In 2007, at its 13th Conference of the Parties, the UN Framework Convention on Climate Change recognized forest degradation as an important contributor to global carbon emissions by incorporating it into the Reducing Emissions from Deforestation and Forest Degradation (REDD+) mechanism (UNFCCC, 2008). According to van der Werf *et al.* (2010), the global sum of deforestation, degradation, and peat fire emissions accounted for about a quarter of total carbon emissions. Another study by Asner *et al.* (2005) estimated that emissions caused only by selective logging were equivalent to between 60 and 123% of previously reported deforestation emissions in five states of the Brazilian Amazon, which accounted for 90% of all deforestation in the region, while Pearson *et al.* (2014) found that Brazil's emissions from logging were small and equivalent to 10% of those from deforestation. Nevertheless, the release of carbon by degradation still remains largely overlooked, and limited information is available to achieve a full carbon accounting for REDD+ (Morton *et al.*, 2011a). The scientific, conservation, and climate policy importance attracted previous studies to analyse forest degradation processes in the Brazilian Amazon through field research (Xaud *et al.*, 2013; Berenguer *et al.*, 2014) and remote sensing observations (Matricardi *et al.*, 2010; Souza Jr. *et al.*, 2013). Further progress, however, is yet to be made in quantifying the extent and intensity of less-visible forms of nonstructural habitat disturbance underneath the forest canopy. In this line, our study pursues the quantification of the degraded area affected by fires in the Brazilian Amazon and also their temporal changes using 30x30 m land-cover information (INPE and EMBRAPA, 2013). Specifically, we answer three main questions. 1) What is the relation between forest degradation and fire? 2) To what extent do fires escaping from managed land contribute to forest degradation? 3) What are the temporal dynamics of degraded areas and their conversion to other land-use types?

Methods

Study area

The Brazilian Amazon contains about 3.2 million square kilometers of the Amazon forest (INPE and EMBRAPA, 2013) and stores the majority of the 126 Pg of carbon reported for the entire Amazonia (Malhi *et al.*, 2006). About 80% of the forest remains intact (FAO-ITTO, 2011), although substantial areas have been deforested (INPE, 2013a), selectively logged (Asner *et al.*, 2005; Matricardi *et al.*, 2010) or affected by fires in recent decades (Morton, 2013; Xaud *et al.*, 2013). As a consequence of that rapid land-cover change, the forest has been fragmented by logging gaps and mosaics of cattle ranching and agricultural settlements, mainly along the arc of deforestation in southern and eastern Brazilian Amazon (Houghton *et al.*, 1991; Lambin *et al.*, 2003; Lepers *et al.*, 2005). In this paper we use the Brazilian Legal Amazon definition, the largest Brazilian socio-geographic division (Figure 1), which, in 2010, was covered by primary or secondary forest (76%), savanna-type vegetation (18%), concentrated mainly in the southeast, and 6% was detected as cleared areas (Figure 1a).

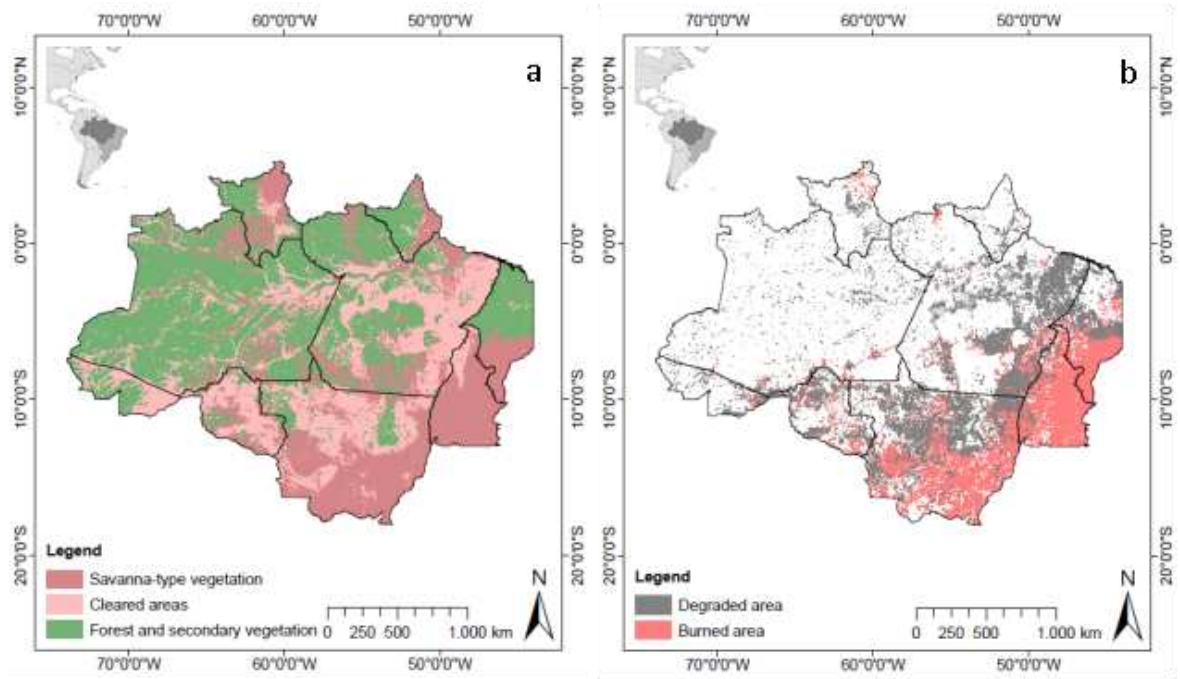

Figure 1. a) Map showing the extension and land-cover of the Brazilian Legal Amazon according to TerraClass 2010. Savanna-type vegetation includes cerrado, campinas and campinaranas. Cleared areas includes agricultural fields, pasture lands and deforested areas. b) Map of degraded and burned area detected from 2007 to 2010.

Datasets

We used degradation maps provided by the DEGRAD project (http://www.obt.inpe.br/degrad/dados/) which monitors the degradation of the Brazilian Amazon forest caused by wood extraction or by recurrent fires (INPE, 2013b). Forest areas likely to become deforested where the canopy has not been totally removed are considered by DEGRAD as degraded areas. It is based on the Landsat Thematic Mapper and CBERS satellites to detect clearings of at least 6.25 ha size annually from 2007 to 2010 at 60 m spatial resolution.

Annual deforestation maps for the same period were obtained from the PRODES project which has been monitoring Brazilian Amazon deforestation since 1988 (INPE, 2013a, http://www.dpi.inpe.br/prodesdigital/prodes.php). PRODES combines satellite data from the Thematic Mapper (LANDSAT), DMC (Disaster Monitoring Constellation) and CCD (CBERS) sensors, and their successors for recent years, and detects clearings of at least 6.25 ha where deforestation by clear cutting has occurred at 60 m spatial resolution and one map each year.

The Moderate Resolution Imaging Spectroradiometer (MODIS) on board the polar orbiting Terra and Aqua satellites maps fire affected areas since 2000 (Roy *et al*., 2008). We used the re-projected monthly Geotiff version of MODIS collection 5 Burned Area Product (MCD45, National Aeronautics and Space Administration, University of Maryland FTP server: ftp://ba1.geog.umd.edu) from 2007 to 2010 (500-m resolution, windows 5 and 6).

Land-cover maps of the Legal Amazon were produced by the TerraClass project (http://www.inpe.br/cra/projetos_pesquisas/terraclass2008.php) showing a very detailed land-use classification in 15 categories at 30-m resolution with data generated from the interpretation of images Landsat/TM5 for the years 2008 and 2010 (Almeida *et al*., 2009; INPE and EMBRAPA, 2013).

2.3. Data analysis

We worked with the geographical information system (GIS) package ArcGIS 10.1 (Esri) to conduct all digital spatial and temporal analysis. While TerraClass and DEGRAD files were provided in Esri

shapefile format, burned area files needed a preliminary transformation into polygon shapefiles. Burned and degraded area maps were overlaid for computing the temporal and spatial relation between them for each year of the study period (2007-2010), after aggregating degradation data to 500 m to fit its resolution to the fire data. The same overlay operation was applied to the degraded area layers and land-use maps (in 2008 and 2010) to track their evolution over time. Potential escaping fires from pasture fields, agricultural lands and deforested areas into the forest contributing to degradation were evaluated by creating buffer zones of different size (from 0.5 to 3 km, every 0.5 km) around the burned areas occurring in managed lands to examine the proportion of forest patches that were burned, and therefore classified as degraded areas (hereafter referred to as fire-related degraded area) within each buffer. The coordinate system of the files was converted to the geographic South American Datum 1969, when working with Amazonia, or to the state corresponding projected coordinate system according to the Universal Transverse Mercator scheme. This way a proper fit between the different information layers was achieved and accurate area calculations of the polygons were performed.

3. Results

In the period from 2007 to 2010, 395549 km² of burned area were detected in the Brazilian Legal Amazonia (8% of the territory) and 64308 km² of forest were registered as degraded (2% of the forested area within the study region in 2010). Both variables showed an uneven spatial distribution. Burned area was concentrated in southern Mato Grosso, Tocantins and southern Maranhão, which corresponds to the extension of the savannah-type vegetation, while degraded area was mainly located along the arc of deforestation (Rondônia, northern Mato Grosso, eastern Pará and northern Maranhão) (Figure 1b). The highest amount of burned area was found in 2010 (177615 km²), while the maximum amount of degraded area was detected in 2008 (27478 km²) (Figure 2a) with all nine states in the region presenting the same trend (Figure 2b). Most burned area was observed in the state of Mato Grosso contributing 44% of the total, followed by Tocantins (30%), Maranhão (13%) and Pará (12%). The states contributing the greatest amounts of degradation were Mato Grosso (51%), Pará (27%) and Maranhão (14%) (Figure 2b). In 2007 and 2010, the two high fire years of the period, 11% of the degraded area was detected as burned in the same year, while figures were lower than 1% in 2008 and 2009 (Figure 3a).

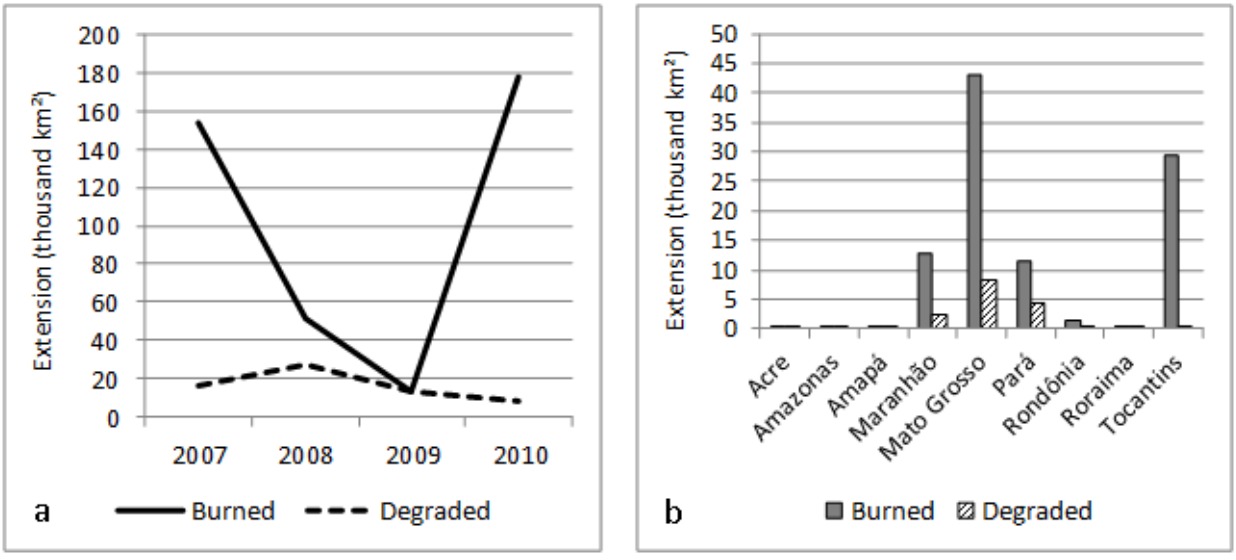

Figure 2. a) Annual burned (solid line) and degraded (dashed line) area for2007-2010 in the Brazilian Legal Amazon (in thousand km²). b) Amount of burned and degraded area in the different states (in thousand km², averaged over the period 2007-2010).

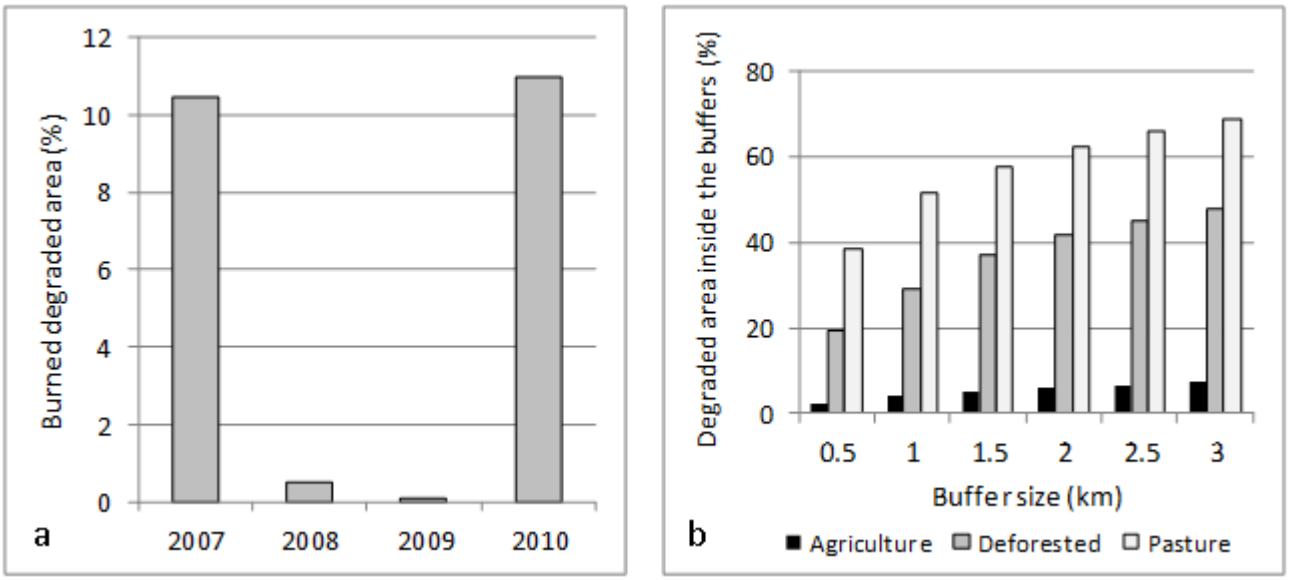

Figure 3. a) Percentage of degraded area that was also detected as burned area by MODIS in the same year. b) Percentage of fire-related degraded area that was connected to burnings in managed lands and deforested areas averaged over 2008 and 2010 in the Brazilian Legal Amazonia.

Fires escaping from agricultural fields in the vicinity of forest may cause between 2 (0.5-km buffer) and 7% (3-km buffer) of forest degradation, which means that between 6 and 31 km² of the fire-related degraded area were within the 0.5-km buffer and 3-km buffer zone, respectively, established around the burned area polygons in agricultural lands, averaged over 2008 and 2010 (Figure 3b). The proportion of the fire-related degraded area that overlapped the buffers delimited around pasture burned area polygons was higher for all the buffer sizes compared to agricultural buffers, between 39 and 69% of the fire-related degraded area (between 107 and 300 km²), averaged over 2008 and 2010 (Figure 3b). Fires occurring in deforested areas may be responsible for 19 to 48% of the forest degradation caused by fire (between 73 and 191 km²), averaged over 2008 and 2010 (Figure 3b). Concurrent with the greatest annual burned area figures in the period, the year 2010 presented higher overlap values between the buffers and the fire-related degraded area than 2008 for all the three land-uses: agricultural, pasture and deforested lands.

Of the degraded area detected in 2007, 23% was still considered as such one year later, 7% two years later and 3% three years later (data not shown). According to Terraclass, 84% of the forest classified as degraded in 2007 remained forest one year later. The remaining degraded area was registered in 2008 as deforestation (11%), secondary vegetation (2%), pasture (1%) and degraded pasture (1%) (Figure 4a). Three years after degradation, 80% of 2007's degraded area was detected as forest, the proportion of deforested area decreased (3%) while the area covered by areas in regeneration after being deforested and used for agriculture or pasture (7%), pasture (4%) and degraded pasture (3%) increased, and a similar extension of secondary vegetation was found (2%), compared to the figures observed in 2008 (Figure 4b).

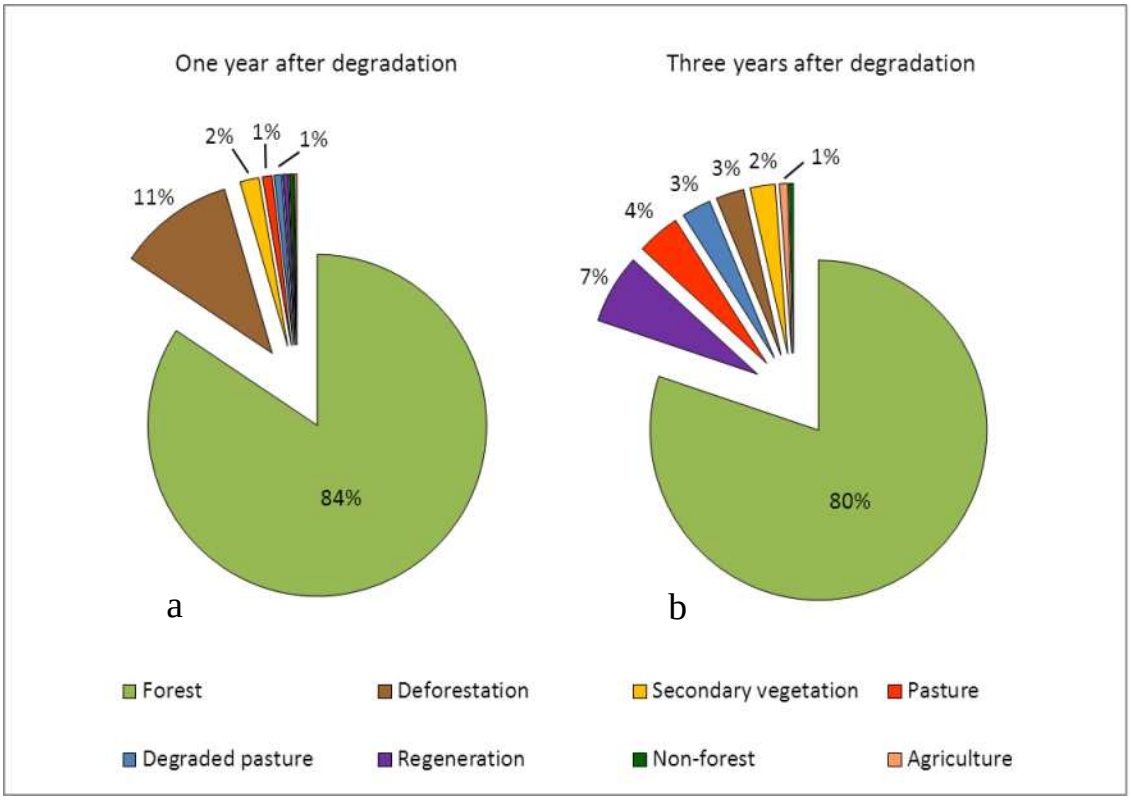

Figure 4. a) Land-use of the degraded area assigned by TerraClass one year after degradation, in 2008, and b) three years after degradation, in 2010 (averaged over the Brazilian Legal Amazonia).

Discussion

The above results underscore the relatively low proportion of degraded area solely related to forest fires, being 11% the maximum percentage of annual degraded area that was connected to burning events in the detection year (Figure 3a). However, it is important to consider the difficulty in obtaining accurate burned area mapping within tropical closed-canopy forest by MODIS (Giglio *et al.*, 2006), which can lead to underestimation of burning occurrence in the forest, e.g., small surface fires can be overlooked (Morton *et al.*, 2013). The analysis detected evidence of the link between degradation fires and land-use change processes. Even when considering the conservative 0.5-km buffer, 2, 19 and 39% of the fire-related degraded area may be the result of escaping fires from the adjacent agricultural lands, deforested areas and pasture fields, respectively, and the figures increase as the buffer size grows (Figure 3b). These findings support the idea of burning events becoming much more frequent and widespread across the Amazon forests as a consequence of deliberate fire use for land clearing and field maintenance (Cochrane, 2003; Cardoso *et al.*, 2009; Davidson *et al.*, 2012).

Since the forest degradation drivers contemplated by the DEGRAD system are selective logging and fire (INPE, 2008), the results of the fire vs. degraded area analysis indicated a stronger influence of selective logging in degradation. Unfortunately, we do not have logging data for the study period to confirm this premise, but different studies have identified logging as the process responsible for the largest proportion of forest degradation (Matricardi *et al.*, 2010). Kissinger *et al.*, (2012) in their report for REDD+ policymakers stated that unsustainable logging accounted for more than 70% of forest degradation in Latin America. Moreover, once disturbed by selective logging activities, the amount of dead slash or dried biomass increases and forest becomes more susceptible to fire (Uhl and Kauffman, 1990; Holdsworth and Uhl, 1997).

Around 80% of the degraded forest was still classified as forest one and three years later (Figure 4). After 12 years, Matricardi *et al.* (2010) found that 70% of the total forest area disturbed in their study area in the state of Mato Grosso had sufficiently recovered to become undetectable using satellite data. Degraded forests can often remain in a degraded state for long periods of time if degradation drivers remain, or if ecological thresholds have been passed, and yet remain officially defined as forests for classification purposes (Murdiyarso *et al.*, 2008; Sasaki and Putz, 2009), thus, regrowing vegetation can lead to misclassification in the absence of accompanying field data. The climax of forest regeneration seems to be 3 to 5 years following logging activities and 3 to 10 years after a forest fire event (Matricardi *et al.*, 2010), which explains why Stone and Lefevre (1998) observed in their study in the state of Pará that within 3 to 5 years degradation signal by selective logging was obscured by the regenerating forest canopy. Even though most of the degraded forest regenerated, 11% was deforested one year later, which is comparable with previous estimates of 16% due to logging alone by Asner *et al.* (2006) for the early 2000s, when deforestation rates were higher.

Recent research has contributed to substantial improvements in remote sensing based techniques to evaluate extent and impacts caused by selective logging and forest fires (Matricardi *et al.*, 2010; Morton *et al.*, 2011b; Andersen *et al.*, 2013). However, a large-scale and long-term evaluation of processes causing forest degradation is still lacking, but is required to understand ecological and climate-related consequences of tropical forest impoverishment through logging and fire.

Conclusions

Based on these research results we can conclude that forest degradation is not mainly controlled by fire, which suggests that the major driver in the Brazilian Amazonia is selective logging. The occurrence of fire in the forest, in most of the cases, is the result of land-use change processes, and escaping fires from pasture management play a crucial role. Only a small percentage of degraded forest becomes deforested or develops to other land-uses one and three years after degradation, while the majority of it recovers and is still detected as forest. Continuous monitoring of forest degradation across tropical forests is critical for developing land management policies, as well as for an accurate estimation of carbon stocks/emissions. At the same time, global Earth system models must incorporate dynamic models of land-use change driving deforestation, forest degradation and vegetation fires for a better carbon balance simulation.

Abstract
Extinguishing fires of forests is a serious problem for fire services since vast areas can be involved in a relatively short time. For extinguishing fire of forests and peat-bogs is indispensable employment of wetting agents, which by its specificity multiplies speed of penetration burning material. Water is the most frequently used extinguishing agent, but when it is used to extinguish the fires of forests, shrubs, peat-bogs or wildland its efficiency is poor because of its weak capacity to wet and penetrate the cracks of the hydrophobic forest floor. The extinguishing efficiency can be enhanced by adding extinguishing concentrates which reduce the water surface tension. The optimum solution is to use wetting extinguishing agents which hamper the development of a fire by reducing the rate of the fire spread and the combustion intensity.
Wetting agent are mixtures of many components inclusive of surfactants, which are well soluble in water and which lower surface tension value of aqueous solutions and boost ability of solution to wetting of surface hydrophobic material. When added to water, those compounds improve its fire extinguishing properties, and thus improve efficiency of rescue actions. Wetting agents are assigned for extinguishing fire of wood (forest) and peat-bogs, cotton, coal and other smoldering and glowing fires.
This study presents the results of laboratory tests of wetting compositions. The purpose of this study was to determine the wetting power, adsorbing power and extinguishing tests for the wetting agents intended to fight forest fires.

Keywords*: wetting agent, wildland fire-fighting, forest fire*

Introduction

Extinguishing fires of forests is a serious problem for fire brigades since vast areas can be involved in a relatively short time. For extinguishing fire of forests and peat-bogs is indispensable employment of wetting agents, which by its specificity multiplies speed of penetration burning material. Wetting agent are mixtures of many components inclusive of surfactants, which are well soluble in water and which lower surface tension value of aqueous solutions and boost ability of solution to wetting of surface hydrophobic material. Wetting agents are used to extinguish both the flaming and glowing phases of combustion by application on the burning fuel. Their effectiveness relies also on their ability to retain moisture and absorb heat by cooling. They remain effective until all water has been removed from the fuel by evaporation [1].
When added to water, those compounds improve its fire extinguishing properties, and thus improve efficiency of rescue actions. Wetting agents are assigned for extinguishing fire of wood (forest) and peat-bogs, cotton, coal and other smoldering and glowing fires. Surfactants in this type of compounds are selected under their abilities to reduce surface tension value in water solutions and increase wetting. The purpose of tests and search for new agents is certainly development and implementation of the best and most effective arrangements. Efficiency of wetting agent is a function of the concentrations and types of the active ingredients that are delivered into the solution. The foam generation, more or less important depending on additive quality and concentration, gives a better insulation of the fire by

flame covering. Additionally, the water coming from drainage helps to cool down the fire and so enhances the extinction.
The wettability is an advantage for forest fire-fighting as it makes better the penetration and spreading of the liquid over a thick vegetal cover.
The foam achieved from solutions of commercial wetting agent and in a concentration 1.0% (v/v), prepared by using municipal water were also compared.

Materials and Methods

Materials

In our studies five commercial extinguishing and wetting agents were used. Characteristic of tested compositions is showed in Table 1.

Table 1. Commercial fire-fighting agents

Commercial fire-fighting agent	Field of application	Recommended concentration [%]	Basic surfactants
Biofor C	forest fires and urban fires plastics, tyres, cotton hydrocarbon fuel	0,1-1,0	salts of fatty alcohol ether sulfates C_{12}-C_{14} - anionic surfactant
Prosintex A	structures and buildings hydrocarbon fuel rubber, plastic, tyres paper, wood, forest fires	0,1-1,0	salts of fatty alcohol ether sulfates C_{10}-C_{14} - anionic surfactant
Forexpan S	forestry and wildland fire structural fires tyres and rubber fires hydrocarbon spill fires	0,1-1,0	salts of fatty alcohol ether sulfates C_{10}-C_{16} - anionic surfactant
Sthamex cl. A	cotton, peat, pulverised coal fires forest and bush fires	0,1 – 1,0	polyoxyethylene glycol dodecyl ether- nonionic
Amber One	forest fires, bush fires and peat bog fires, cotton, wood, paper, pulverised coal fires	0,1 – 1,0	fatty alcohol C12-C15 ethoxy sodium sulphates

Surface tension

Equilibrium surface tension was measured using the du Noüy ring technique with a Krüss K9 ET tensiometer (Germany) with platinum ring [2]. The surface of each solution was cleaned immediately prior to measurement.
Aqueous solutions were prepared in a wide range of concentrations immediately prior to measurements. All measurements were carried out at 294 K. The average standard deviation of these determinations was equal to 0.2 $mN \cdot m^{-1}$. In all the systems, re-distilled water with conductivity equal to 3 μS was used as the aqueous phase.

Foaming power

The foam was generated according to standard EN 1568-3 [3] from an aqueous solution of the wetting agent at a concentration of 1.0 %. This method consists of measuring the foam volume in a 1 L cylinder.

The expansion ratio (E), given in Eq. (1), is the proportion of the volume of foam (V_{foam}) to the volume of solution ($V_{solution}$) from which it was made.

$$E = \frac{V_{foam}}{V_{solution}} \quad (1)$$

All measurements were carried out at 294±2 K. The average standard deviation of expansion ratio determinations was equal to 1.5 %.

2.4. Wettability

100 g of wetted material (peat or wood bark) was dried in order to achieve moisture content of approximately 8–10 % . Next the wetted material was placed in steel mesh baskets, weighed, and spayed by studied solutions of wetting mixtures. Then, the bottom of the basket was dried with absorbent paper and the basket with wetted material was weighed. For estimating wettability W (%) the following equation was used:

$$W = \frac{m_1 + m_0}{m_0} \cdot 100\% \quad (2)$$

where m_1 is the mass of wetted material after spaying by tested solution and m_0 is the mass of dry peat or wood bark which is equal to 100 g.

Measurements were conducted at 294±2 K. The average standard deviation of these determinations was equal to 3 %.

2.5. Extinguishing test

Tests of the effectiveness of extinguishing fires of solid materials were performed in accordance to method described in standard EN 3-7 [4] using portable fire extinguishers of 2 L volume filled with 1% solutions of the wetting mixtures analysed. After extinction no burnback was observed for any studied compositions.

Measurements were carried out at 294±5 K. The average standard deviation of extinction time determinations was up to 2s.

2.6. Retardancy

The peat was soaked by 1% solutions of wetting compositions and dried to obtain moisture below 13%. Next the 100 g of peat was put in basket and ignited by propan (propan-butan) pilot burner. Measurements were conducted from the start of ignition of pilot burner till the smoldering of fuel was observed.

Measurements were carried out at 294±5 K. The average standard deviation of extinction time determinations was up to 2s.

Results

3.1. Surface tension

In the Figure 1 values of surface tension of studied agents were showed. The surface tension of the analysed wetting compositions varies between 26 mN/m (for Sthamex A) to almost 30 mN/m (for Amber One). Typical values of surface tension for solutions of extinguishing agents is below 35 $mN \cdot m^{-1}$.

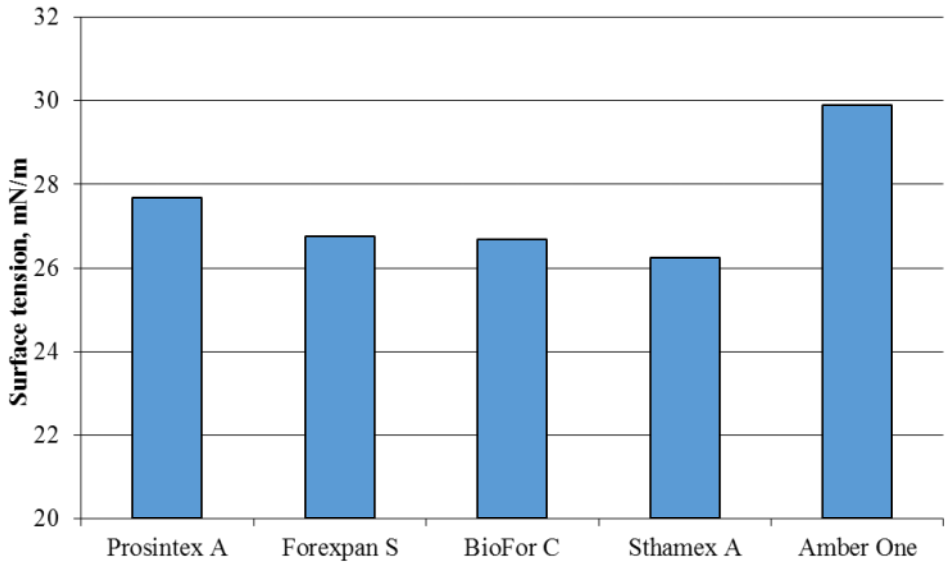

Figure 1. Surface tension of the analysed wetting compositions

Foaming power

The results of foaming properties were presented in the Figure 2. The foaming power of analysed wetting compositions varies between 5 (for Prosintex A) to 8 (for Sthamex). For good properties of wetting and extinguishing fire of natural hydrophobic material a low foamability (between 4-6) is required.

In the Fig 3 time to drainage of 25% and 50% of foam volume were showed. Short time of draining is demanded for quick speeding of wetting agent on the flammable surface.

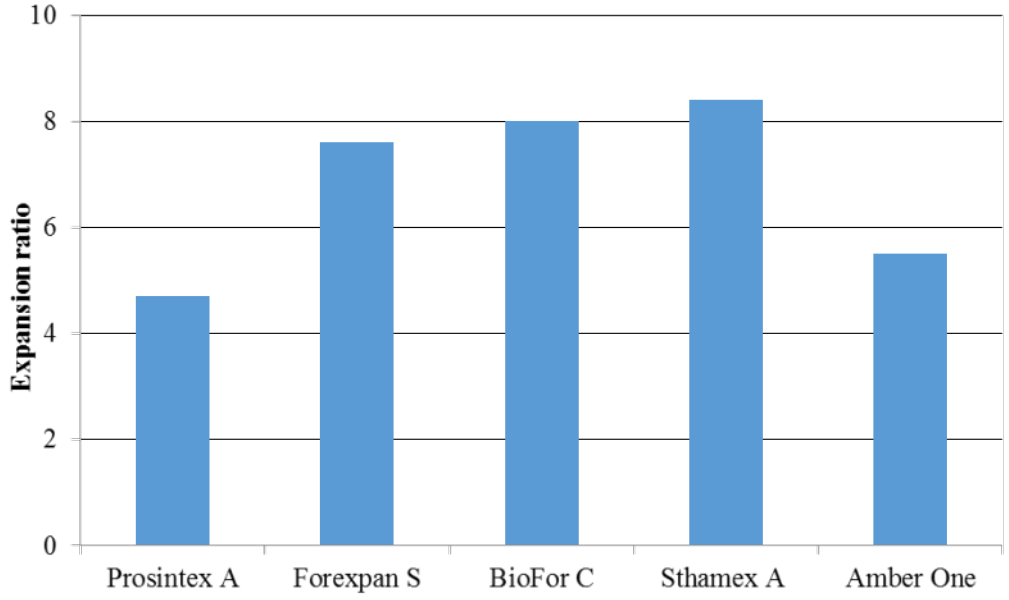

Figure 2. Foaming power of analysed wetting compositions

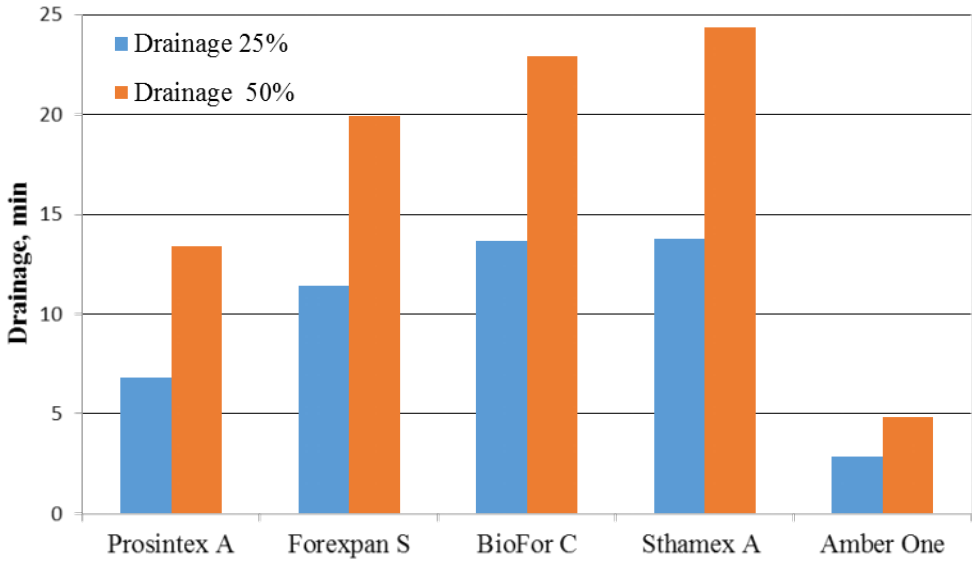

Figure 3. Drainage time of the produced foam for analysed wetting compositions

3.3. Wettability

In the Fig 4 and Figure 5 the wetting power of studied wetting agents were showed. At the concentration of 0,10% all of the analysed wetting compositions have comparable wettability of peat. The highest wettability was recorded for Amber One and Forexpan S. Wettability for this two wetting compositions was comparable at concentration 0,5% and 1,0%.

The highest wettability of bark was recorded at the concentration of 1,0%. In this respect the best was BioFor C and next Sthamex A, Forexpan S and Amber One.

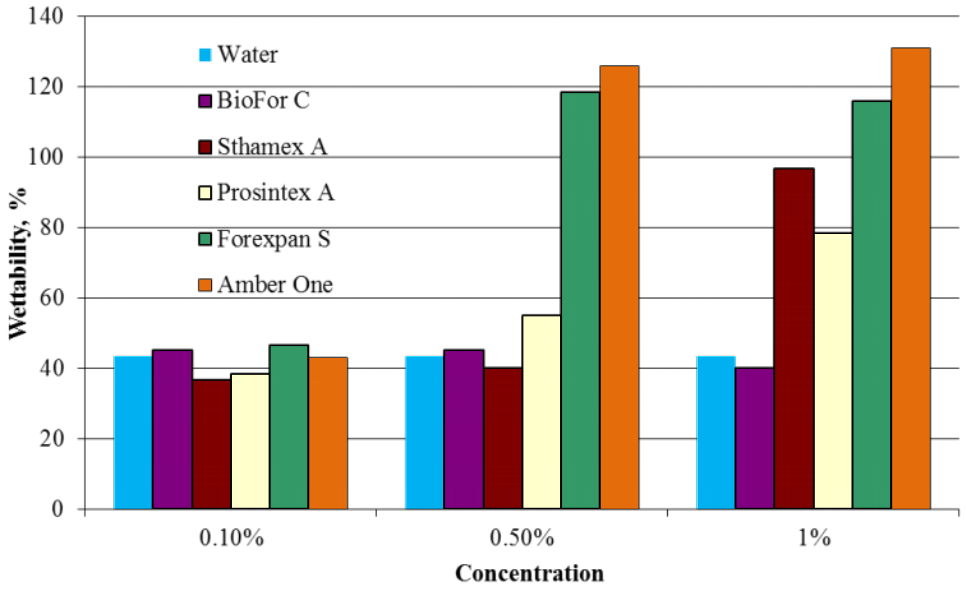

Figure 4. Wettability of peat with the analysed wetting compositions versus to concentration

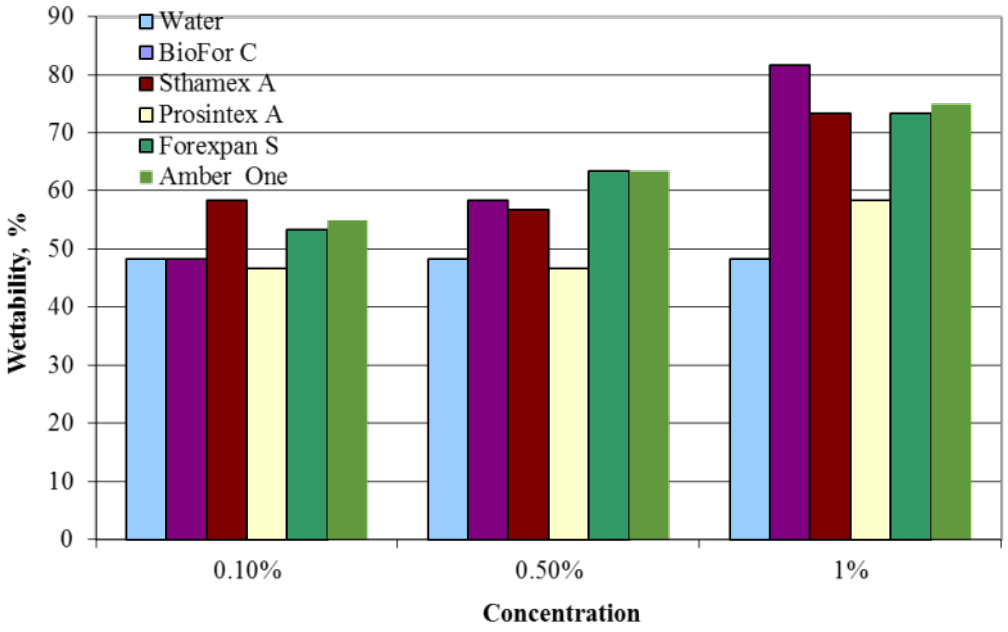

Figure 5. Wettability of bark with dispersed stream of the analysed wetting compositions.

3.4. Extinguishing test

The results of extinguishing tests were presented in the Figure 6. The times required for the wetting agents used to extinguish fires proved to be up to two times shorter than the time required for synthetic extinguishing agents typically applied in fighting fires of solid porous materials. Once the flames were extinguished by applying each of the solutions investigated, no return of fire was observed.

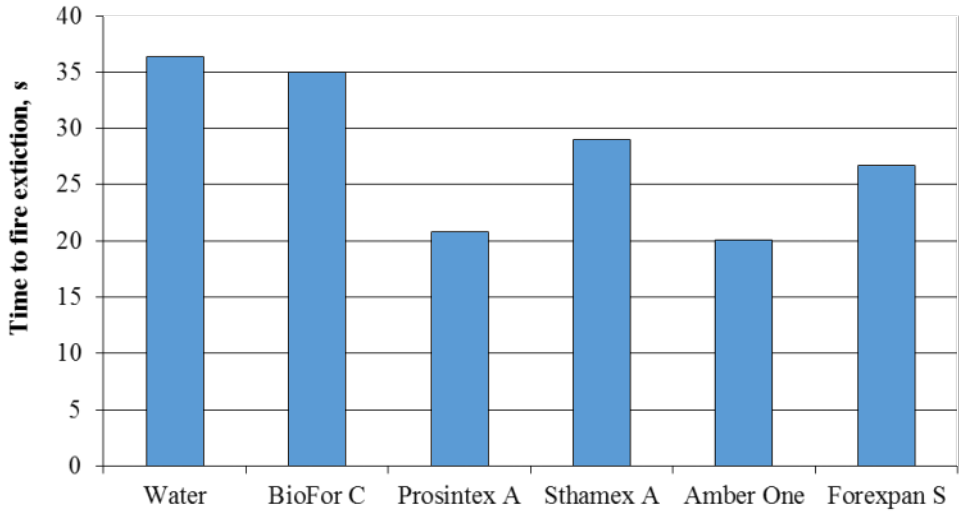

Figure 6. Extinguishing time of test fire 5A [5]

3.5. Retardancy

In the Figure 7 a comparison of delaying time to inflammation of dry peat was presented. Unprotected peat sample has an inflammation time of 25s. After wetting composition treatment inflammation time was extended by 5s (for Biofor C) up to 15s (Forexpan S).

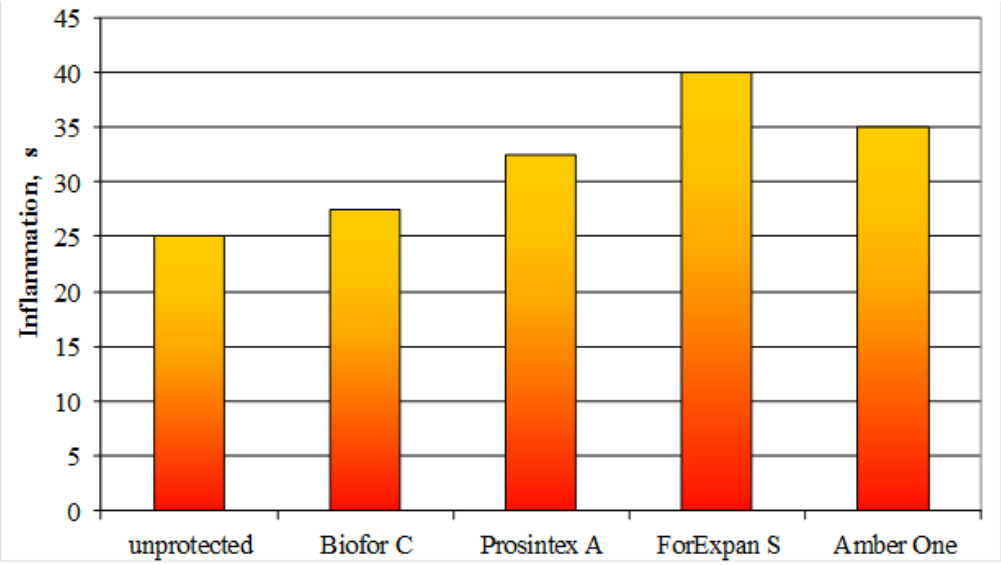

Figure 7. Inflammation time of peat sample

Conclusions

- Wetting agents added to water for lowering surface tension and improving wettability. The foaming of extinguishing agent for suppression wildland fire should not be so high like to agent used to extinction for liquid fuel.
- The use of wetting agents reduces the time to extinguish the fire and delaying burnback.
- Wetting agents can be used as a short-term retardants.
- Application of the wetting agent helps to reduce the size of burnt areas of forest and decreases the number of fatalities, as well as material and ecological losses.

Chapter 6
Forest Management

A fire effects index for overall assessment of wildfire events in Greece

Kostas Kalabokidis, Palaiologos Palaiologou, Nikolaos Athanasis

Department of Geography, University of the Aegean, GR-81100 Mytilene, GREECE.
kalabokidis@aegean.gr

Abstract
Greece is faced with increased wildfire activity on an annual basis. Large-scale wildfires along with limited economic resources do not allow application of rehabilitation measures for the vast majority of burned areas, and when restoration takes place it is not based on sound scientific evidence. A scientific approach is missing based on wildfire classification and overall assessment of fire effects. Severity of a wildfire is perceived by the authorities only from the total area burned. These facts prompted our research thoughts about the need for introducing a new ranking method that will be based on expert judgment, with scientific evaluation of what has happened and what it is expected to occur based on several fire related aspects and parameters. The backbone of our proposed Fire Ranking and Effects Index (FIRE Index) is the Analytical Hierarchical Process (AHP) that is used to combine the scores of seven categories and 56 criteria that comprise them. These categories form two groups of effects: Environmental Fire Effects with three categories (Landscape and Vegetation; General Environment Impacts; Regeneration Potential/Vegetation Recovery); and Socioeconomic Fire Effects with four categories (Casualties and Fatalities; Destructions/Damages on Infrastructure; Economic Losses; Firefighting/Wildfire Confrontation). Each of the 56 criteria, along with four different general multipliers, describes a different anticipated fire effect. The magnitude of the effects is estimated by one or more persons/ assessors in a multi-level evaluation procedure. Then, AHP pair-wise comparisons are applied in two levels, i.e. within the criteria of each category and among the seven categories. Weighted scores of criteria are summed and normalized in a 0-100 scale; and the same procedure is applied on categories to calculate the final FIRE Index value. End-users are thus able to estimate the FIRE Index in a user-friendly, web-based platform that provides all the necessary feedback and literature justification, while conducting all the necessary calculations in the background.

Keywords*: Wildfire Effects Evaluation; Analytical Hierarchical Process; Fire Index; Greece*

Introduction

Increased frequency and intensity of wildfire events for the past two decades in the Mediterranean Basin resulted in millions hectares of burned land, causing hundreds of fatalities and extensive losses on socioeconomic and natural resources (Moreira *et al.* 2011). There are several explanations for this large wildfire breakout, ranging from climate change (Trigo *et al.* 2006; Founda and Giannakopoulos 2009) to socioeconomic reasons, but it is generally agreed that human activities is the main cause for their geometrical increase (Pausas 2004). Either from arsons, negligence or need, the human-ignited fires are constantly destroying forest lands, accelerating phenomena such as erosion, desertification, land use changes, species extinction and degradation of the natural environment (Shakesby and Doerr 2006; Pausas *et al.* 2008; Moreira *et al.* 2011). Furthermore, the cost of rehabilitating the landscape, repairs on infrastructures and properties and economic compensations burden the national budgets (Butry *et al.* 2001; Steelman and Burke 2007). Societies are forced to spend vast amounts of economic and human resources to confront these events and to mitigate their catastrophic effects. Inability of evaluating each wildfire event from the importance of the causing effects usually leads to overestimate or underestimate of the real situation that emerged after the event, resulting in enforcing either a wrong recipe for post-fire management or do nothing.
Our proposed Fire Ranking and Effects Index (FIRE Index) in this study adds to the current fire effects evaluation procedures a comprehensive methodology that allows the classification of wildfires based

on an evaluation of multiple fire effects categories and criteria. Its primary evaluation principle considers the social perspective of wildfires, by incorporating into the evaluation procedure a logic derived from how people understand fire effects during their lifetimes. The social perspective of wildfires dominates most of the criteria but co-exists with the ecological perspective of others. In the case of a conflict between those two approaches, the social always prevails. The above indicate that the assessor must rate the criteria based on what is important for human beings and societies, as well as, how they understand and experience ecology and environment.

Materials and Methods

The main tools used for the conceptual design and implementation of the proposed FIRE Index are based on approaches and applications used to estimate and assess burn severity and first order fire effects on the field (Composite Burn Index - CBI) from Key and Benson (2006); in conjunction with ranking the academic performance of world universities (The World University Rankings - Thomson Reuters[1]). The backbone of the ranking method among the different fire effects is the Analytical Hierarchical Process (AHP) (Saaty 1977). The FIRE Index has been designed for fire events that occur in Greece, but, given the necessary modifications and inputs can be expanded to other countries and regions.

The first level of wildfire evaluation is the *Fire Effect Category* (FEC: seven in total). Each category is composed of *Criteria* (56 in total). Each criterion has its own set of *Choices*, defining the magnitude of fire effects it describes on a scale of 0 (No effect) to 100 (High effect) (Table 1). The choices for each criterion were derived by the detailed study of the relevant local and international literature (wildfire and ecology studies) for several wildfire incidents as well as from the knowledge and experiences gained from several case studies across Greece. These choices portray the significance of the effects and outcomes caused by the wildfire. The assessor has the ability to provide any value through the predefined scale, with the exception of those values for certain choices that have been excluded or are not available by the initial criterion design. For example, if a criterion has two available choices that can both describe a certain fire effect with values 100 and 60, then the assessor can choose either the middle values of the two choices (80) or, a value that is closer to one choice depending on his judgment for the current situation (70 or 90).

Table 1. Fire effects evaluation scale from 0 (none) to 100 (high)

No Effect		Low		Moderate		High
0	10	20	40	60	80	100

Two criteria were assigned with *Additive Terms* (AT) that can aid in a more detailed description of the fire effects. The criterion score is modified by the AT value, but, eventually the final score will fall in the range of 0 to 100, due to an average estimation of the scores. For example, a forest under protection status will receive the highest value if it is an old-growth forest that comprises more than 50% of the burned area. Another concept in the evaluation procedure is the *Criterion Descriptor* that allows the attribution of a percentage value to each choice to achieve a better description of what has happened on a landscape level. For example, the assessor can describe the percentage of area occupied by pine trees or other vegetation types, achieving a more detailed allocation of the criterion value. The sum of all the values of criterion descriptor should not exceed 100%.

Some of the FEC's (five out of seven) were assigned with a *General Multiplier* (GM) that is evaluated on a scale of 0.5 to 3 having a 0.5 interval. These GM's were derived from evaluation of important

[1] http://www.timeshighereducation.co.uk/world-university-rankings/2013-14/world-ranking/methodology

wildfire attributes and characteristics, such as fire size, ecological condition and protection status, and post-fire vegetation condition. They provide the ability to decrease (by selecting a value from 0.5 to 0.9), keep it the same (values equal to 1) or increase (values greater than 1) the overall FEC score based on the assessor's answer. AT's were also assigned to two GM's and their value is defined by the average of all answers. The majority of criteria and multipliers can be evaluated by simply selecting one from the available choices or provide a user defined score; but there are some that have a particular logic behind them that it is noted in their description.

Prioritization of Categories and Criteria

For each category and criterion, weights were derived to achieve a prioritization among them based on their relative importance at the category and final index levels, by using the AHP method developed by Saaty (1977). Initially, a pair-wise comparison matrix is designed (Equation 1), where the relative importance between two criteria is measured according to a numerical scale from 1 to 9, where 1 denotes equal importance and 9 denotes that the first is absolutely more important than the second criterion.

$$A = \begin{bmatrix} 1 & a_{12} & \cdots & a_{1n} \\ a_{21} & 1 & & a_{2n} \\ \vdots & & \ddots & \vdots \\ a_{n1} & a_{n2} & \cdots & 1 \end{bmatrix} \qquad (1)$$

where, $\alpha_{jk} = 1/ a_{kj}$ and k,j = 1, …., *n*.

Once the matrix is built, it is possible to derive a normalized pair-wise comparison matrix (i.e. A_{norm}) by making equal to 1 the sum of the entries on each column. Each entry $\bar{a}_{jk}$ is computed by Equation 2:

$$\overline{a}_{jk} = \frac{a_{jk}}{\sum_{l=1}^{m} a_{lk}} \qquad (2)$$

Then, the criteria weight vector w (that is an m-dimensional column vector) is built by averaging the entries on each row of the A_{norm} matrix with Equation 3 (results were checked to ensure that they are consistent):

$$w_j = \frac{\sum_{l=1}^{m} \bar{a}_{jl}}{m} \qquad (3)$$

To conduct all the necessary calculations for the final FIRE Index estimation, the calculation of all criteria and multipliers scores is required. Each criterion is weighted and then summed with the others from the same category. If a GM exists, it is applied on the weighted sum. Then, a normalization of the outcome is performed on a scale of 0 to 100 by using the higher and lower value that each category can achieve with the Equation 4:

$$x_i = \frac{(R_i - R_{min})}{(R_{max} - R_{min})} * SR \qquad (4)$$

where, R_i is the outcome weighted value of the category i, R_{min} and R_{max} are the lower and higher values respectively the category can achieve, and SR is the standardized range.

Finally, the value from each of the seven categories is also weighted and then summed with the others to derive the final FIRE Index value on a scale of 1-100.

Results

Categories and Criteria of Fire Effects

By studying several wildfire case studies that occurred during the past 40 years in Greece, seven general wildfire effects categories were derived, forming two groups: the Environmental Fire Effects (Figure 1) and the Socioeconomic Fire Effects (Figure 2). The first fire effects category is the "Effects on Landscape and Vegetation" and examines the wildfire consequences on the landscape in terms of air quality and soil condition. It also examines the vegetation type, rarity, protection status based on a social perspective of the prioritization of forest resources. It is composed by five criteria and one GM. Initially, the assessor must define the landscape type in which the wildfire took place, by choosing among flat terrain/agricultural land, highlands, wildland-urban interface and mountainous areas. Then, in the criterion "Dominant Land Use/Land Cover types" (LULC), the vegetation composition inside the burned area is defined by providing the percentage estimation of its cover. The available choices are: bare soil; grass or short shrub; shrubland; agricultural land or orchard; mixed or broadleaf forest; and conifer forest. Then, the percentage fraction provided for each choice is multiplied by its relevant score. If the choices involve either "Mixed/Broadleaf forest" or "Conifer forest", then the two AT are activated, defining the vegetation types that exist inside the fire perimeter. For the case of mixed/broadleaf forest types, the available choices are: *Quercus* spp. or *Olea sylvestris*; *Fagus* spp. or *Juglans regia* or *Castanea* spp. or Cold Climate Broadleaf Evergreens; and mixed conifer/broadleaf forest. For the case of conifer forest types the available choices are: *Pinus brutia* or *Pinus halepensis*; *Juniperus* spp. or *Cupressus* spp.; *Pinus nigra* or *Pinus pinea*; and *Abies* spp. or mixed Fir/Pine forest or *Pinus sylvestris* or *Pinus heldreichii*. The assessor must provide the type of each forest and, depending on what is chosen, the AT score is multiplied by the fraction of cover for this particular LULC, summed with the initial LULC score and then averaged. The final criterion value is derived by summing the scores of each LULC type, including the average values derived by the possible usage of AT.

The next criterion defines if the burned area is under Greek or international conservation and protection status of forested areas and on what percentage it is inside the fire perimeter. The choices are: lake or seashore forests; recreational forests; national parks; and old-growth forest. If the assessor chooses a value different from "None" (which means a zero value for the criterion), he must then define the percentage that this protected area type is occupying inside the burned area. The two scores are then summed and averaged to derive the final criterion value. The effects on air quality are defined by providing information that describes the size and type of the affected populated areas and to what extent (Sastry 2002; Vedal and Dutton 2006). The available choices are: away from settlements; small-scale visibility reduction and smoke impacts near small villages; visibility reduction inside medium/large sized populated areas; and severe smoke impacts inside medium/large sized populated areas. Finally, the last criterion describes the probabilities to occur land degradation, erosion and soil losses phenomena (none; low; moderate; high) (Robichaud 2000; Parsons *et al.* 2010). The assessor must also define the percentage of area that is expected to have those probabilities. The percent fraction is then multiplied with the score of each choice and summed to derive the final criterion score. Upon the completion of the above criteria, the size of burned area must be defined to act as the category's GM. Based on a detailed study of the frequency, size and number of fire events on Greece, the available choices are: fire size <10 ha; 10 to <100 ha; 100 to <500 ha; 500 to < 2,000 ha; 2,000 to <7,000; and >7,000 ha.

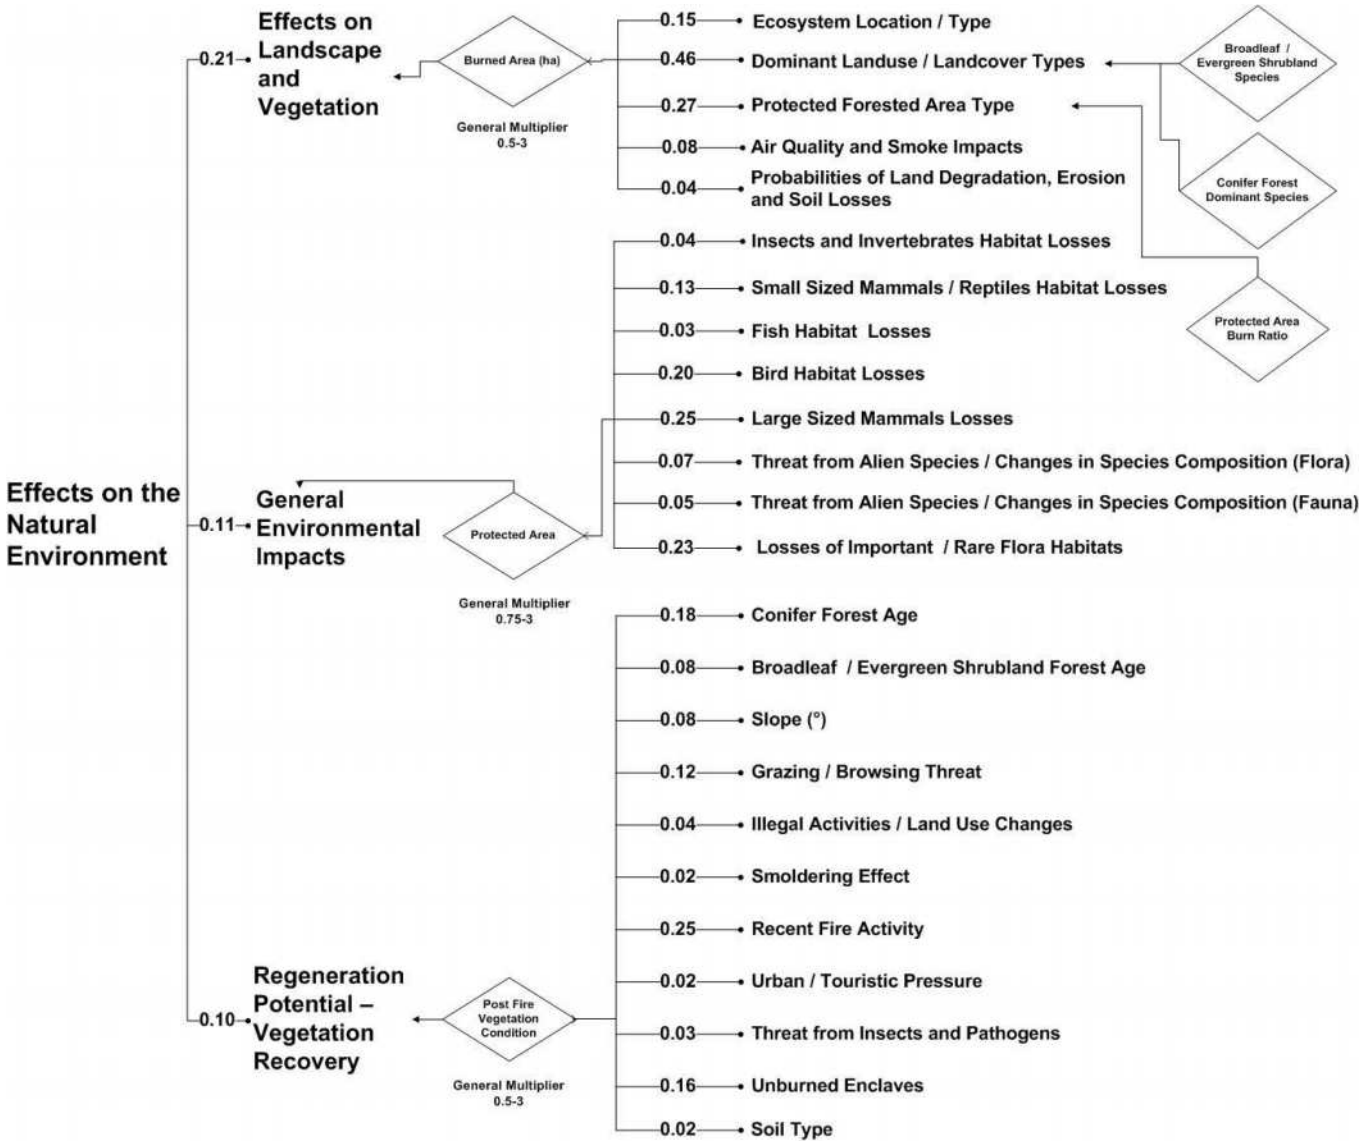

Figure 1. Structure of criteria and categories with their attributed weights for natural environment fire effects evaluation

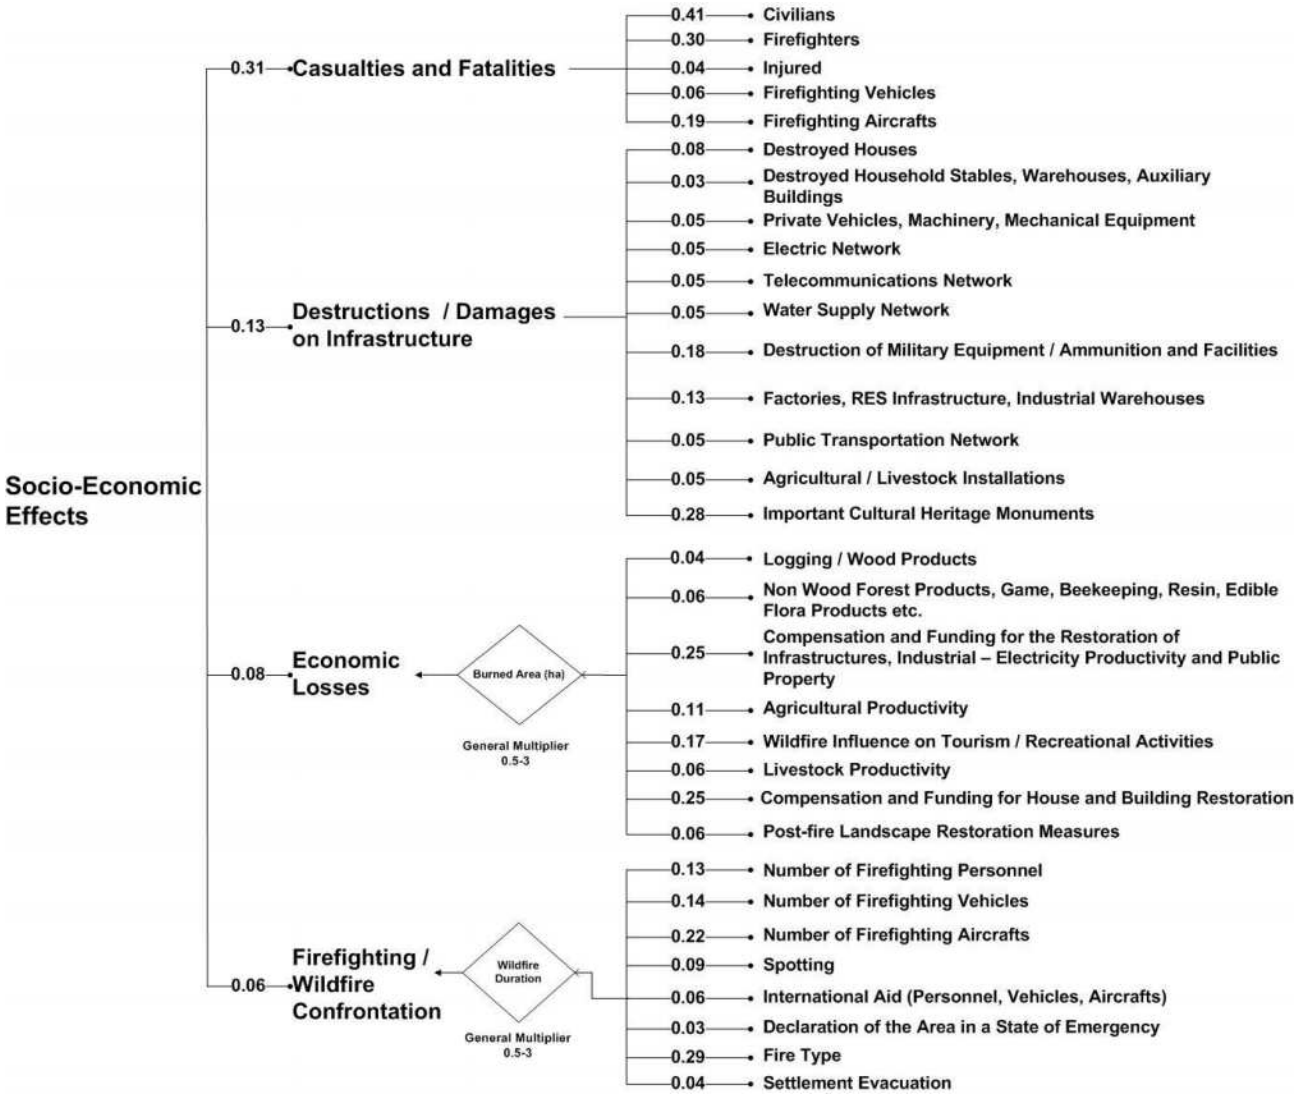

Figure 2. Structure of criteria and categories with their attributed weights for socioeconomic fire effects evaluation

The second category is the "General Environmental Impacts" that evaluates the wildfire effects on the fauna and flora of the affected area, as well as on the environmental quality and biodiversity. It is composed of eight criteria and one GM. Initially, the assessor must define the losses (if any) on important fauna habitats for five criteria (insects and invertebrates; small mammals/reptiles; fish; birds; and large-size mammals) (Smith 2000). The available choices are: none; few; several; and extended. The assessor must, prior to any judgment, acquire knowledge about the species composition of the area, their vulnerability to wildfires, their projected population response, their rarity and the extent of their habitat on the broader area. The sixth criterion evaluates the losses and possible endangering of important/rare flora species (Phitos *et al*. 1995; Brown and Smith 2000; Georghiou and Delipetrou 2010). The available choices for the assessor include: zero losses due to the lack of important/rare species; few losses with regeneration potential; extended losses with alteration on habitat conditions and strong population stresses; and intense, with possible species extinction or disappearance from the area. The next two criteria estimate the threat for exotic species invasion or the modification of the current abundance of local fauna and flora species. The available choices for both criteria are: none; local; extended; and intense. The assessor must gain knowledge about possible exotic species/invaders that reside inside or adjacent to the affected area that can encroach into it and to estimate if there will be any changes in species abundance and composition (Vitousek 1990; D 'Antonio and Vitousek 1992; Daehler and Strong 1994; Wilcove *et al.* 1998; Pimente 2002). Finally, one GM with an AT will define if the affected area is under any protection status and to what extent (Dimopoulos 2005; Mazaris *et al.* 2008). The available choices for the assessor are: none; wildlife habitats/NATURA 2000 areas; protected natural areas; areas of complete and strict protection; and biogenetic/biosphere reserves. If the choice is different than "None" (score = 1), the percentage of burned area that belongs to the selected type should be defined on the AT. The two scores are summed and averaged to derive the final GM score.

The third category is the «Regeneration Potential/Vegetation Recovery» and examines the fire behavior, pre-fire landscape and vegetation conditions, fire history and human pressures on the affected area. It is composed of 11 criteria and one GM. Initially, the assessor must define the age of conifer species that existed in the area prior to the fire (if present). The available choices are: not applicable; >100 years; 60-100 years; 20-60 years; 15-20 years; and <15 years. It is assumed that the younger the conifer forest is the more difficult it is to regenerate (Thanos and Daskalakou 2000; Tapias *et al*. 2001; Ne'eman *et al.* 2004; Climent *et al.* 2008). In the second criterion, the age of broadleaf species/evergreen shrublands must be defined (if present). The available choices are: not applicable; 10-15 years; 15-20 years; 20-60 years; 60-80 years; and >80 years or <10 years old. It is assumed that the older (or very younger) the broadleaf forest/evergreen shrublands is the more difficult it is to regenerate (Johnson and Godman 1983; Stroempl 1983). For these two criteria, it is important to define the age of the dominant vegetation types across the landscape instead of a detailed approximation at a stand level. The next criterion describes the topography of the area in terms of slope, and the assessor must calculate and provide information about the portions of the landscape that have a certain slope choice. The available choices are: 0-5°; 5-10°; 10-15°; 15-20°; 20-30°; 30-45°; and >45°.

The imminent threat from grazing must be evaluated by understanding the amount of livestock that resides inside or on the periphery of the burned area. It is assumed that as the grazing is increased in frequency and range, the conditions for potential successful vegetation regeneration are dramatically reduced (Perevolotsky and Haimov 1992; Campbell and Donlan 2005). The available choices are: none; partial; extended; and intense. The recent fire activity is an important parameter that has a substantial effect on regeneration. It is assumed that there are more chances for a successful regeneration if the fire return interval is large (Agee 1990). The available choices are: >100 years; >50 years; >30 years; and <30 years. It is frequent that post-fire vegetation recovery is depended on unburned forest patches and individual trees, providing a seed bank to colonize and repopulate the burned area, and it is assumed that the more dispersed and abundant these unburned patches are, the better is for regeneration (Lentile *et al.* 2005; Arianoutsou *et al.* 2010). The available choices are:

many (dispersed); many (gathered); few (dispersed); few (gathered); none. Illegal activities that may cause land use changes or interference into formerly vegetated areas can have a substantial negative effect, so the assessor must identify if there is any evidence that such activities have happened in the past (e.g. illegal logging, construction of buildings, roads and houses, conversion of forests into agricultural lands, etc.) (Tacconi *et al.* 2003). The available choices are: none; partial; extended; and intense. Another important criterion is the influence humans can have into the burned area by applying urban or touristic pressures. This can usually take the form of frequent tourist trips into the burned forests and people visits for recreational activities (Kuvan 2005). These pressures are usually performed into the wildland urban interface environment (Atmiş *et al.* 2007). The available choices are: none; partial; extended; and intense.

Fire smoldering effect can cause serious implications in vegetation recovery, mainly by modifying significant soil properties that prevent seeds from growing or resprouting (Ryan and Noste 1985). The assessor must have evidence if smoldering has happened and to what extent. The available choices are: none; partial; extended; and intense. Another important threat is the outbreak of diseases or harmful insect's population expansion that can cause negative effects on areas that survived the fire (de Dios 2007; Hansen 2008). Often, seeds and genetic material is transferred from these areas to other nearby burned parts, colonizing the landscape and reestablishing vegetation. If those surviving areas or individuals are affected, then the process of forest regeneration can be halted or lead to vegetation alterations (Winder and Shamoun 2006). The available choices are: none; partial; extended; and intense. Finally, the soil type plays an important role on resprouting and seed germination ability. This criterion assumes that deep soils with small amount of rocks are more preferable compared to shallow skeletal soils (steep slopes or exposed parent material) (López-Soria and Castell 1992; Minotta and Pinzauti 1996; Spanos *et al.* 2001). The available choices are: deep soils with small amount of rocks; deep soils with moderate amount of rocks; moderate depth soils with small amount of rocks; moderate depth soils with moderate amount of rocks; shallow soils with moderate amount of rocks; and shallow exposed soils with large amount of rocks. The GM is composed of three parts that must be evaluated and averaged. In particular, the assessor must define the percentage of burned, scorched and unburned vegetation (black, brown and green), in a similar way to CBI estimation for the overstory vegetation condition (Key and Benson 2006). The sum of the percentage choices from the three answers should not exceed 100%.

The main operational priority for most firefighting agencies across the world is focused on the protection of civilian and personnel lives, followed by the protection of firefighting infrastructure, properties and the natural environment. Societies often evaluate the importance of a wildfire from the number of fatalities it has caused and the total burned area (Haynes *et al.* 2010). Thus, a category with criteria able to estimate what has happened in terms of casualties is extremely important. The category «Casualties and Fatalities» determines the human death toll caused by the fire, along with the number of injured individuals and the number of destroyed firefighting vehicles and aircrafts. This category is composed of five criteria; three of them describe the fire effects on human lives and two on firefighting infrastructure. The last two criteria were selected for that they are caused due to the operational activities of firefighting forces and can be seen as causalities (Mangan 2007).

To include the proper choices on each criterion, a detailed study on the number of fatalities caused during the past 40 years from fire events across Greece was conducted. The available choices for the civilian fatalities criterion are: 0; 1; <5; 5 to 10; and >10. The available choices for firefighting personnel deaths criterion are: 0; 1; 2 to 3; 4 to 5; and >5. Usually, the firefighting personnel losses are less compared to civilians from a single fire event. The available choices for injured people criterion are: 0; 1; <5; <10; 10 to 20; 20 to 30; and >30. It is more common to have destroyed firefighting vehicles compared to aircrafts, thus, the available choices for firefighting vehicles losses criterion are: 0; 1; 2; 3; 4 to 5; and >5. Finally, the available choices for firefighting aircraft losses criterion are: 0; 1; 2; and >2.

The fire effects Category «Destructions/Damages on Infrastructure» is composed of 11 criteria and estimates the magnitude of destructions and damages caused by the fire event on property, public infrastructures, monuments and capital. Initially, the assessor must provide data regarding the destroyed houses due to the fire activity, providing their absolute number by selecting among these choices: 0; 1; 3; 5; <10 and >10. Based on the same logic, the number of destroyed household stables, warehouses or auxiliary buildings must be provided by selecting among these choices: 0; 1; 3; 5; <10; <20; and >20. The following eight criteria are evaluated based on their repair or acquisition cost. The assessor must provide estimation of the cost required to replace or restore this infrastructure to its pre-fire working condition. The third criterion estimates the fire damage cost caused on mobile property such as cars, machinery and other equipment. For the next four criteria, the fire damage cost on transportation, electric, water supply and telecommunication networks is estimated. The available choices for the above criteria are: no damages; minor costs <15,000€; small cost <30,000€; medium cost <100,000€; and important high cost damages >200,000€. The next three criteria examine the cost of damages on military facilities, ammunition and equipment; on factories, renewable energy sources (RES) installations and industrial warehouses; and on Agricultural/Livestock installations. The available choices for the above criteria are: no damages; minor costs <50,000€; small cost <100,000€; medium cost <200,000€; and important high cost damages >300,000€. Finally, it is very important to assess if there were any damages or destruction of important cultural heritage monuments, and if so, the assessor must select a monument category that is based on time. The following choices are available: no damages; recent monuments aged <200 years; historic monuments aged >200 years; and world heritage sites and monuments.

The category «Economic Losses» accounts for the changes that are expected to occur on the local or regional economic structure, emphasizing on the market price drop of some valued items/products, the inability to produce or collect them and the amount of money that will be spent for productivity restoration or compensations (Donovan and Rideout 2003; Calkin *et al.* 2007). It also estimates the relative cost of post-fire landscape treatment measures that are going to be applied on the affected area. The main difference with the previous category is that it does not just account the costs of damages and destructions the fire has caused, but the cost of anticipated rehabilitation measures and future economic losses. It is composed by eight criteria and one GM.

Initially, the assessor must provide information about the timber production and wood harvesting practices of the affected area. If the area was under a management status with frequent or upcoming timber harvesting then it is very probable that some kind of economic losses might occur. Several individuals or industries exploit the non-timber forest/nature products, such as game, honey production, resin extraction, pharmaceutics and medicine products, wild food, etc. These lead to the development of a small scale local or regional economy around these activities. The assessor must evaluate which were the fire effects on them and if economic losses have already happened or is expected to occur in the future. In Greece, it is very often for a wildfire to cause negative effects on agricultural and livestock production (Henderson *et al.* 2005; Moreira *et al.* 2011). This is usually done by destroying the means to produce income from these activities (animal deaths, burning of crops or orchards, destruction of infrastructure such as greenhouses, etc.). The cost includes possible compensations and future revenue losses from the inability to produce (e.g. in case of destroyed orchards). The assessor must assess those costs for these criteria. The available choices for the four criteria are: non productive area; minor; small; moderate; high economic losses; and total destruction. To restore the industrial and electric production, or to repair infrastructures and public property, compensations or funding must be paid from the state or insurance companies, otherwise negative effects can arise for the whole society. The same applies for houses and buildings. The available choices for these two criteria are: no cost; minor; small; moderate; and very high costs. The next criterion assesses the fire effect on tourism by evaluating the aesthetic, recreational and tourist infrastructure potential of the area (Kuvan 2005). The assessor must understand how large the touristic value of the area is and what kind of activities take place in the broader affected landscape. A link

must also be established between the values of the burned area and how important is for selecting it for tourist purposes, along with the predicted economic losses it might be caused. The available choices are: non touristic area; seashore related tourism area, scenery landscape close to intensely developed touristic areas; and forested area used for recreational/touristic purposes. The last criterion estimates the cost of landscape rehabilitation measures that are expected to be applied on the affected area. Usually, the type and range of their application depends on the available money the state is willing to spend. It is assumed that as the type changes and range of application increases, so does the cost (Napper 2006). The available choices are: no measures; small; medium; or high scale reforestations/counter-erosion/counter-flooding measures. Finally, one GM will define the size of burned area, assuming that as the fire size increase so does the overall economic losses.

The last category is the «Firefighting/Wildfire Confrontation» and evaluates the wildfire effects caused during firefighting activities and the wildfire confrontation strategy implemented. The category is composed of eight criteria and one GM, defining the general firefighting context and its operational costs. Furthermore, it considers the equipment and machinery wear, as well as the personnel fatigue. In the first criterion, the assessor must describe the fire behavior type that occurred in the majority of the burned area. This information can be derived either from observations or from the firefighting personnel. The available choices are: surface fire; torching/ passive crown fire; and active crown fire. Next, it must be defined if any spotting of fire re-bursts occurred. The available choices are: none; few; constant. The next three criteria count the number of people and vehicles that participated during the firefighting operations, to figure out confrontation difficulty. The available choices for the number of people/ firefighting personnel are: <10; 10-24; 25-39; 40-54; 55-70; and >70. The available choices for the number of ground vehicles are: 1-4; 5-9; 10-14; 15-19; 20-25; and >25. The available choices for the number of firefighting aircrafts are: 0; ≤2; 3-5; 4-5; and >5. All the above choices were derived by the study of several past wildfire events of Greece and are in proportion with their severity and confrontation costs. The international aid and reinforcements on personnel, vehicles and aircrafts add substantially to the firefighting operations, but is an indicative fact of the wildfire suppression difficulty, as well as of the costs associated with them. The available choices are: none; personnel; vehicles; and aircrafts. The declaration of the area in a state of emergency has two options (either no or yes), and is another indicative criterion of the wildfire difficulty. The evacuation of settlements adds a very complex parameter in the whole operation, increasing the costs and difficulty of operation. The available choices are: none; <2; 2 to 5; and >5 settlements. Finally, the category has one GM which accounts for the fire duration, providing the following choices: 0-2; 3-15; <24; <48; <72; and >72 hours.

3.2. Web-Based Software Architecture

To easily calculate and account for the complex interactions between and among criteria and categories, it was necessary to design a web-based software/ platform that will enable the assessor to provide inputs in a user-friendly Graphical User Interface (GUI), thus automating the calculation procedures and return the intermediate and final FIRE Index values (Figure 3). Furthermore, users can instantly test several different choices and options and understand their influence on the final index value (Figure 4). A detailed help section exists inside the GUI covering all the aspects of the methodology, providing explanation and documentation about what is being evaluated and the logic behind the available provided choices.

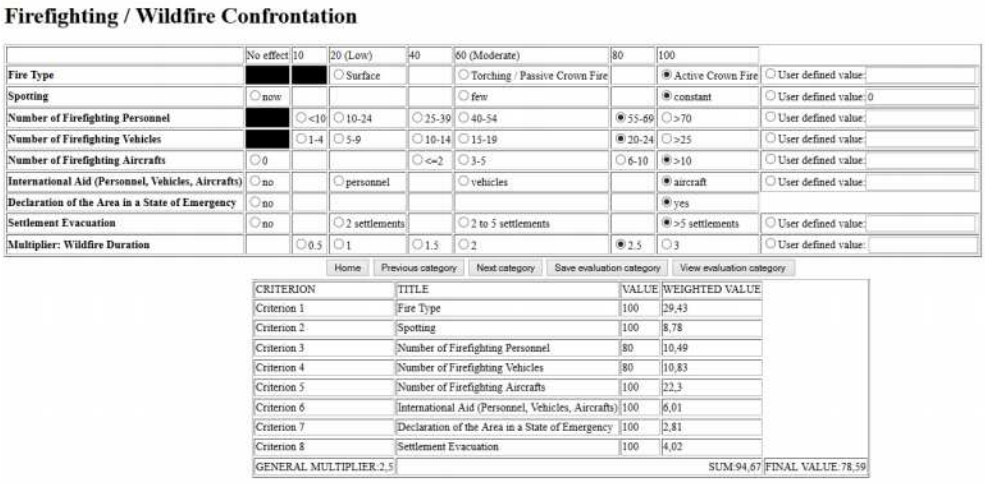

Figure 4. Web-based fire effects evaluation for the firefighting/wildfire confrontation category

Discussion and Conclusions

This version of FIRE Index is the first and has the primary goal of defining an evaluation context by creating a hierarchy among the categories, criteria and choices and by setting the rules that determine the combination of scores. Given its limitations and assumptions, the FIRE Index attempts to reveal an aspect of reality that allows people to evaluate possible scenarios that might happen in the future or to better understand what is been happening during the present time or to discover what has happened in the past. The FIRE Index does not portray or explains with full detail all the complexity, interrelationships and multivariate range that appear after a wildfire but, rather, it can quantify and

record systematically what has happened for a large number of fire effects, while for some others can estimate what is going to happen.
There is a large number of criteria, AT's and GM's (approximately 1/3 of the total number) that can be evaluated by providing spatial data together with their descriptive information. The usage of Geographic Information Systems (GIS) in a next version of the FIRE Index can perform the necessary spatial queries and interactions that are required to provide answers for several criteria. For example, the size of burned area and their boundaries can be provided in a very short time after the wildfire event by EFFIS[1]. These data can be used to derive information from other spatial layers such as the LULC types or the location of protected areas. Spatial data from satellite products or other study methods (such as burn severity, erosion and soil type maps) can also be included in the process if they are provided. The assessor then just has just to accept, reject or apply corrections on the derived choices.
There are several limitations and assumptions in the FIRE Index evaluation context. The main assumption is that each fire effect can be evaluated by a single criterion that has predefined choices on a scale from 0 to 100, thus providing a numerical value for its significance. This is not a problem for criteria like "Burned Area", but for example applying scores on fatalities may cause misinterpretations, disagreement and confuse. However, choices were derived from detailed studies of hundreds of fire events. The way those choices have been placed on the scale is more a descriptive/ qualitative approach rather than a numerical one. The current approach scales the choices from lower to higher impacts, and thus, the assessor should rate them with this logic. The numerical values are used primarily for the calculations, but their meaning lies on the way the assessor chooses them on the predefined scale. Another assumption that has been made for the "Destructions/Damages of Infrastructure" category, where there are several criteria on which a market value has been applied. The main limitation on this approach is that the total damage cost can greatly exceed the predefined choices and the assessor is limited on the higher ranked choice, without the ability of inserting this extra amount on the procedure. The evaluation context of the FIRE Index is designed to catch the variability between and among the different wildfires and not to actually portray everything that has happened and with absolute detail. The last assumption, that is simultaneously a limitation, is the usage of AHP method to derive criteria and categories weights. The AHP method requires user inputs to set a hierarchy among criteria and categories, thus, it is vulnerable to subjective judgment. Different people can consider differently their importance and this will lead to alterations in weights. The AHP was evaluated by the authors of this study by considering the social perspective of fire effects as the most important issue that determines the FIRE Index value, followed by environmental and economic perspectives.
By combining the scores of criteria for each category and by producing a total score for the wildfire event, public authorities and societies will be able to understand if during this event more or less serious effects have happened to one or more environmental and socioeconomic attributes; an approach that is beyond a simple measure of the burned area. This will allow a shift to occur in the current perspective of wildfires in Greece (and maybe elsewhere) and will enable the introduction of a scientific approach in the evaluation of each wildfire. It is anticipated that fire effects will be seen as an overall sum of negative and positive consequences that should be dealt either combined or individually to mitigate their impacts on nature and humans. It will also enhance the public awareness and will provide a comprehensive information source regarding several aspects of wildfires. The FIRE Index will not substitute a thorough study for the wildfire event with well established methods and techniques for the estimation of first and second order fire effects, but, in contrary, it will be enhanced by those studies that can provide the necessary inputs, with scientific evidence, and increased detail and accuracy.

Abstract
Classification and mapping of wildland fuel is one of the most important factors that should be taken into consideration for wildland fire prevention and planning. In this paper we demonstrate the accuracy assessment of "ArcFUEL" project which has delivered a complete, up-to-date, methodology for Fuel Classification Mapping (FCM on a Web-Geodatabase) based on "readily available" data, harmonized, accessible & interoperable according to INSPIRE principles, for the Mediterranean Region. The fuel layer has been evaluated in terms of spatial and thematic thematic accuracy by employing an extensive field campaign in Portugal and Greece and standard photointerpretation procedures. For Greece, the overall accuracy was found to be 80.59 % , while the Kappa value was 0.74. For Portugal the overall accuracy was found to be 67% and the Kappa value was 0.63.The spatial fuel maps is an end-product essential for computing spatial fuel hazard, fire risk and simulation, fire growth and intensity and post fire effects across a landscape at national and regional scale.

Keywords*: Fuel Mapping, Fuel Management, Accuracy Assessment, Greece, Portugal, Fire Management*

Introduction

Increased wildland fire activity over the last 30 years has had profound effects on budgets and operational priorities of the Forest Service, Civil Protection agencies, Fire Service and local entities with wildland fire responsibilities in Mediterranean Basin. Both the number and the average size of large fires have shown an increasing trend over the last several decades causing extensive financial and ecological losses and often human casualties (Dimitrakopoulos and Mitsopoulos 2006). Mediterranean region is also considered a ''hot spot'' for fire studies, not only because of its high sensitivity to changes in recent decades such as processes of rural depopulation, land abandonment and reduction of traditional forest use but also for the reason that according to the majority of climate models the most likely evolution of this region is towards a hotter and drier climate, with a significantly higher risk of intense heat wave episodes as well as an increase in fire hazard and occurrence (Giannakopoulos *et al*. 2009; Dimitrakopoulos *et al*. 2011; Koutsias at al. 2013).
Fuel maps are an essential tool in fire management since they characterize, in a landscape level, the only factor that fire and land managers can control over many scales – fuel parameters. Coarse resolution fuel maps are useful in global and national fire and fuel hazards assessments because they help fire managers effectively plan, allocate, and mobilize suppression resources (Burgan *et al*. 1998). Regional fuel maps are useful as inputs for simulating fire behavior, fuel consumption, carbon release, smoke dispersion scenarios, as well as for describing fire hazards to support fire suppression and resources deployment (Leenhouts 1998; Leinhan *et al*. 1998). Medium and fine-resolution fuel maps are important for proposing and evaluating tactical fuel treatments, assessing fire hazard and risk, helping in environmental assessments and computing fire danger (Gonzalez *et al*. 2007). However, landscape-level fuel maps have been proved the most appropriate in fire management because they provide the required inputs for the spatially explicit fire behavior and growth models used to simulate fire propagation (Keane *et al*. 2006).
Many different approaches have been used in order to map wildland fuels (Keane at al. 2001; Arroyo *et al*. 2008). Most efforts have tried to map important fuel characteristics such as the fuel model as a

function of vegetation type (Menakis *et al*. 2000) and topography (Rollins *et al*. 2004) to create spatial layers in a Geographical Information System (GIS). Some researchers have qualitatively or quantitatively related fuel information to various forms of remote sensing data at multiple scales, including digital photographs (Oswald *et al*. 1999), LANDSAT images (Wilson *et al*. 1994), ASTER images (Falkowski *et al*. 2005), AVHRR images (Burgan *et al*. 2005), Quickbird and EO-1 Hyperion (Mallinis *et al*. 2014), microwave-radar images (Arroyo *et al*. 2008), and LIDAR data (Mutlu *et al*. 2008). Other efforts have mapped fuels using statistical modeling techniques coupled with detailed field data and knowledge-based systems (De Vasconcelos *et al*. 1994). Recently, the "ArcFUEL" project delivered a complete, up-to-date, methodology for Fuel Classification Mapping (FCM on a Web-Geodatabase) based on "readily available" data, harmonized, accessible & interoperable according to INSPIRE principles, for the Mediterranean region (Bonazountas *et al*. 2012). ArcFuel utilized many and various ancillary data and delivered a consistent and systematic ex novo methodology and workflow for large scale classification and mapping of forest fuels and production of Fuel Classification Maps.

For many reasons it is difficult to map wildland fuels. The most notable factor that prevent accurate mapping is the high temporal and spatial variability of fuel parameters (Keane 2008). Fuel properties are also highly variable and vary across multiple scales; fuel strata consists of many fuel components, including litter, duff, dead twigs, shrubs, herbs and the properties of each component, such as its heat content, moisture content, and size, can be highly variable even within a single type of fuel. The variability of fuel loads within a stand, for example, can be as high as the variability across a landscape, and this variability can be different for each fuel component and property. The main objective of the current study was to assess and validate the accuracy of the Fuel Types maps developed at national scale in Greece and Portugal using the ArcFuel production chain.

Methods

Plots selection

In order to select the validation dataset in both countries the next steps were followed:

- Selection of LUCAS plots matching to the ArcFUEL classification: Based on SQL queries the LUCAS dataset was separated into two subsets of data, one with the LUCAS points of which the description coincided with ArcFUEL characterization and another with the LUCAS points of which it differed (FPP sample). The first subset was used as part of the ArcFUEL validation data set.
- Selection of plots visited in the field, based on the LUCAS dataset: Based on the first step, a stratified random sampling design (considering minimum representation) was applied in representative regions of the two countries and an additional subset created including a number of plots defined for field visit. This subset included conflicting with ArcFuel, LUCAS points and plots located above 1000m of altitude, which aren't considered in the LUCAS data set. Additional plots were added ad hoc during the field survey based on the fuel types occurring in each region according to the estimation of the surveyors. Field surveys have been carried out by trained personnel through the entire country in Greece and Portugal.

Field work

Field work organized for validating ArcFuel map created for the participating countries. It should be stated that ArcFuel map covering the entire country created only for Greece and Portugal. A proper field data collection protocol was defined and field campaings organized in order to create the appropriate data sets for validating the accuracy of the maps for Greece and Portugal. Although a common protocol was used the field survey implemented based on the use of different data collection

technologies. A extended field campaign for collecting information necessary to validate the accuracy of the ArcFuel map was planned covering all the geographic regions of Greece. A suitable field survey daily plan was elaborated, using GPS routing optimization, for reducing travel distances, minimizing total time required for the data collection and comply with vegetation growth status in the regions visited. A commercial GPS application (Navigon) allows reaching nearby the plot, providing its coordinates. In the plot, a properly developed mobile android application installed in a tablet was used for collecting and storing in-situ the information required for the validation purpose. The information collected is based on observations referred to the description of the vegetation composition and the fuel bed horizontal and vertical structure. The ArcFuel android application provides access to a previously uploaded list of survey plots and their relevant data according to the ArcFuel map. These data are presented in a digital form, in which field data are also recorded, supporting thus a direct comparison between mapped and observed data. The field recorded data are uploaded through the web to a proper server on a daily base. Sample screens of the mobile application are shown in Figure 1. The application is available in the Google play store of android applications.

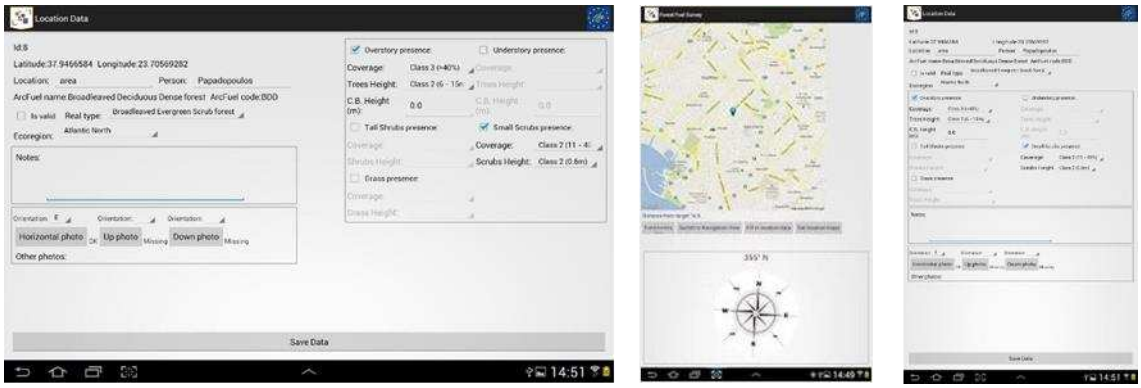

Figure 1. Fuel data collection mobile application of ArcFuel

The field data stored in the server were organized in an on-line data base (http://webservices.g-fmis.com:48080/WebArcfuel/login.jsp) with web interface. Screens of the web interface of the on-line ArcFuel data base of fuel sample plots are shown in Figure 2.

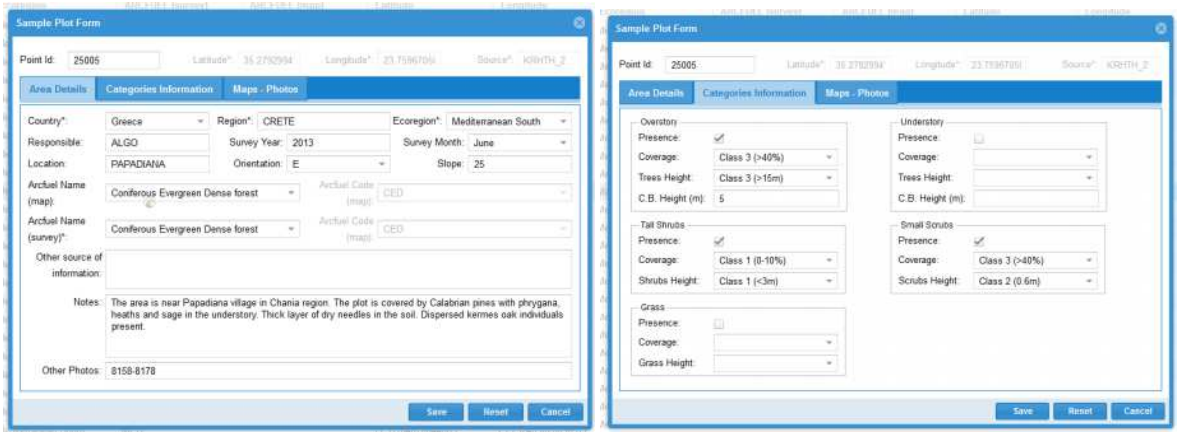

Figure 2. On-line data base of ArcFuel field plots

The data base can be extended with additional data collected in context of relevant forest fuel management campaigns. Thus map validation can be continuous and the ArcFuel mapping accuracy can be improved significantly.

2.3. Accuracy assessment

All the data from the above subsets were aggregated in order to derive the final ArcFUEL validation data set consisting of 1288 points in Greece and 275 in Portugal. In addition, information obtained through photointerpretation of large scale orthophotographs of the KTIMATOLOGIO SA for Greece (http://gis.ktimanet.gr/wms/ktbasemap/default.aspx) which are publicly available through a WMS server and VHR satellite imagery available through Google Earth, was considered along the validation process. During the photointerpretation process, an area equal to 0.25 ha corresponding to the ArcFUEL pixel size, around each point was inspected. To estimate the accuracy of the ArcFUEL map an error matrix was derived. The Kappa coefficient of agreement was also calculated (Fleiss *et al*. 2003). A slightly different methodology was applied in Portugal, deriving the accuracy matrices independently for LUCAS and the remaining field points. Furthermore, three classes that identified "deciduous conifers" during the methodology application were removed from the final analysis as they were considered erroneous a priori. There are no deciduous conifers in Portugal, at least not at a scale that would allow its identification using ArcFUEL methodology.

Results and discussion

For Greece, the overall accuracy was found to be 80.59 % (Figure 3), while the Kappa value was 0.74. For Portugal the overall accuracy was found to be 67% (Figure 4), the Kappa value was 0.63.

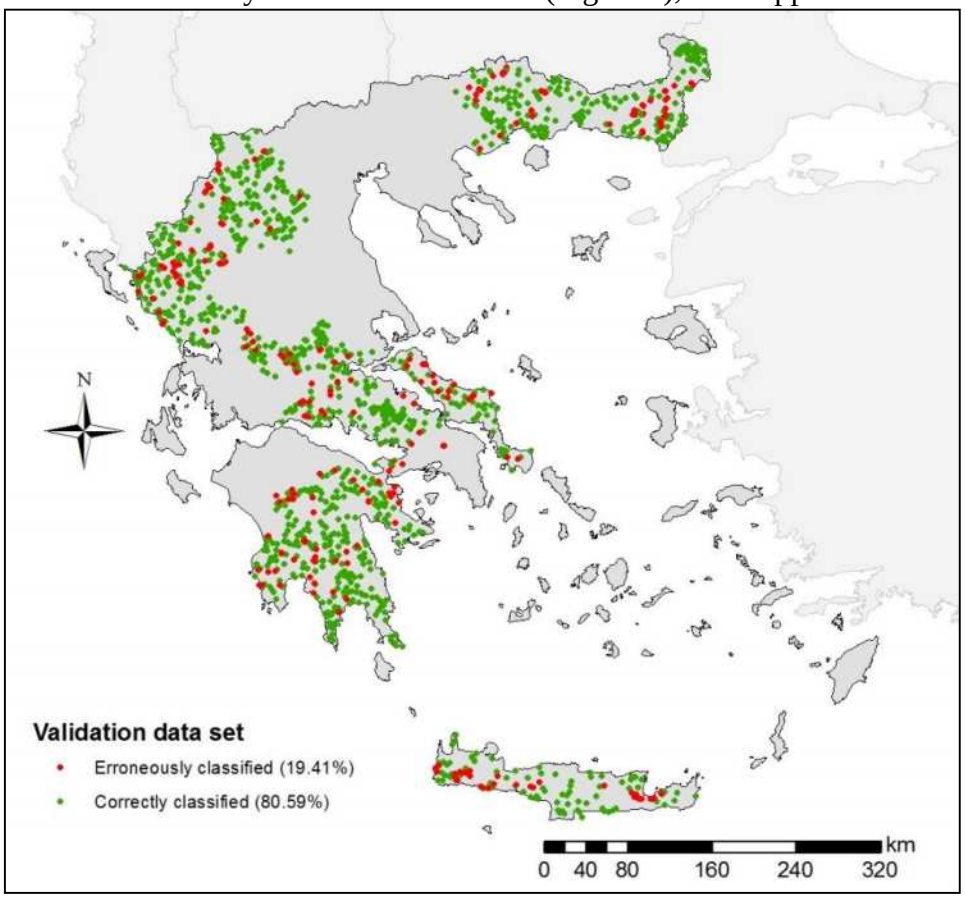

Figure 3. Validation findings based the 1288 point dataset in Greece

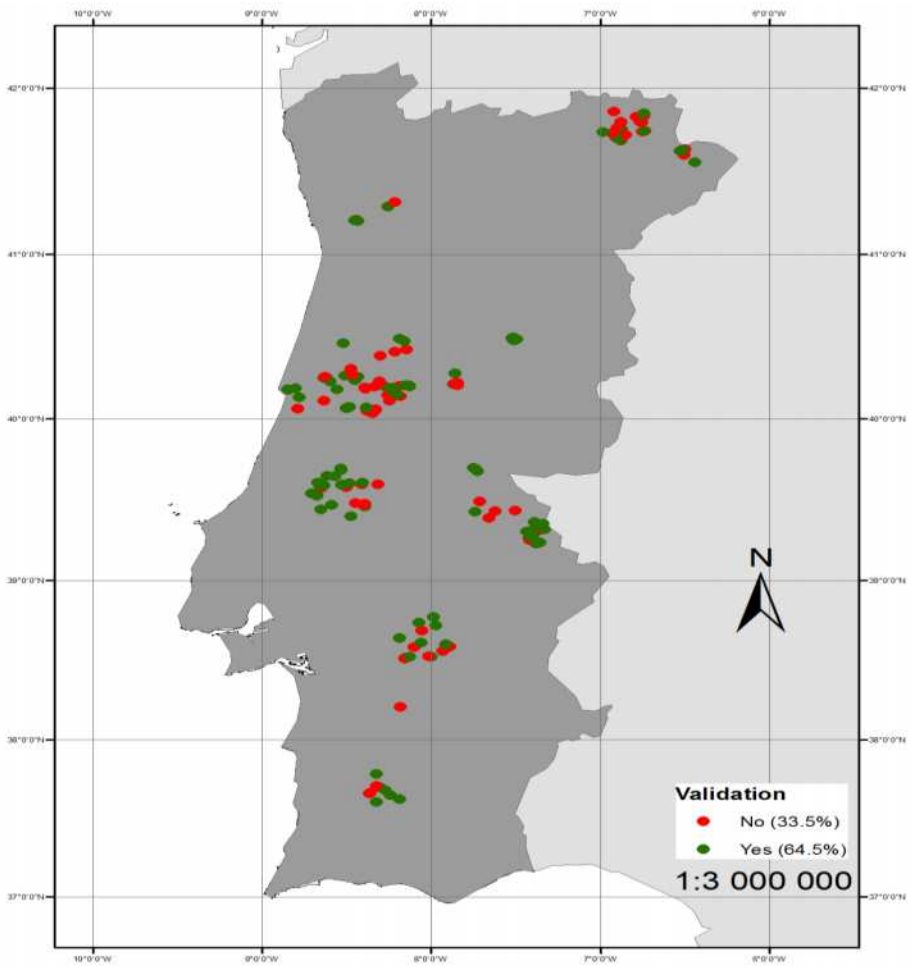

Figure 4. Validation findings based the 1288 point dataset in Greece

Two main efforts have been conducted in Europe for generating fuel maps at large scale. The European Fuel Map developed by Joint Research Center (JRC) (Sebastián López *et al*. 2002), where 44 fuel types were classified by using two databases: the CORINE Land Cover (CLC) and the Map of Natural Vegetation of Europe (MNVE). The CLC classes were stratified into sub-regions according to phyto-sociological criteria, which accounted for the floristic composition and other factors governing the distribution of the vegetation. These sub-regions were then linked to the National Fire-Danger Rating System (NFDRS) Fuel Model map in order to assign a fuel type to each of the sub-regions. The NFDRS fuel load corresponding to each of the fuel model classes was then assigned to each of the fuel models. However, the fairly poor spatial resolution of the datasets prevents the use of the data set for fine scale fire behavior and effects modeling. In 1999, the Prometheus project a new fuel type classification system was developed to better represent the fuel characteristic of the European Mediterranean ecosystems (Lasaponara and Lanorte 2006). However, this classification is principally based on the height and density of fuel, which directly influences the intensity of a wildfire and does not take into consideration the fuel physical and chemical properties which are required for simulating fire behavior and growth. In the USA, the recent LANDFIRE project feature 30-m raster grids of fuel models at national scale by integrating many geospatial technologies including biophysical gradient analyses, remote sensing, vegetation modeling, ecological simulation, landscape disturbance and successional modeling (Rollins 2009).

In United States the most commonly used fuel classifications are the 13 models of Anderson (1982) and the 40 models of Scott and Burgan (2005), all of which are used as inputs in the BEHAVE, FARSITE and FLAMMAP fire prediction systems, and the 26 fire danger models of Deeming *et al*.

(1977) that are used in the US National Fire Danger Rating System. Several surface fuel models are currently used by fire and forest management agencies in the United States, Europe, Canada and Australia, and most of these systems have the same categories, components and description variables (Sandberg 2001). In Mediterranean Basin, Mallinis *et al*. (2008) created a set of custom fuel models that were mapped across a large landscape using Quickbird imagery for input to the FARSITE model. In Italy, Santoni *et al*. (2011) developed two fuel models in order to simulate fire behaviour for various shrubland ecosystems and Bacciu *et al*. (2009) used field loading data to create fuel models for Mediterranean vegetation types for FARSITE simulations. To evaluate fire hazard in Portugal, Fernandes (2009) created a set of 19 fuel models based on the dominant vegetation types in Portuguese forests. Despite of fire behavior studies, fuel classification systems have been used as primary inputs for estimating fuel consumption and smoke emissions models (Reinhardt *et al* 2001), fire danger models (Deeming *et al*. 1977) and fire risk studies (Thompson *et al*. 2011).

Quantitative accuracy assessments are essential for evaluating map quality and fire simulation outputs. Fire growth predictions should, for example, identify those fuel types that generate high fire intensities but are mapped with poor accuracy. Furthermore, accuracy assessments should indicate if additional fuel sampling is needed for the fuel models mapped with a low level of reliability. Accuracy assessments are critical in fuel mapping because most fuel classifications efforts use indirect techniques where the vegetation types are the main mapped entity and not the fuel beds. For that reason, accuracy assessments should be explicitly built into any standardized fuel mapping approach. Moreover, low accuracies could also be a result of inherent sampling and analysis errors such as scale differences in field data and mapped elements, improper use of vegetation as fuels classifications and differences fuel spatial variation.

Conclusions

This study performed an extensive accuracy assessment of the ArcFUEL fuel types based on a field campaign and standard photointerpretation procedures The resulted fuel type maps accompanied by accurate measurements of fuel physical and chemical properties (fuel load, bulk density, surface area to volume ratio, moisture of extinction, heat content) would provide high resolution raster files of fuels which are the required inputs in most fire simulation systems, such as FARSITE and FlamMap. Further validation of the data set by sampling a larger number of field plots would substantially improve the ArcFUEL spatial data set.

Maps depicting fuel types are essential to fire and land management at many scales because they can be used to compute fire hazard, risk, behavior, and effects for planning and real time wildfire applications. Future efforts for classifying and mapping fuels need to incorporate measurements of canopy fuels (e.g., Mediterranean conifer forests), as well as, the quantification of fuel spatial variability in order to play an important role in revising and refining the resulted fuels maps. Since no other spatial fuel data sets exist with capabilities in wildfire behavior and effects, the proposed fuel classification scheme could be applied for supporting fire management activities on interim basis.

Abstract
Addressing sustainability concerns in Mediterranean forest ecosystems management with the growing incidence of fires impacting the forest areas over the past decades is a complex task. The current framework was driven taking into account several decision support tools of the United States Wildfire Modeling System for wildfire risk management, which focuses on a three-tiered approach strategy calibrated and applied in Portugal. In addition, contains spatial and temporal dimensions to integrate landscape-scale properties required to meet fire management goals, without encroaching budget constraints, while meeting demands for timber values. Explicitly : i) Developing and applying a Forest System Dynamic Model for identifying temporal stand-scale and understory fuel dynamics, including a site and regional percentage of burnt probability; ii) Building for each landscapes fuel population distribution the expected fire behaviour curve trends, i.e. the corresponding spread rate and flame length using EXRATE tool and FlamMap simulator, respectively, thereby allowing the calculation of changes in the annual expected wood loss; iii) Spatially optimize in the Landscape Treatment Designer tool (LTD) the location of fuel treatments distribution. For testing and demonstration purposes, the research considered an application encompassing three properties of pulp mill's from the Grupo Portucel Soporcel (gPS) in the North, Central and South of Portugal, where eucalypt (E. globulus) is predominant (extent ≈ 3665 ha). A sensitivity analysis was performed by measuring trade-offs among specific treatment scenarios: "treated" vs "untreated" or "treated considering neighbors". The effect of each scenario was changed by a set percentage of optimal parameters and a series of LTD runs was recorded as a project. The protection of the eucalyptus trees from potential wildfires loss was assumed as a key primary goal, following by a set of quantitative target stand structures, budgets and policies constraints in proportion of area treated, and fire behaviour thresholds for each farm. Parameters decisions were assessed to address the identification of thresholds for radical change in fire behavior, and further insight to support hazard-reduction fuel practices. The accuracy of the results demonstrates the usefulness and relevance of the pursued to calculate the potential effect of treatments strategies on improving fire resiliency. Further, the approach provided an overview of management guidelines for fuel modifications to make the gPS eucalyptus farms in Portuguese conditions more resistant to fire, selecting priority intervention areas and designing effective strategies.

***Keywords**: Forest System dynamic Model; Fire behavior; Spread rate; budget constraints; Landscape Treatment Designer; Fuel management strategies.*

Introduction

About 35.4% of the area of Portugal is covered by forest. Nonetheless in the Mediterranean and in Portugal the forest composition is strongly determined by wildfires. Indeed, is the smallest country in southern Europe but has the highest fire incidence in the region. The management of such ecosystems sustaining the forest ecological base, in a changing physical, socio-economic, cultural, demographic and political context is a challenge. Thus, fires should be taken into account when developing forest management plans. We have little or no control over most factors in the fire behavior triangles. However, one element we can control is the common denominator - fuel. Indeed, fire risk and wildfire damage can be reduced by removing or reducing fuels in strategic locations. Fuel structure and flammability are primary conditions for fire spread (Pausas and Paula 2012) and fuel treatments have been found to decrease wildfire size (e.g. Baeza and Vallejo 2008; Rideout *et al.* 2008; Boer *et al.* 2009). Fuel treatment positively affects suppression efforts by reducing fire spread and fire intensity (Rideout *et al.* 2008). Thus, the emphasis today in forest management is on forest restoration and fuels reduction. Nevertheless, there is an urgent need for decision support tools to enable effective fire management.

Where to treat? How much? Shape and size? In this sense, for handling with the complexity of such forest management problems that wildfire risk implies for forest owners and policy-makers, the present research try to answer the above-mentioned questions focusing on techniques for address the problem of spatially optimize treatments to prioritize fuel management activities, aimed at disrupt fire spread and protect eucalyptus areas from burning without have loss of important ecological and commercial timber values. For that purpose, a Forest System Dynamic Model have been developed and coupled with spatial optimization software (Landscape Treatment Designer - LTD, Ager *et al.* 2012) to design efficient landscape fuel treatment plans.

The current framework includes a three-tiered approach strategy such as i) developing a Forest System Dynamic Model; ii) Characterizing the expected fire behaviour characteristics (e.g. spread rate and flame length); iii) Explore the optimal levels of fuel landscape treatment configurations in the LTD tool. The pursued are tested and results are discussed for a large-scale application encompassing over 3365 ha of eucalyptus in North, Centre and Southern Portugal.

Methods

The framework presented here was based on an extensive literature review (e.g. Finney 2003; Alan *et al.* 2013), field work to assign fuel model distribution, and analysis of a database within three Eucalyptus farms located in the North (1471, 48 ha), Centre (173, 34 ha) and South region (2020, 34 ha) from the Grupo Portucel Soporcel (gPS), a European company dedicated to produce and market high quality paper for office and offset uses (Figure 1). Inventory data represent conditions of the year 2013 in the study area.

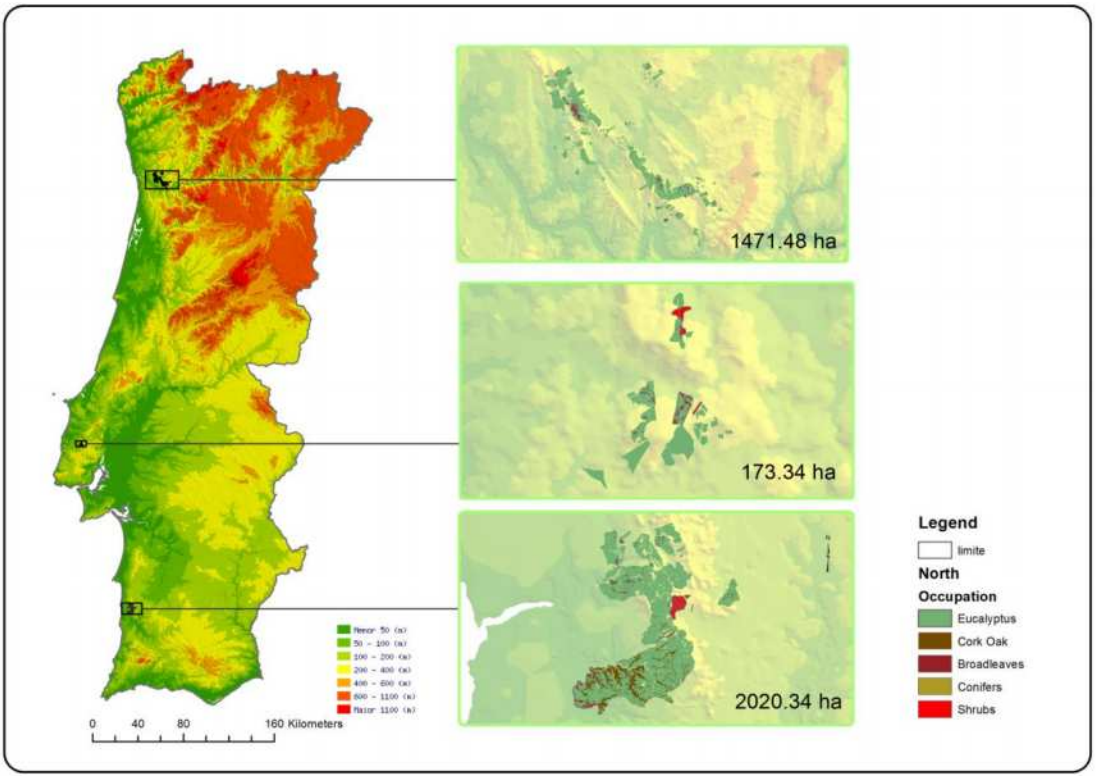

Figure 1. Portugal: location and cover types of the three farms from the Grupo Portucel Soporcel

Developing a Forest System Dynamic Model

In order to identify temporal trends for guiding LTD, a Forest System Dynamic Model (FSDM) was developed to examine stand-scale and fuel dynamics. The model incorporates both well-defined, quantitative field data and qualitative expert gPS opinion. Note that all the spatial fuel types under eucalyptus cover were collected "in loco" and assessed by the field guide-fuel from Project Vesta (Cheney *et al.* 1998; Gould *et al.* 2007). Further, enumerated using a set of customized fuel models developed for eucalyptus stands in Portugal (Fernandes *et al.* 2009). Such dynamic model was used to classify fuel over time due to planting operations, harvesting, and vegetation regrowth.

In addition, an estimate of total burnt probabilities (TBP, %) on each eucalyptus farm was also integrated in the model as a "burnt factor" based on landscape and site scale wildfire modelling information available in Portugal. In the former, each stand burns considering an adjusted burnt probability based on the regional fire frequency analysis (Oliveira *et al.* 2012) and the fire regimes at the municipality-level obtained by multiple correspondence analysis and spatial clustering (Pereira *et al*. submitted). For the site-scale the probability of wildfire occurrence in Eucalyptus stands was calculated by Botequim *et al.* (2013). Furthermore, wildfire impacts and resulting damage over time at stand and tree level across the eucalyptus farms was include using Marques *et al.* (2012) post- fire mortality equations. Thus, landscape data were generated for random mixtures of several fuel types in various proportions over time and replicated because of expected variation in weather scenarios (increase the number of additional fuel configurations).

2.2. Characterizing the expected fire behaviour characteristics

Current fire behavior characteristics for each stand, i.e. spread rate (SR, m/min) and flame length (FL, m) for randomness of the fuel arrangements was calculated on the program EX-RATE (Finney 2003) and FlamMap simulator (Finney 2006), respectively. Each fuel configuration has a well-defined maximum spread rate (minimum travel time algorithm, Finney 2003). Different spread rate ratios show a sigmoid trend over the range of proportions of fuel populations. These outputs can be used to estimate

the change in the annual expected timber loss (TL), as well to demonstrate reductions in the ΔSR and ΔFL from the effect of fuel treatments, to further aid in spatial allocation of fuel strategies across the eucalypt farms.

2.3. Explore the optimal levels of fuel landscape treatments

Spatial data for each farm indicating: (i) potential fire behavior as represented by SR and FL, (ii) expected TL in the stand for both treat and untreated conditions (iii) stand area (ha), (iv) biometric patterns such as crown base height (CBH), crown bulk density (CBD), type of fuel model (shrub or litter) for predicting fire activity (Botequim *et al.* in preparation); and (v) annual budget capacity for gPS fire management, was created to explore in LTD tool (Ager *et al.* 2012) the optimal levels of fuel landscape treatment configurations.

The protection of the eucalyptus trees from potential wildfires loss was assumed as primary goal, i.e. minimize the total predicted expected TL and maximize delta SR. Activity constraints on policy and annual budget restrictions to represent the total treatment allowance (area, ha) for fire management were considered. Thresholds were measured by potential FL, and a set of biometric patterns for each eucalypt stands.

In addition, to better understand how expected loss was affected by the above treatment parameters a sensitivity analysis using several LTD simulations was performed across all the stands in response to different investment levels, treatment intensity. The trade-offs associated with these divergent management strategies including percentage of treated and untreated areas to calculate potential mortality to eucalyptus trees were quantified to examine change in risk on improving fire resiliency.

Results

The current work expands the application in fuel spatial optimization for eucalyptus stands, and demonstrates a decision support approach computationally feasible to address the most fire-prone areas in each region and prioritize fuel management efforts based on respective management goals. The model seeks to locate project areas to most efficiently reduce potential wildfire loss of fire resilient eucalyptus trees while creating contiguous areas within which managed fire can be effectively used to maintain low-hazard conditions. Indeed, the approach identifies the aggregate of polygons that minimize the expected timber loss E(TL), and maximize the delta Spread rate (ΔSR) objectives, and the polygons that require treatment, i.e. the percentage of stand - treatment densities optimal in terms of the overall reduction in the potential wildfire mortality. Furthermore, the sensitivity analyses based on a series of test landscapes allows the identification of investment trade-offs with easily interpretable results. Finally, this research have real implications for spatial strategies of fuel treatments on gPS farms, and can contribute to enhance the coordination of seasonal budget for fire prevention, directing their actions to the most susceptible areas in case of extreme, and uncontrollable, weather events.

Abstract
The Iberian peninsula has suffered for many years from large scale forest fires, which in the past decades have been devastating for all components of the environment: destruction of biological systems, loss of organic matter from soils and alteration of atmospheric and climatic processes.
In this study we analyse the variation in number and burnt areas in the Iberian Peninsula (Portugal and Spain), using mathematical functions. The results obtained are compared with other European Mediterranean countries such as France, Italy and Greece. More than 1.5 million fires were recorded in the Mediterranean countries between 1980 and 2011, involving a burnt area of approximately 15 million hectares, where 67% of the fires and 60% of the burnt area lay in the Iberian Peninsula. Upon using the adjustment functions, the evolution of the number of fires in the Iberian Peninsula shows a growth rate between 1980 and 2000, while a decline in fires was observed after 2001. There is a continuous decrease in burnt area throughout these years.
The evolution of the number of fires in Spain and Portugal presents a behaviour that is quite similar to that in the Mediterranean countries. However, this is not true for the burnt areas, where an increase in Spain from 1980 to1985 was observed, and this decreased after 1986. Portugal on the other hand presents an increase in burnt areas from 1985 to 2003.

***Keywords**: Iberian peninsula, burnt areas, number of forest fire, mathematical function*

Introduction

Spain like Portugal and other Mediterranean countries are suffering the dramatic consequences of the forest fires, which in the last years have produced a big deforestation that provokes degradation of the environment and important socio-economical losses. Their direct destructive effects are manifested in all components of the environment: the vast forest area burnt (forest and scrub); the destruction of the fauna; the loss of soil organic matter, with the consequent variation of all its properties and the loss of soil quality; and altering atmospheric and climatic processes due to particles and smoke released by the fire, which also contains hydrocarbons, greenhouse gases and toxic substances for humans and animals In addition, there are indirect effects caused by the destruction of the vegetation cover, which leaves the soil unprotected against the impact of the rain, and subsequent post-fire erosion, producing the drag of the finest components of topsoil (seeds, organic and inorganic substances) necessary for normal development of the vegetation, and in extreme conditions, the irreversible loss of soil and even the rock outcrop. The drag of water and sediments caused by the erosion and deposition away from the fire epicenter will alter aquatic and marine ecosystems and habitat for fish, shellfish, etc. This has

negative social and economic impacts. Consequently, it is of paramount importance to develop efficient tools for the integral forest fire fighting.

Most of the total burned area and the largest numbers of fires in Europe are found in southern European countries, namely in Portugal, Spain, France, Italy and Greece. The characteristics that define the fire events have been characterised using qualitative or quantitative methods, from local to regional or global scales. For example, San-Miguel-Ayanz *et al*. (2013) published an analysis of trends in the number of forest fires and burnt areas in the Mediterranean region (Galicia-Spain, Portugal and Greece). Pereira *et al.* (2011) studied the number of fires per year and burnt area per year for five Mediterranean countries (Portugal, Spain, France, Italy and Greece). Sarris and Koutsias (2014) investigated correlations between climate, vegetation and fire statistics in four Mediterranean countries (Spain, France, Italy and Greece). Oliveira *et al*. (2012) identified the main structural factors that explain the likelihood of fire occurrence at Europan scale (Portugal, Spain, France, Italy, Greece). The factors influencing fire occurrence, fire risk, or fire statistics in Mediterranean countries, have been investigated at local or regional level by several authors who have focused on Portugal (Viegas *et al*. 1992; Moreira *et al*. 2001), Spain (Chuvieco *et al.* 2009; Fuentes-Santos *et al*. 2013; Moreno and Chuvieco 2013; Martínez-Fernández *et al*. 2013; Turco *et al.* 2013; Martin-Martin *et al*. 2013), France (Ganteaume and Jappiot 2013; Sarris and Koutsias 2014), Italy (Salis *et al.* 2014), Croatia (Jurjevic *et al.* 2009) and Greece (Koutsias *et al*. 2012; Koutsias *et al*. 2013; Sarris and Koutsias 2014; Polychronaki and Gitas 2012).

The principal aim of this paper is to analyse the variation in number of fires and burnt areas in the Iberian Peninsula (Portugal and Spain), using mathematical functions.

Methods

Study area and fire databases

The study area for this investigation is the entire Iberian Peninsula (figure 1). This region is located in south-western Europe (western Mediterranean Basin), and includes two countries: Portugal and Spain. The results obtained are compared with other European Mediterranean countries such as France, Italy and Greece.

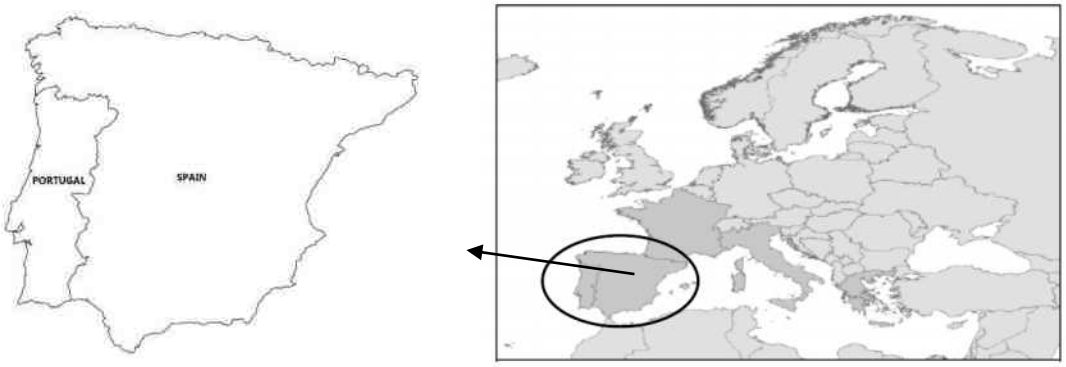

Figure 1. Study area.

In order to compile the required information for the temporal analysis on the variation in number of fires and burnt area in the Iberian Peninsula, a fire database for the Iberian Peninsula was developed from the information contained in both national official databases. The Spanish Forest Fire Prevention Service compiles a fire database based on the forest fire reports by the autonomous regions and provinces, since 1968. Data of fire occurrence and burned area in Portugal and Southern most affected European Countries (Spain, Portugal, France, Italy and Greece) were obtained from the Autoridade

Florestal Nacional (AFN) and from Join Research Center (JRC Tecnical Reports, Forest Fires in Europe Middle East and North Africa 2011), respectively. The data series from 1980 to 2011 was used in the present study.
More than 1.5 million fires were recorded in the Mediterranean countries between 1980 and 2011, involving a burnt area of approximately 15 million hectares, where 67% of the fires and 60% of the burnt area lay in the Iberian Peninsula and 31% of the fires and 36% of the burnt area corresponding to Spain.

Equations

In this study, data of the number of forest fires and burnt area in the Spain, Portugal, Iberian Peninsula and European Mediterranean countries (Portugal, Spain, France, Italy and Greece) from 1980 to 2011 were fitted to variable-degree polynomials such as:

$$f(x) = \sum_{i=1}^{n} A_i \cdot x^{i-1} \qquad (1)$$

where $x = x' - x_o$, x' is the year of study, $x_o = 1979$ is the year zero, f(x) is the number of fires or the burn area in the study interval. The fitting parameters A_i were computed from the unweighed least-squares method using a non-linear optimization algorithm.

In addition, the burned area and the number of fires have been considered to assess the evolution of forest fires in the different temporal periods. Then, mean number of fires and mean area burned are studied in periods of two years, three years, four years, and so on.

Results

Trends in number of fires and burnt areas in the Iberian Peninsula, Spain and Portugal was analysed. The results obtained in this study were compared with the trends followed by the set of several Mediterranean countries. Figure 2 shows the annual series of burned area and number of fires in the Iberian Peninsula, in España and Portugal, and in the set of Mediterranean countries (España, Portugal, France, Italy and Greece).

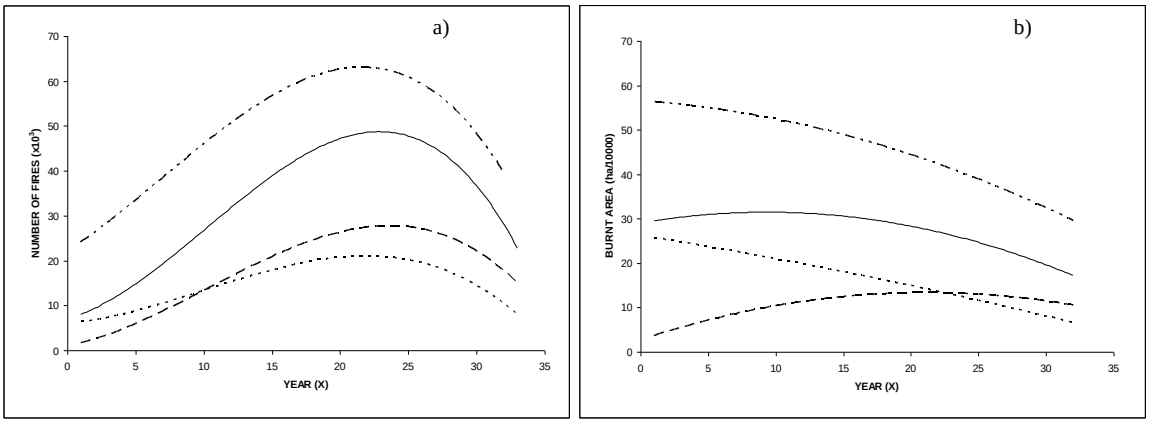

Figure 2. a) Evolution of the forest fire number registered between 1980 and 2011, b) Evolution of the burned area between 1980 and 2011. — · · — Set of the mediterranean countries, ——Iberian peninsula, – – – – Portugal, ·····Spain

It can be seen that the evolution of the number of fires in the Iberian Peninsula shows a growth rate between 1980 and 2000, while a decrease of fires is observed after 2001. The number of fires in Spain and Portugal has a very similar trend. Moreover, there is a continuing decline in the area burned along these years in Spain, Iberia Peninsula and in the set of Mediterranean countries studied. However, it is noted that in Portugal the area burned increases smoothly along these years.
The functions obtained for annual data shown in Figure 2 are compared with the obtained functions for the mean data in several time intervals, of between 2 and 5 years, presented in Figure 3. The best correlations were obtained with polynomials of degree three for the number of fires and polynomials of degree two for area burned. The coefficients of correlation obtained from the fitting curves of degree three for the mean number of fires are shown in Table 1.

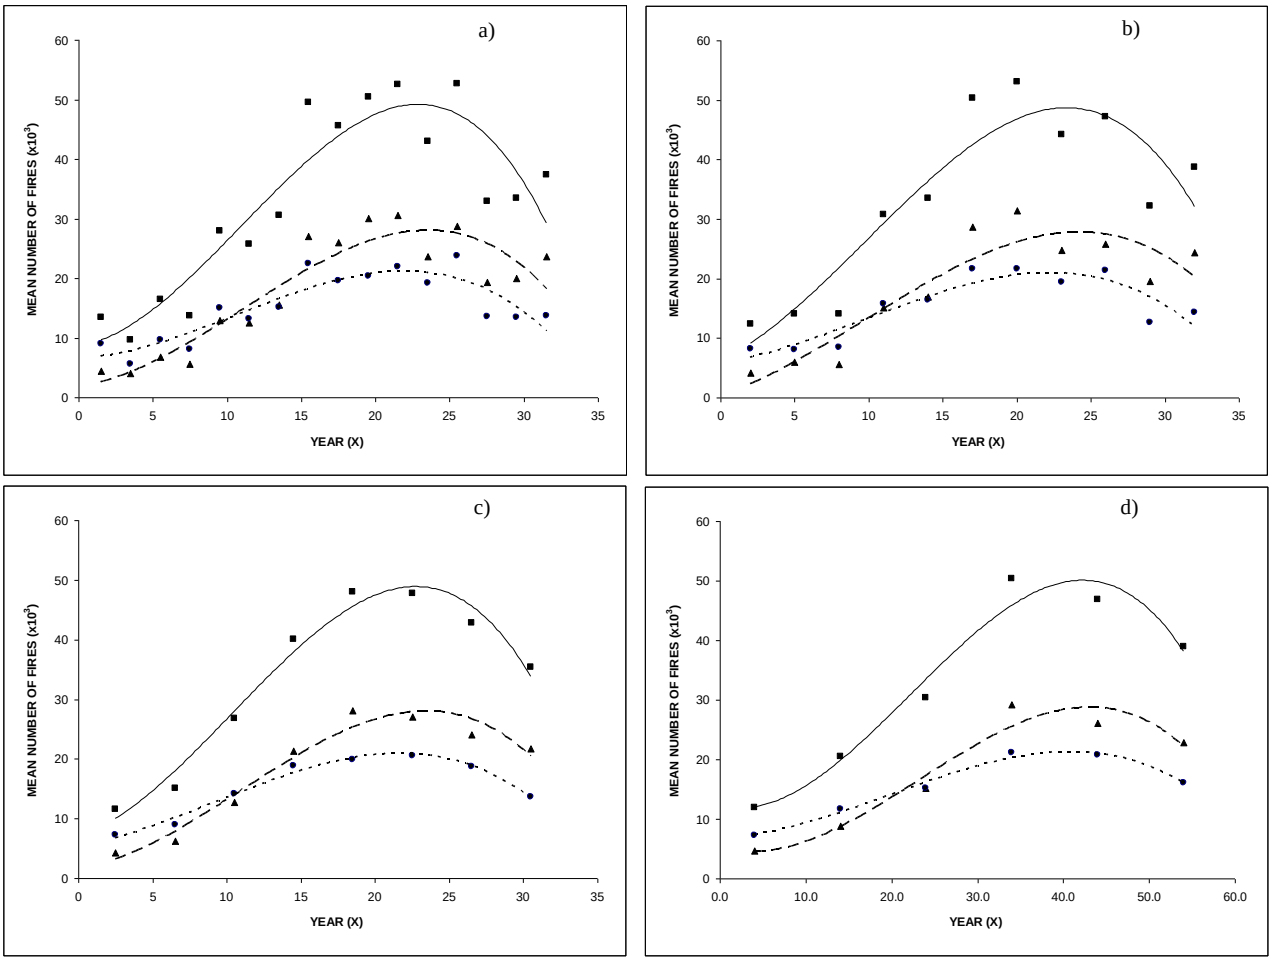

Figure 3- Evolution in several time intervals of the forest fire number registered between 1980 and 2011. a) 2 years, b) 3 years, c) 4 years, d) 5 years. Fitting curves: —— Iberian peninsula, – – – – Portugal, ·····Spain. Mean number of fires: ■ Iberian Peninsula, ▲ Portugal, ● Spain.

Table 1. The correlation coefficients, R^2, of the fitting curves of degree three for the number of fires.

	1 year	2 years	3 years	4 years	5 years
Iberian Peninsula	0.7163	0.8453	0.8433	0.9752	0.9647
Portugal	0.7709	0.8568	0.8411	0.9606	0.9466
Spain	0.6591	0.7967	0.8302	0.9815	0.9849

A similar study to that presented in Table 1 for the number of fires was performed to analize the area burned. The best results were obtained with a time interval of 4 years, for both the number of fires as for the burned area.
From the fitting curves, the maximum value for the mean number of fires in the Iberian Peninsula is about 47 000 fires in 2002, around 28 000 fires in Portugal for 2002, and 22 000 fires in Spain for 2001. In accordance with real data.

Abstract
Climate and weather are major drivers of fire activity in Portugal. The aim of the present study is to assess the role of meteorological factors on the inter-annual variability of burned area, for the period 1980-2011, over a region of Central Portugal. Although occupying only 18% of the territory of Portugal, the chosen area is responsible for 43% of all the burned area in August during the study period.
A normal distribution model is fitted to the decimal logarithms of monthly burned area during August over the study area. This model is then improved by introducing as covariates two different measures of prevailing meteorological conditions as derived from Daily Severity Rate (DSR), namely a top-down factor which consists of daily cumulated values of DSR from April up to July and a bottom-up factor defined as the square root of the mean of the squared daily positive deviations of DSR in August from the daily climatology. The two models are used to derive a model of fire severity that allows quantifying the probability of having a severe or weak fire season.

Keywords*: fire activity, burned area, indices of fire danger, meteorological conditions, statistical models*

Introduction

The number and extension of fires and the large amounts of burned area that are observed in Mediterranean Europe have strong adverse impacts at the social, economic, ecological and environmental levels that include the destruction and change of the landscape and the emission of greenhouse gases (Pausas and Vallejo, 1999). The increase in temperature that is to be expected according to future climate scenarios may also turn more frequent fire episodes of large magnitude (Flannigan *et al*., 2013; Liu *et al*., 2010; Mori and Johnson, 2013; Yongqiang *et al*., 2010). It is therefore crucial to improve our knowledge about fire behaviour (especially about extreme fire events), that will help taking adequate measures to mitigate the adverse effects.
The Mediterranean region is responsible for 85% of burned area in Europe, causing extensive economic losses and ecological damages (San-Miguel-Ayanaz *et al*., 2013). In particular, Portugal presents the highest score of fire occurrences in the Mediterranean Basin (Pereira *et al*., 2005). According to official records of *Instituto de Conservação da Natureza e das Florestas* (ICNF), the Portuguese authority for forests, 3,468,986 hectares have burned in Continental Portugal during the period 1980-2011, the equivalent to three fifths of the total forested area of the country; in the last few years, a significant increase has also been observed in the amount of total burned area, number of large fires and fire severity (Pereira *et al*., 2011).
Fire activity in Mediterranean Europe, is a natural phenomenon linking climate, humans and vegetation (Lavorel *et al*., 2007). Fire activity is therefore conditioned by natural and anthropogenic factors (San-Miguel-Ayanz *et al*., 2003). According to Costa *et al*. (2011) and Ganteaume *et al*. (2013) the most important factors for fire occurrence in Mediterranean Europe are anthropogenic and environmental. The first one is the main cause of ignition, reaching 95% of all cases (San-Miguel-Ayanz *et al*., 2013) whereas the most significant environmental factors are weather, fuel availability and topography. Even though most of fire events are human caused, several studies show that climate

and associated weather conditions are major drivers for fires with extensive burned area. For instance, rainy and mild winters followed by warm and dry summers lead to high levels of vegetation stress making the region particularly prone to the occurrence of fire events (Pereira *et al*., 2005); while precipitation and temperature in the pre-fire season have a determinant role in fuel availability and vegetation stress, temperature, wind and precipitation in the fire season are crucial for the development and extinction stages (Aldersley *et al*., 2011; Dale *et al*., 2001; Pereira *et al*., 2013; Trigo *et al*., 2013). The aim of the present study is to contribute to a better understanding of the meteorological factors that affect the inter-annual variability of burned area in August over a region in Central Portugal. Meteorological information is used to derive the so-called Daily Severity Rate (DSR), an index of fire danger that is part of the Canadian Forest Fire Weather Index System (CFFWIS). This index is then used to characterize the pre-fire season in terms of levels of heat and stress of vegetation, as well as an indicator of extreme meteorological conditions taking place in summer. A normal distribution model is fitted to the decimal logarithms of monthly burned area during August over the study area. This model is then improved by introducing as covariates two different measures of prevailing meteorological conditions as derived from the Daily Severity Rate (DSR); a top-down factor, DSR_{td}, which consists of daily cumulated values of DSR from April up to July and a bottom-up factor, DSR_{bu}, defined as the square root of the mean of the squared daily positive deviations of DSR in August from the daily climatology. A model of fire severity is finally derived that allows quantifying the probability of having a severe or weak fire season.

Data and methods

Study area and period

The study area is located in Central Portugal (Figure 1) and encompasses 53 counties (*concelhos*). The study area covers 1,805,226 ha, 30% of which are covered by forest. The two main species in the forested area are *Pinus Pinaster* (58%) and *Eucalyptus* (22%). The high percentage values of maritime pine and eucalyptus, that are extremely flammable in summer (Núñez-Regueira *et al*., 1996), can explain the fact that although the study area occupies only 18% of all the territory of Portugal it is responsible for 43% of the total burned area in August during the study period (Figure 2).

Figure 1. Location of the study area (left panel), RGB zoom image of the area from ArcGlobe 10 (middle panel) and GLC2000 map (right panel) identifying forest (green), cultivated and managed areas (cyan), shrubland (orange) and bare soils and sparse vegetation (red).

The study covers the 32-year period 1980-2011, and focuses on yearly amounts of cumulated burned area (*BA*) in August over the study area. As shown in Figure 2, the time series of *BA* presents a very large inter-annual variability and is highly correlated (r = 0.93) with the time series of Continental Portugal.

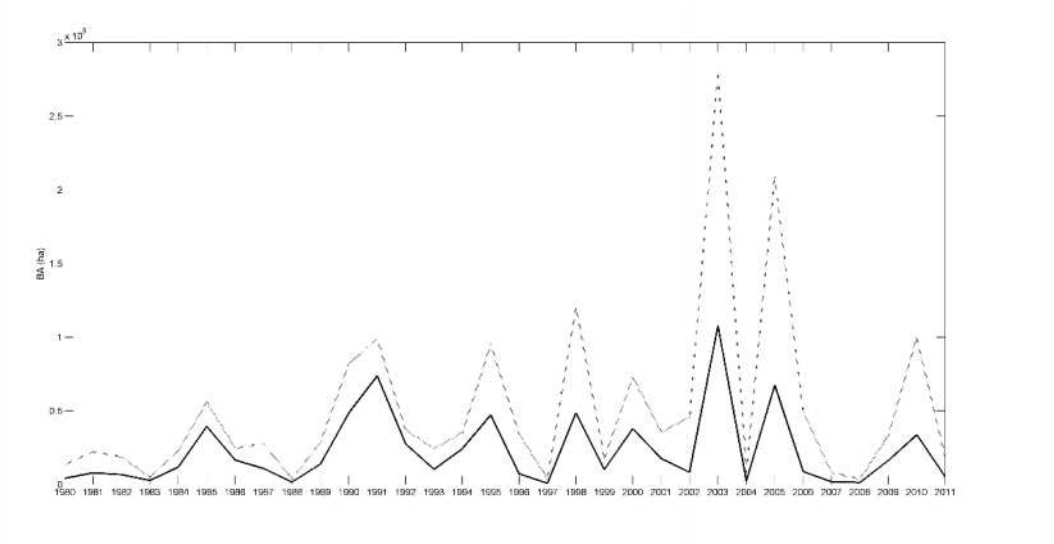

Figure 2. Time series of cumulated burned area in August over the study area (black curve) and over Continental Portugal (dotted curve)

2.2. Fire database

Values of burned area in Portugal are derived from the official Portuguese Rural Fire Database (PRFD) provided by ICNF. The database covers a 32-year period (1980-2011) and includes more than half a million records of fire events over forest, shrubland, grassland and agricultural land. It includes the data and time of ignition and extinction, total burned area, cause of fire, land cover type and location of ignition in terms of administrative division of Portugal.

The database was screened for inconsistencies, such as records with null values of burned area, with the same date, time and spatial location, negative durations, missing and/or suspicious information about area and duration. Pereira *et al*. (2011) provide a full description of these inconsistencies and a detailed description of the corrected PRFD.

2.3. Fire danger rating

Fire danger is based on the so-called Daily Severity Rating (DSR) that is part of the the Canadian Forest Fire Weather Index System (CFFWIS). This system has been in operational use in Portugal since 1998 by the national weather service (*Instituto Português do Mar e da Atmosfera*, IPMA) (Pereira *et al*., 2013). CFFWIS involves six different components based on fuel moisture and wind; three fuel based mechanisms and three fire behaviour indices that are based on daily fields of temperature, relative humidity, wind speed and 24-hour cumulated precipitation at 12 UTC (Van Wagner, 1987). DSR is derived from the Fire Weather Index (FWI), the last component of CFFWIS by means of a simple power function and may be viewed as a numeric rate of the difficulty of controlling fires. DSR was specifically designed for averaging or accumulation in time or space and is currently used in the official annual reports of fire activity in Portugal.

2.4. Statistic model of burned area

Pereira *et al*. (2013) have shown that the decimal logarithm of *BA* recorded in July and August over Portugal in the 32-year period 1980-2011 follows a normal distribution. Normal models were accordingly fitted to the recorded sample of $x=\log_{10}(BA)$. Estimates of the mean (μ) and standard deviation (σ) were obtained by maximum likelihood (Wilks, 2006).

Following DaCamara *et al*. (2014) the fitted model, hereafter referred to as null model of fire danger, may be used to estimate baseline danger D_{bo} which is defined as the probability that a prescribed threshold x_0 of $\log_{10}(BA)$ is exceeded:

$$D_{bo} = D_b(x_0) = 1 - N_x(x_0|\mu, \sigma) \quad (1)$$

Conversely, the excess threshold associated to a prescribed level of baseline danger D_{bo} may be estimated by inverting the previous equation:

$$x_0 = x(D_{b0}) = N^{-1}(1 - D_{b0}) \quad (2)$$

Normal models for $\log_{10}(BA)$ may be improved by incorporating meteorological covariates that numerically rates fire danger at different temporal and spatial scales. Let ψ and χ be two such meteorological covariates and let us assume a linear dependence of the mean (μ) of the normal distribution on the covariates:

$$\mu = a \times \psi + b \times \chi + c \quad (3)$$

Estimates of coefficients *a*, *b*, *c* and of σ are again obtained by maximum likelihood. Performance of the new alternate model, hereafter referred to as the meteorological model of fire danger, is compared against the null model (i.e. the normal without covariates) by using the standard likelihood ratio test.

The meteorological model allows estimating the "climate + weather" danger D_{c+w} which is defined as the probability that a certain threshold, x_0, of $\log_{10}(BA)$ is exceeded given two values of ψ and χ:

$$D_{c+w}(x_0, \psi, \chi \mid a, b, c, \sigma) = 1 - \mathrm{N}(x_0 \mid a \times \psi + b \times \chi + c, \sigma) \quad (4)$$

Results

Null model

A normal model was fitted to the 32-year sample (1980-2011) of cumulated BA in August (Figure 3). Obtained maximum likelihood estimates of mean and standard deviation are μ = 4.07 and σ = 0.55 and the probability associated to the Anderson-Darling statistics is 0.66, meaning that the null hypothesis that the sample is normally distributed cannot be rejected at the level of 5%.

Two different thresholds were chosen, one to discriminate between severe and non-severe years and the other one to discriminate between moderate and weak years. The first threshold, x_{20}, is associated to a baseline danger of 20%, whereas the second one, x_{80}, is associated to a baseline danger of 80%. Values were estimating using Eq. (2), leading to x_{20}=4.6 and x_{80}=3.6 that correspond to values of BA of 34,295 ha and 4,025 ha, respectively. These thresholds were then used to classify each year into one of three categories, namely severe, moderate and weak; as shown in Figure 3, severe (weak) years are those such that $x > x_{20}$ ($x < x_{80}$), the remaining ones being classified as moderate.

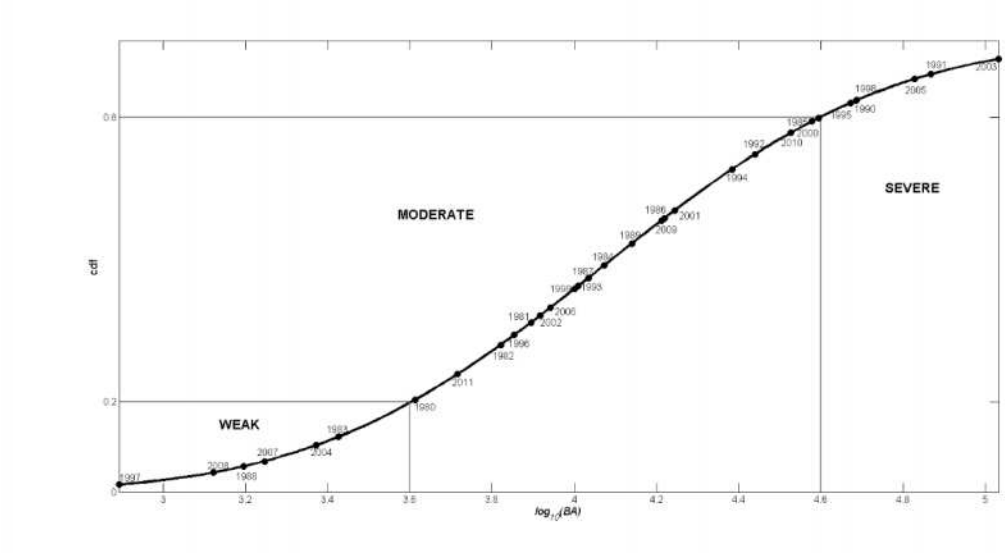

Figure 3. Cumulative distribution function of the baseline model. Dashed lines indicate thresholds x_{20} and x_{80} associated to baseline risks of 20% and 80%, which are used to stratify the 36-year sample into classes of weak, moderate and severe years represented by black squares, open triangles and black circles, respectively.

Meteorological factors

Pereira *et al*. (2005) have shown that the inter-annual variability of burned area in Portugal during the fire season is conditioned by two main meteorological factors that work at different temporal and spatial scales; i) a top-down factor (referred to as the "climate anomaly"), linked to long dry periods with absence of precipitation in late spring and early summer, which induce heat and water stress in the vegetation and ii) a bottom-up factor (referred to as the "weather anomaly"), related to the occurrence of very intense dry spells in days of extreme synoptic situations.

Top-down factor

Pereira *et al* (2013) have recently shown that the "climate anomaly" may be quantified using cumulated values of DSR in the pre-fire season (May and June). As shown in Figure 4 (left panel) severe (weak) years tend to present larger (smaller) values of cumulated DSR than the overall median. As discussed in Pereira *et al* (2013) the larger values of cumulated DSR in the case of severe years is associated to systematic increases in temperature and decreases in precipitation that take place in the pre-fire season and drive biomass to high levels of heat and water stress, making them prone to trigger large wildfires in case of favourable meteorological conditions in the fire season, which are very likely to occur in hot and dry summers. The opposite situation is observed in the case of weak years, where the tendency towards lower values of DSR than the overall median is associated to decreases in temperature and to increases in precipitation that make vegetation much less prone to trigger large wildfires, even in case of favourable meteorological conditions.

The role played by the "climatological background" associated to the prevailing meteorological conditions during the pre-fire season was therefore characterized by means of cumulated values of DSR since April 1 till June 15 / June 30 / July 15 / July 31, depending on the model to be developed. Values of cumulated DSR will be hereafter referred to as the top-down factor and denoted DSR_{td},. Choice of the term top-down is because DSR_{td} has a time scale longer than the monthly scale of BA.

Bottom-up factor

Trigo *et al*. (2006) and Amraoui *et al*. (2013) pointed out the crucial role played by heatwaves associated to extreme synoptic situations in the onset and spreading of extreme fire events. In the case of Portugal such extreme synoptic situations favour the advection of very hot and dry air throughout central Iberia (Pereira, *et al*., 2005) and are usually associated to sequences of days, within the month, characterized by large positive departures of DSR from the respective daily climatology, i.e. days with values of anomaly A_d defined as:

$$A_d = DSR_d - \overline{DSR_d} \tag{5}$$

where DSR_d and $\overline{DSR_d}$ denote the daily value of DSR for August on day d of a given year and the respective daily climatological mean performed over the 32-year period. The role played by "daily weather " associated to extreme synoptic conditions that favour or prevent fire onset and spreading within a given month was characterized by hereafter referred to bottom-up factor, DSR_{bu}, defined by the square root of the mean of squared anomalies performed over the days where $DSR > \overline{DSR_d}$, hereafter referred to as:

$$DSR_{bu} = \sqrt{\frac{\sum_{d=1}^{31} H[A_d]\,(A_d)^2}{\sum_{d=1}^{31} H[A_d]}} \tag{6}$$

where H[x] is the Heaviside step function whose value is zero for negative argument and one for positive argument. As opposed to DSR_{td}, the bottom-up factor DSR_{bu} reflects the effects associated to daily time scales that are smaller than the monthly scale of BA. As shown in Figure 4 (right panel), severe (weak) years tend to present larger (smaller) values of DSR_{bu} than the overall median.

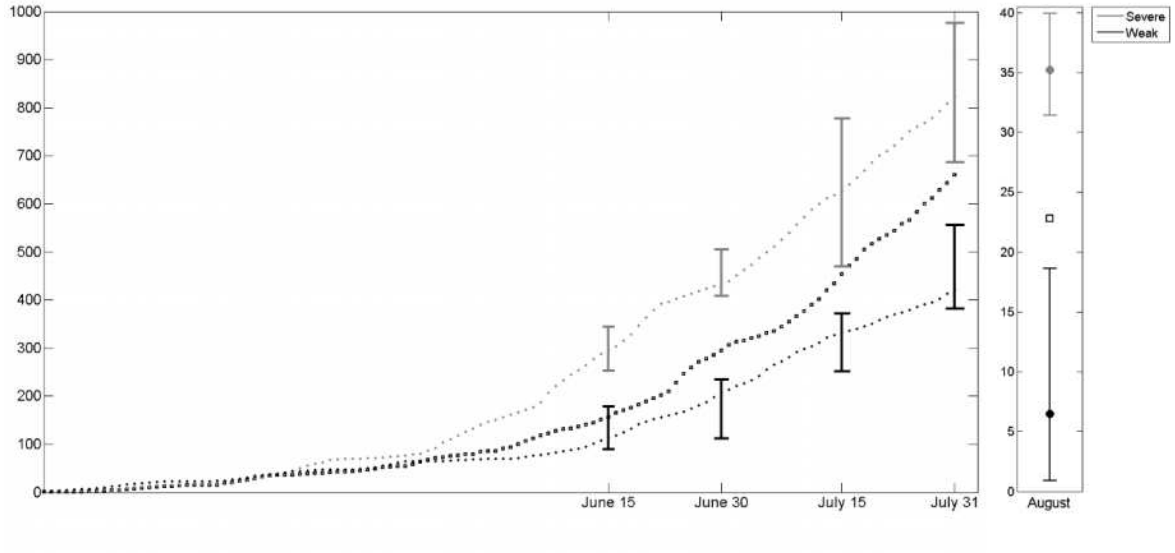

Figure 4. Left panel: daily values from April 1 to July 31 of median values of DSR_{td} for the entire period (1980-2011) (large black circle) and for the subsample of severe years (small light grey circles) and of weak years (small dark grey circles); whiskers in the two subsamples delimit the first and third quartiles of DSR_{td}. Right panel: as in the left panel but for the distribution of DSR_{bu} in August.

Meteorological model

Values of DSR_{td} and DSR_{bu} were used as covariates of the normal model of x, assuming a linear dependence in μ as in Equation (3) with $\psi = DSR_{td}$ and $\chi = DSR_{bu}$.. Obtained maximum likelihood estimates are a=0.09, b=0.02, c=3.07 and σ = 0.55 and the p-value of the likelihood ratio test is 0.0001, indicaing that adding the two covariates results in an improvement in the model that is statistically significant at the 0.01% level.

3.3. Model of fire severity

Model in diagnostic mode

Following DaCamara *et al*. (2014), the impact of the top-down and bottom up factor on burned area was statistically characterized by defining meteorological fire danger *MFD*, according to the following procedure:

1. A given threshold of baseline danger, D_{b0}, is fixed over the entire study area and the corresponding threshold x_0 is computed using Eq. (2);
2. For each year, the meteorological model is used to estimate the "climate + weather" danger, D_{c+w}, using Eq. (4) with threshold x_0 as defined in the previous step and the values of DSR_{td} and DSR_{bu};
3. Meteorological fire danger, *MFD*, is finally defined as the ratio between "climate + weather" danger, D_{c+w} and prescribed baseline danger D_{b0}:

$$MFD = \frac{D_{c+w}}{D_{b0}} \qquad (7)$$

The usefulness of meteorological fire danger may be assessed by making a model of fire severity that assigns levels of severity (low, medium, high) to a given year based on values of D_{md} associated to values of baseline danger D_{b0} of 20% and 80%. The procedure is shown in Figure 5, where values, MFD_{20} (MFD_{80}) of meteorological fire danger associated to a baseline danger D_{b0} of 20% (80%) are shown in the upper (lower) panel, using values of top-down factor DSR_{td} accumulated until July 31. The severity level of a given year is classified as high (not-high) if $MFD_{20} \geq 1.5$ ($MFD_{20} < 1.5$); a not-high year is then classified as a low (medium) level year if $MFD_{80} \leq 0.76$ ($MFD_{80} > 0.76$).
Results obtained are shown in Tables 1 and 2. There is a very good agreement between categories based on observed values of BA (weak, moderate and severe) and modelled levels of fire severity (low, medium, high); 25 (78%) were correctly classified out of 32 cases; all the remaining years were nevertheless attributed the immediate level and 2007 is the only misclassified extreme year (i.e. a weak year classified as one of medium level).

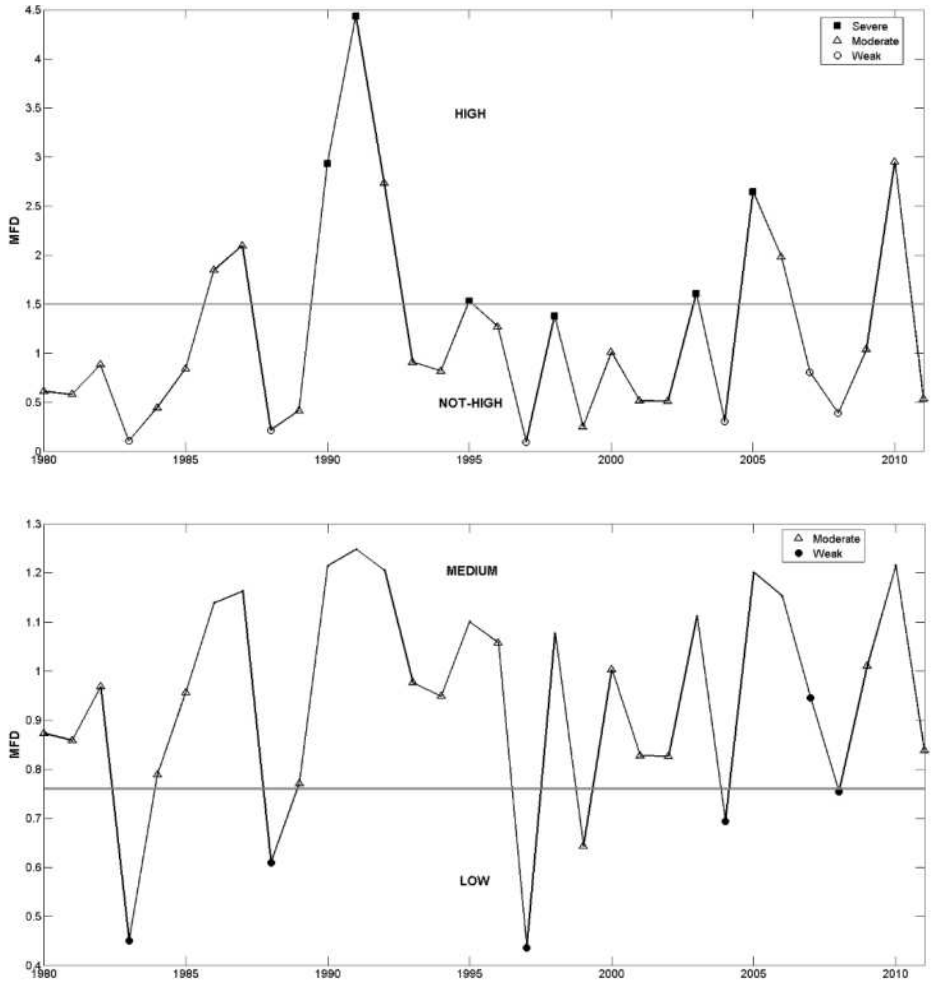

Figure 5. Time series of Meteorological Fire Danger (MFD) associated to values of baseline danger D_{b0} of 20% (upper panel) and 80% (lower panel). The horizontal dotted lines define the thresholds of 1.50 (upper panel) and of 0.76 (lower pane) that are used to classify a given year as high/not high (upper panel) and as low/medium level (lower panel). Squares, triangles and circles indicate years according to the categories of severe, moderate and weak according to the observed value of BA (Figure 3).

Table 1. Quality assessment of the fire danger model; years correctly classified by the model are printed in bold.

Modelled		**Years**
High		1986 1987 **1990 1991** 1992 **1995 1998 2003 2005** 2006 2010
Not high	*Medium*	**1980 1981 1982 1984 1985 1989 1993 1994 1996 2000 2001 2002** 2007 **2009 2011**
	Low	**1983 1988 1997** 1999 **2004 2008**

Table 2. Contingency tables of observed categories of burned severity (Figure 3) versus modelled levels of severity.

		Modelled levels of Severity		
		High	*Medium*	*Low*
Observed Categorie	*Severe*	**6**	0	0
	Moderate	5	**14**	1
	Weak	0	1	**5**

Model in prediction mode

The developed model of fire severity may be used in prediction mode at different stages of the year, namely. June 15, June 30, July 15 and July 31 when only the corresponding value of top-down danger D_{td} is known. The procedure is as follows:

1. Maximum likelihood estimates of parameters a, b and c of meteorological models are estimated that use as covariates D_{bu} in August and D_{td} accumulated until each stage (Table 3):
2. Value of D_{c+w}=0.3 for the high severity threshold is obtained by inverting Eq. (7) using MFD_{20}=1.50 and D_{b0}=20%. In a similar way value of D_{c+w}=0.6 for low severity is obtained using MFD_{80}=0.76 and D_{b0}=80%.
3. Value of μ^{+}=4.25 is obtained by inverting Eq. (4) using D_{c+w}=0.3, x_{20}=4.6 and σ=0.55. Value of μ^{-}=3.76 is similarly obtained using D_{c+w}=0.6, x_{80}=3.6 and σ=0.55.
4. Values of DSR_{bu}^{+} and DSR_{bu}^{-} are obtained by inverting Eq. (3) and using observed value of DSR_{td}: and appropriate coefficients a, b and c (Table 3):

$$DSR_{bu}^{+} = \frac{\mu^{+} - a \times DSR_{td} - c}{b} \quad (8)$$

$$DSR_{bu}^{-} = \frac{\mu^{-} - a \times DSR_{td} - c}{b} \quad (9)$$

5. The severity of the year is classified as "not high" if Prob$\{DSR_{bu} > DSR_{bu}^{+}\}$<20%; in a similar way the severity is classified as "not low" if Prob$\{DSR_{bu} < DSR_{bu}^{-}\}$<20%. When none of the two conditions is satisfied the level of severity is considered unknown. Probabilities are empirically estimated by fitting a normal distribution to the 32-year sample of observed values of DSR_{bu} (1980-2011).

Table 3. Maximum likelihood estimates of parameters a, b and c for meteorological models of fire danger using values of* DSR_{td} *observed at four different stages of the year.

	June 15	**June 30**	**July 15**	**July 31**
a	0.05	0.09	0.08	0.09
b	0.02	0.02	0.02	0.02
c	3.39	3.25	3.19	3.07

Obtained results are shown in Table 4 and it may be noted that models for June 15, June 30, July 15 and July 30 correctly anticipate years with levels of severity of "not low" in 17 out of 19 classifiable cases, in 18 out of 19, in 18 out of 19 and in 20 out of 21 years, respectively; the models are also able to correctly anticipate years with levels of severity of "not high" in 1 out of 2 classifiable cases, in 9 out of 10, in 8 out of 9 and in 10 out of 11 years, respectively. It is apparent that years with levels of "not low" may be correctly anticipated at an earlier stage of the year than those with levels of "not high"; this is especially true when comparing severe years that are never classified as "unknown" by the model with the case of weak years where the same only occurs for the model of July 31. Finally it is worth noting that all model (since June 15) are able to correctly classify as "not low" all but one of the severe years, the only exception (1998) being erroneously classified as "not severe" by models at all stages of the year. A possible explanation is an anomalous accumulation of biomass, given the fact that 1997 was by far the year with lowest burned area. Predictions seem less robust for weak years, all but one year (2004) being correctly classified as "not high" at the last stage (July 31); again the exception is incorrectly classified at all stages but it is worth noting that large fires occurred in the first days of September (which if included would turn 2004 into a moderate year).

Conclusions

A study was performed aiming to assess the role of meteorological factors on the inter-annual variability of burned area over a region of Central Portugal. The study covers a 32-year period that extends from 1980 to 2011. The study region is dominated by forest, the predominant species being maritime pine and eucalyptus. The large fractions of the forested area and the high percentages of tree species that are extremely flammable in summer explain the fact that, although occupying only 18% of the territory of Portugal, the chosen study area is responsible for 43% of the burned area in August during the study period.

A normal distribution model was fitted to the 32-year sample of decimal logarithms of monthly burned area. This model was then improved by introducing as covariates two different measures of prevailing meteorological conditions as derived from Daily Severity Rate (DSR), an indicator of meteorological fire danger; a top-down factor, DSR_{td}, which consists of cumulated values of monthly means of DSR from April 1 to July 31 and a bottom up factor, DSR_{bu}, defined as the square root of the mean of the squared daily deviations of DSR in August from daily climatology, the average being performed only over days of positive deviation.

The two models, the one without and the one with meteorological covariates, allow estimating baseline and climate+weather fire danger, both defined as the probability that the monthly burned area exceeds a given threshold. These two quantities allow defining meteorological fire danger, based on which a probabilistic model of fire severity is built that assigns levels of severity to a given year. This model may be used in either diagnostic or prognostic modes. When used in diagnostic mode, 25 (78%) out of 32 cases were correctly classified. When used in prognostic mode, at four different stages of the year (June 15, June 30, July 15 and July 31), the very large majority of years with levels of severity classified as "not low" (17 out of 19 classifiable cases, 18 out of 19, 18 out of 19 and 20 out of 21 years, respectively) were correctly anticipated. Good results were also obtained for years with levels of severity classified as "not high" (1 out of 2 classifiable cases, 9 out of 10, 8 out of 9 and in 10 out of 11 years, respectively).

Results from the present study put into perspective the key roles played by meteorological factors associated to different spatial and temporal scales on the occurrence of fire seasons characterized by very high or very low fire activity. This information may be of use to forest managers when organizing fire preventing measures and firefighting capacity and when allocating resources for both. It may be also useful when developing an on-line alarm system to predict the event of extreme fires since such a system depends on constructing a sound model that links the fire size process to the multivariate exploratory variables.

Abstract

The growing incidence of large wildfires impacting urban interfaces and values of interest over the past decades has led to extensive research on decision support tools for fire risk assessment and management. The inherent complexity of risk management and fuel treatment planning has led to a rapid increase in the application of fire spread and behavior modeling software for both research and operational applications. Simulation models are now routinely used to analyze potential fire behavior and to develop risk assessments and mitigation strategies, over a range of scales, from forest stands (a few hectares) to large landscapes. Fire behavior models mainly used for fuels planning in the US and elsewhere include NEXUS, FVS-FFE, FARSITE, FlamMap, RANDIG, and FSIM. The geospatial interface to these models, ArcFuels, is used to streamline preparation of input files and post-process simulation outputs. The majority of these landscape fire simulation models use the minimum travel time algorithm, a compact fire simulation algorithm that makes it computationally feasible to simulate thousands of fires and generate burn probability and intensity maps over large areas. The outputs can be used to study wildfire topology on complex landscapes, and analyze uncertainty associated with wildfire events in terms of timing, location, intensity, and duration. Wildfire simulation models have also been coupled with spatial optimization software to design efficient landscape fuel treatment plans. From a risk assessment standpoint, the key benefit of newer wildfire simulation approaches, compared to previous work on spatial patterns in ignition patterns, is that the former accounts for risk factors that influence landscape wildfire spread, while the latter does not. Overall, properly calibrated and validated, wildfire simulation methods offer a dramatic increase in information content for conservation, restoration, and fire protection planning on fire-prone landscapes. Risk assessments using simulation methods have now been completed for a range of issues including carbon offsets, endangered wildlife species, habitat conservation, watersheds and WUI protection, and protection of biodiversity. In this talk, we will discuss the application of wildfire simulation models and geospatial tools for wildfire risk assessment and management for several study areas including the western US and the Mediterranean Basin.

Introduction

To reduce the growing financial and ecological losses from large wildfires, risk assessment and cost-effective mitigation activities have become a challenge for planners, policy makers, fuel managers and

Forest Services (Ager *et al.* 2011; Calkin *et al.* 2011). The relevant importance of wildfire risk assessment and fuel management will play a key role with urban expansion into the wildlands, land use variations and climate-change effects on fire occurrence frequency, burn probability, fire intensity and the related consequences (Brown *et al.* 2004; Westerling *et al.* 2006; Moreira *et al.* 2011; Arca *et al.* 2012; Kloster *et al.* 2012; Brotons *et al.* 2013; Ager *et al.* 2014). Since weather and topography are beyond human control (Finney 2007), wildfire mitigation activities encompass a wide range of operational methods including thinning, mechanical treatments for limiting fuel load and continuity, prescribed burning, and creation of infrastructures and fuelbreaks (Agee and Skinner 2005; Montiel and Kraus 2010). These activities have the aim of reducing both surface and canopy fuel load and continuity, to ultimately bring down the occurrence of uncharacteristic wildfires (Agee *et al.* 2000; Cochrane *et al.* 2012). Fire mitigation projects vary widely depending on ecosystems and ecological conditions, a strong role being played by historical fire regimes, weather, topography, and the spatial pattern of values at risk. For instance, some treatments are designed as localized fuelbreaks to minimize fire occurrence within highly valued social and ecological values as well as susceptibility, while others are designed to impede or slow down the spread of fire over large landscapes (Ager *et al.* 2011).
In this paper, we define fire risk as the expected loss or benefit after the fire, and fire exposure as the analysis of the probability of a fire at given intensities (Figure 1; Fairbrother and Turnley 2005; Finney 2005; Salis *et al.* 2013). We define risk factors as the individual contributing components to risk (likelihood, intensity and susceptibility). Quantitative assessment of wildfire risk requires (a) the probability of a fire at a specific location; (b) the conditional fire intensity, measured by flame length; (c) the resulting net value change in financial or ecological value (Finney 2005; Miller and Ager 2013). Wildfire exposure is a necessary step in risk assessment and does not include the quantification of expected wildfire impacts.

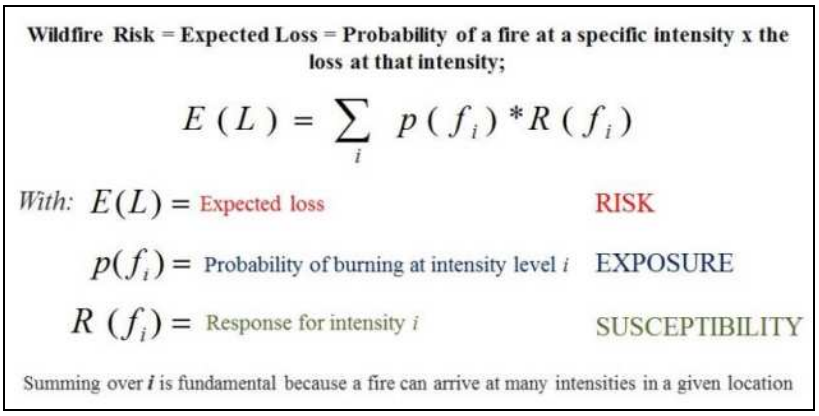

Figure 1. Overview of the definition used for fire risk, exposure, and susceptibility in this paper

From a risk standpoint, it is important to note that in all ecosystems a very small proportion of wildfires globally accounts for most of the burned area, as well as the resulting damages and human casualties: thus, accounting for the risk posed by large destructive wildfires requires consideration of their behavior and spread over large areas (Viegas 2004; Finney *et al.* 2005; Viegas *et al.* 2006; Ager *et al.* 2010*a*, 2013; Salis *et al.* 2013). The complexity of fire risk assessment and management and the abovementioned points have led to a rapid increase in the application of fire behavior modeling software in both research and operational contexts. Simulation models are now routinely used to analyze potential fire behavior and to develop risk assessments and mitigation strategies, over a range of scales, from forest stands (a few hectares) to landscapes ($< 10^5$ ha), regional ($< 10^7$ ha) or national scales (Calkin *et al.* 2011). Fire behavior models used for fuels planning include NEXUS (Scott 1999), BehavePlus (Andrews 2007), FVS-FFE (Rebain 2010), FARSITE (Finney 1998), FlamMap (Finney 2006), RANDIG (Finney 2002), and FSIM (Finney *et al.* 2011). The geospatial interface to these

models, ArcFuels, is used to streamline preparation of input files and post-process simulation outputs (Vaillant *et al.* 2013). To analyze uncertainty associated with wildfire events in terms of timing, location, rate of spread, intensity, and duration, simulation of thousands fires at landscape scales are commonly performed. A number of supporting models and software can be used, in conjunction with historical databases, to estimate appropriate wind, weather, dead and live fuel moisture, and other input variables required to run a fire behavior model (Nelson 2000; Butler *et al.* 2006; Stratton 2006; Forthofer 2007). While the application of non-spatial fire behavior models for a single fuel type and constant weather conditions is relatively straightforward, the design and evaluation of large-scale risk assessment and management activities requires more complex landscape fire modeling to fully characterize fire exposure and potential effects of events burning with diverse conditions in an area. The abovementioned issues have created a strong demand for an integrated modeling system to assess current wildfire exposure and risk, and to analyze the potential benefits of proposed fuel management and other mitigation activities (Miller and Ager 2013). The majority of these landscape fire simulation models use the minimum travel time algorithm (MTT, Finney 2002), a compact fire simulation algorithm that makes it computationally feasible to simulate thousands of fires and generate burn probability and intensity maps over large areas (Ager *et al.* 2012). The MTT algorithm searches for the fastest path of fire spread along straight-line transects connected by the cell corners (nodes) (Figure 2; Finney 2002, 2006): MTT pathways are then interpolated to reveal the fire perimeter positions at specific instants in time.

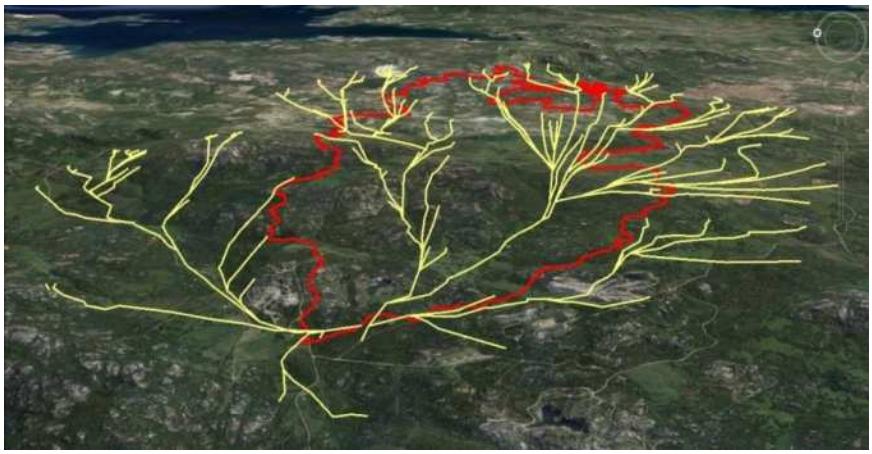

Figure 2. Major fire flow paths (yellow) and observed wildfire perimeter (red) over an aerial photograph. The flow paths, obtained by the MTT spread algorithm, searches for the fastest path of fire spread along straight-line transects connected by nodes. The example refers to a wildfire occurred in North-East Sardinia, Italy (Lu Lioni, Arzachena, August 2004).

The outputs can be used to study wildfire topology on complex landscapes, and analyze uncertainty associated with wildfire events in terms of timing, location, intensity, and duration. Wildfire simulation models have also been coupled with spatial optimization software to design efficient landscape fuel treatment plans (Finney 2006; Seli *et al.* 2008). From a risk assessment standpoint, the key benefit of newer wildfire simulation approaches, compared to previous works on spatial patterns in ignition occurrence patterns, is that the former accounts for risk factors that influence landscape wildfire spread, while the latter does not (Ager *et al.* 2011, 2014). Overall, properly calibrated and validated, wildfire simulation methods offer a dramatic increase in information content for conservation, restoration, and fire protection planning on fire-prone landscapes (Arca *et al.* 2007; Ager *et al.* 2007, 2010*a*; Salis *et al.* 2013). Risk assessments using simulation methods have now been completed for a range of issues including carbon offsets, wildlife habitat conservation, WUI protection, and protection of biodiversity. In this paper, we will discuss the application of wildfire simulation models and

geospatial tools for wildfire risk assessment and management for several study areas including the western US and the Mediterranean Basin.

Methods

The majority of fire behavior models are derived from systems that model one-dimensional fire behavior as part of a spreading line fire. Most models linked or integrated Rothermel's models for predicting surface and crown fire rates of spread with VanWagner's or Scott's crown fire transition and propagation models, and provided outputs of diverse fire behavior characteristics (rate of spread, fireline intensity, flame length, crown fire activity, etc.) (Rothermel 1972; Anderson 1983, Van Wagner 1993; Scott and Reinhardt 2001). In depth discussions of these models and their limitations, as well as programs and tools to determine appropriate weather inputs, to select fuel management scenarios, or to streamline preparation of input files and post-process simulation outputs, can be found in several recent papers, as presented in the Introduction.
The minimum travel time (MTT) fire spread algorithm of Finney (2002) is one of the most used to analyze fire exposure and characterize fire behavior. The MTT algorithm has been extensively described elsewhere and is routinely applied to fire management problems in the US and elsewhere; initial calibration (Figure 2) and validation of the Rothermel's fire spread model as implemented in FARSITE and the MTT were performed and described by several research papers (Ager *et al.* 2007, 2012; Arca *et al.* 2007; Duguy *et al.* 2007; Andrews 2009; Salis 2008; Salis *et al.* 2013, 2014).
FlamMap MTT utilizes the same set of gridded spatial inputs as the FARSITE simulation system. The spatial inputs include eight grid themes that describe fuel canopy characteristics, surface fuel model, and topography, which are combined into a binary landscape (LCP) file (Figure 3; Finney 1998). Surface fuels are described by fuel models that characterize dead and live fuel load (by size class), surface-area-to-volume ratio for live and dead fuels, fuelbed depth, moisture of extinction, and heat content. Fuel models are derived by field measurements, selected using photo guides, or obtained from other data sources (Anderson 1982; Scott and Burgan 2005; Arca *et al.* 2009). Canopy fuels are described by percentage of cover, crown bulk density, crown base height, and average height.

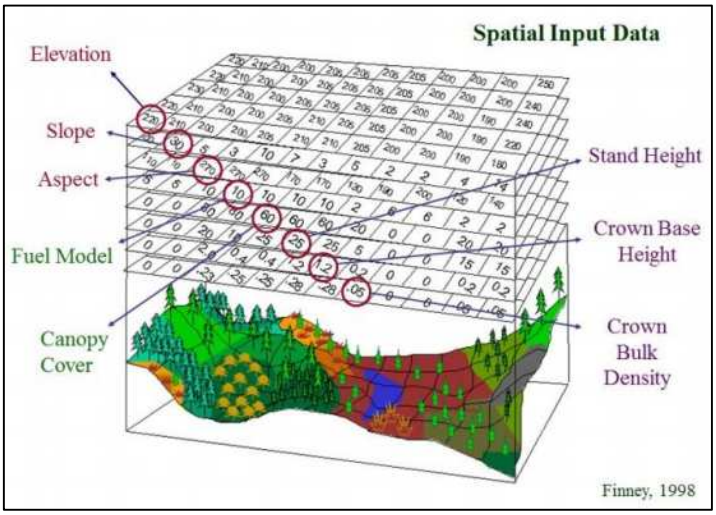

Figure 3. Topography, surface and crown fuels grid data used for wildfire simulations by FlamMap, FARSITE, Randig, and FSIM. The data are easily converted with ArcFuels scripts to the binary format (landscape file) required by the abovementioned fire models.

With the MTT approach, multiple fires are simulated to generate burn probabilities and fire behavior outputs (Figure 4). A user-defined number of random or historic based ignitions (from 1 to more than 100,000) for fixed or variable burn periods are simulated. The MTT reports a conditional burn

probability at each pixel for twenty 0.5-m intervals (0–10m). The conditional burn probability is the chance that a pixel will burn at a given flame length interval, considering one ignition in the whole study area under the assumed conditions. Fireline intensity outputs are converted to flame length based on Byram's (1959) equation: the modeled intensity depends on the direction in which the fire encounters a pixel relative to the major direction of spread (i.e. heading, flanking or backing fire), as well as slope and aspect (Finney 2002). Fire size and ignition coordinates for each simulated fire are also generated as output.

Overall, three widely recognized issues with the application of the fire behavior models are the choice of the most appropriate fuel model, the quantification of canopy fuels, and the limitation of Rothermel's model in complex terrains. About the first point, several fire behavior models require a surface fuel model, which is typically chosen from standard or custom models. Fuel models are difficult to calibrate and are rarely validated with observed fire behavior (Arca *et al.* 2007; Salis 2008; Ager *et al.* 2011). Also, known limitations exist with estimates of canopy fuel characteristics, critical to model crown fire behavior (Cruz and Alexander 2010). Canopy base height and foliar moisture content are both used to calculate the critical fireline intensity, and canopy bulk density is used to determine active crown fire rate of spread. Because destructive measuring on canopy fuels is not feasible and expensive, indirect methods using tree inventory data are necessary (Reinhardt *et al.* 2006). Vegetation modeling systems such as FVS-FFE are used to process inventory data to determine the effective canopy base height and canopy bulk density using a running mean. Furthermore, fire behavior models rely on the Rothermel's surface fire equations, and fire behavior is only represented for frontal combustion. This is a limitation for wildfires spreading in complex terrains, where specific physical phenomena associated to wildfires (e.g.: fire channeling) are not properly captured by the Rothermel's spread model (Viegas and Pita 2004; Viegas 2006; Sharples *et al.* 2012).

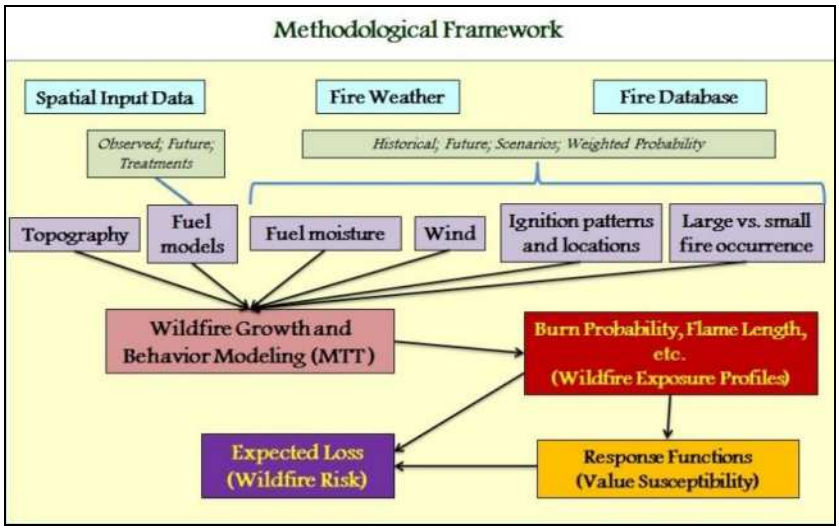

Figure 4. Methodological framework for wildfire growth and behavior modeling and wildfire risk evaluation

Results

The MTT algorithm was applied to complete several case studies in the Mediterranean Basin and in the US, as for instance 1) to quantify landscape wildfire exposure and risk, 2) to determine fire exposure profiles for values at risk, 3) to assess temporal variation in fire exposure, 4) to compare fuel treatment alternatives, and 5) to examine expected carbon offsets from fuel treatments.

In the first application, wildfire risk was calculated for northern spotted owl (*Strix occidentalis caurina*) habitat, old growth forests, and carbon in several studies in Oregon (Figure 5; Ager *et al.*

2007, 2010*a*, 2010*b*). In the first case study, the probabilistic risk analysis system was used for quantifying wildfire threats to spotted owl habitat. 10,000 wildfire simulations with randomly located ignitions were run to calculate spatially explicit probabilities of habitat loss for fuel treatment scenarios on a 70,245 ha study area. A flame length threshold for each spotted owl habitat stand was determined using FVS-FFE and used to predict the proportion of fires that resulted in habitat loss.

In later work, simulation modeling was used to analyze spatial variation in wildfire exposure on the island of Sardinia (24,000 km^2), Italy (Salis *et al.* 2013). Weather conditions associated with large escaped fires were used as input to simulate 100,000 fire events within the study area, randomly drawing from the frequency distribution of burn periods and wind directions. Historical data and wildfire simulations were used to estimate burn probabilities, flame length and fire size. Spatial patterns in modeled outputs were strongly related to fuel loadings and weather conditions, although topographic and other influences were apparent. Both studies allowed to quantify exposure profiles (burn probability, flame length, fire size) and to identify landscapes able to support large and severe fires.

In a subsequent application, the analyses were scaled up to analyze wildfire exposure factors (burn probability, fire intensity) to social and ecological values on Oregon and Washington States, and Sardinia (Italy) (Ager *et al.* 2012; Salis *et al.* 2013). Example plots of fire exposure factors can be used to identify highly valued resources at risk, and to prioritize fuel management activities.

Another application to quantify fire risk based on fire modeling was presented by Thompson *et al.* (2011), which described a quantitative, geospatial fire risk assessment tool based on burn probability modeling, identification of values at risk, and production of response functions.

In another paper, the spatiotemporal changes in wildfire exposure in Sardinia (Italy) from 1980 to 2009 in relation to historical changes in fire ignition patterns, weather, suppression activities, and land uses were analyzed (Figure 6; Salis *et al.* 2014). 100,000 fire events were simulated for two time frames, reflecting the 1980-1994 and 1995-2009 conditions, drawing from the frequency distribution of the specific burn periods and wind directions associated with large wildfires observed in the island. In that research paper, along with a net reduction in area burned and ignitions, an advance of 15 days for the fire season peak, and an increase in spring temperatures, the wildfire modeling highlighted strong spatial variations in burn probability and increments in fire exposure for WUI areas. Considering that little change was observed for land use types and associated fuels for the analyzed timeframes, a combination of social factors and suppression capabilities may be responsible of the above mentioned results.

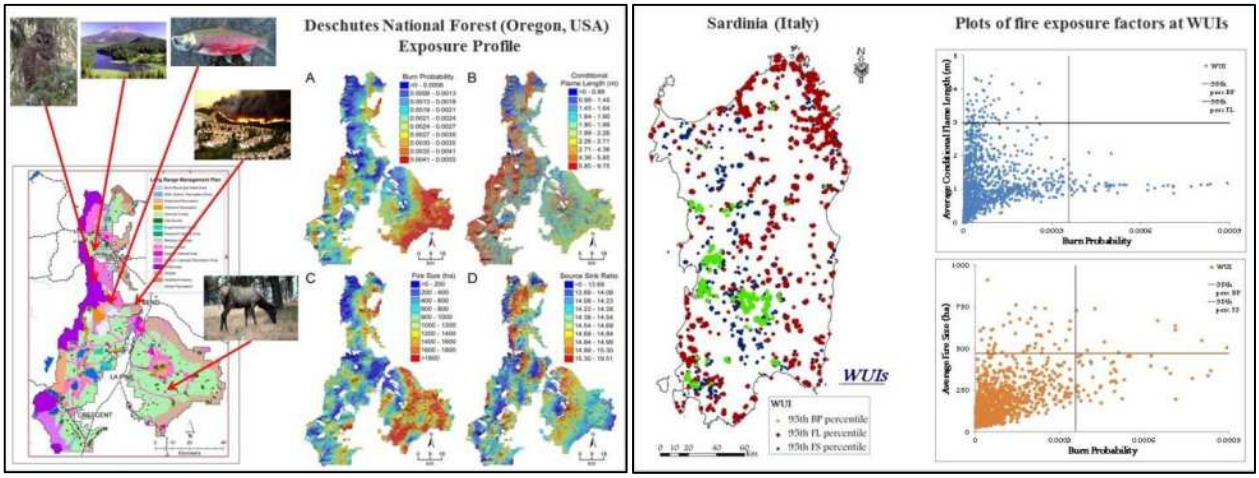

Figure 5. On the left, maps of burn probability (BP, a), conditional flame length (CFL, b), fire size (FS, c), and source sink ratio (SSR, d) for the for northern spotted owl habitat in central Oregon, US. On the right, scatterplots of fire exposure factors (BP vs CFL and BP vs FS) for wildland urban interfaces in Sardinia, Italy. The map shows the WUIs with BP, FL and FS values higher than the 95th percentile

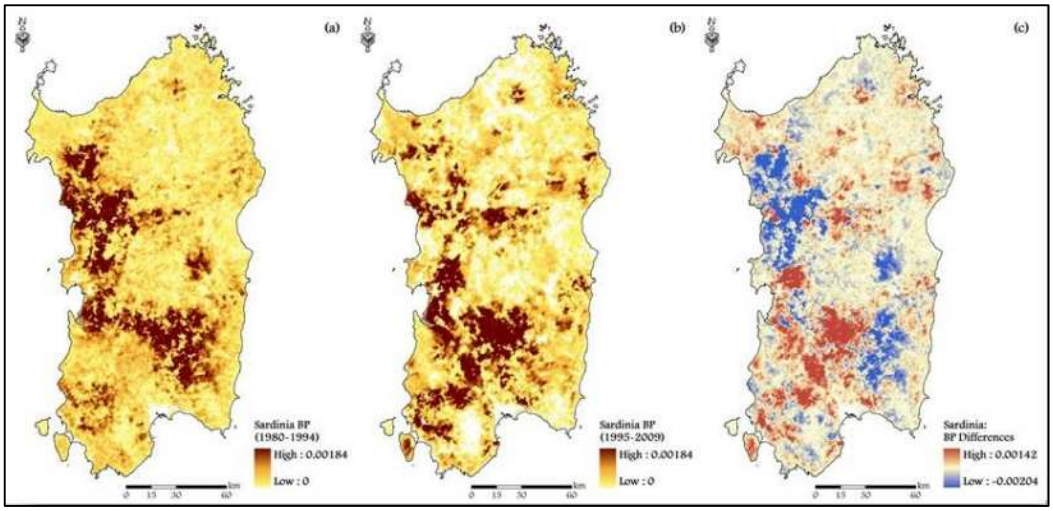

Figure 6. Variation in BP between 1995-2009 and 1980-1994 study periods in Sardinia, Italy. BP is the chance that a pixel will burn, considering one ignition in the whole study area under the assumed conditions

In another study, a risk framework was used to analyze tradeoffs between ecological management objectives (large fire resilient trees) versus the protection of residential structures in the wildland urban interface (WUI) (Figure 7; Ager *et al.* 2010*a*). The former was quantified using the expected mortality of large trees and the latter with burn probability in the location of residential structures. This study was conducted in a 16,000 ha study area in Oregon, US, to examine tradeoffs between placing fuel treatments near residential structures within an urban interface, versus treating stands in the adjacent wildlands to meet forest health and ecological restoration goals. The treatment strategies were evaluated by simulating 10,000 wildfires with random ignition locations, and replicating severe fire events based on 97th percentile historic weather conditions.

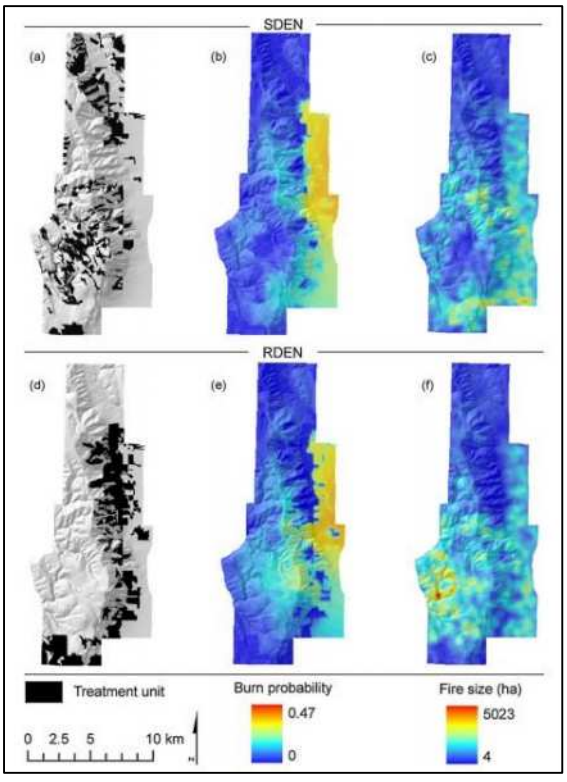

Figure 7. Maps of treatment units (a and d), burn probabilities (b and e), and kernel smoothed fire size (c and f) for the 20% treatment area for the stand density (SDEN) and the residential density (RDEN) treatment priorities, for the study area close to La Grande, OR (USA)

The main findings were that treatments strategically located on a relatively minor percentage of the landscape (10%) resulted in a roughly 70% reduction in the expected wildfire loss of large trees for the restoration scenario; treating stands near residential structures resulted in a higher expected loss of large trees, but relatively lower burn probability and flame length within structure buffers.
About mitigation activities and landscape fuel management, both positive and negative carbon impacts have been reported (Finkral and Evans 2008; Mitchell *et al.* 2009; Reinhardt and Holsinger 2010). A 70,000 ha watershed on the Fremont-Winema National Forest in southern Oregon, US, was used as case study to assess the expected carbon change from fuel treatments, combining carbon loss functions with the flame length probability outputs (Figure 8; Ager *et al.* 2010*b*). As result, a probabilistic estimate of carbon impacts that accounted for the uncertainty about future wildfire events was yielded. In this work, 30,000 wildfires were simulated with random ignition locations under both treated and untreated landscapes. The results suggested that the carbon loss from implementing fuel reduction treatments exceeded the expected carbon benefits associated with lowered burn probabilities and reduced fire severity on the treated landscape.

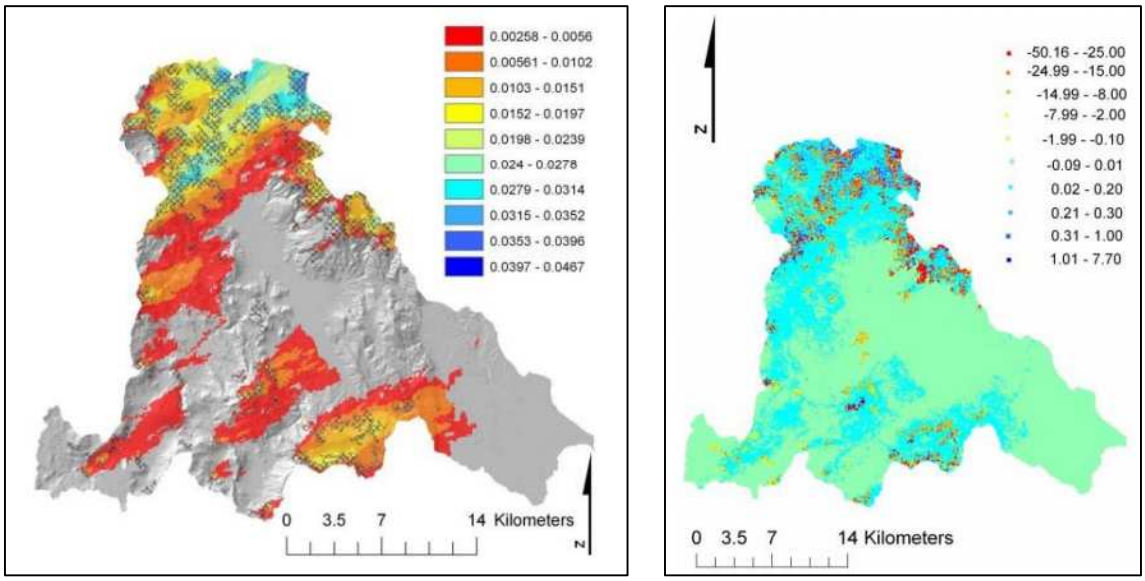

Figure 8. On the left, difference in BP between the non-treatment and treatment scenario for the Drews Creek watershed, Fremont - Winema National Forest (Oregon, USA). Stands selected for fuel treatments are hatched. Areas not shaded had differences less than 0.00258. On the right, expected carbon differences (tonnes ha^{-1}) between non-treatment and treatment scenarios

Discussion and Conclusions

Although our example applications are related to case studies from US national forests and Sardinia (Italy), the proposed methods for quantifying fire exposure and risk and for supporting fuel management planning can be applied elsewhere. When the MTT fire spread algorithm for FlamMap was parallelized for multithreaded processing, it became computationally feasible to simulate thousands of fires to generate spatially explicit fine scale burn probability and intensity maps over large areas (Ager *et al.* 2012). Extensive testing has shown that this algorithm can replicate fire size distributions in the North American ecosystems and the Mediterranean areas (Ager *et al.* 2007, 2010a, 2012; Parisien *et al.* 2007; Bar Massada *et al.* 2009; Salis *et al.* 2013, 2014). In addition, the incorporation of the MTT algorithm into fire behavior models make it feasible to rapidly generate fire exposure and risk maps for different fuel management, weather, fuel conditions, or ignition scenarios (Ager *et al.* 2011).

Newer models that use the MTT algorithm include spatiotemporal probabilities for ignition, escape, and burn conditions, and yield estimates of annual burn probabilities; the identification of the areas characterized by the highest exposure and risk, as well as the zones to be prioritized for mitigation strategies, can be easily determined with the abovementioned approach. A strong effort in the integration of tools, scientific findings and data for an operational application of the fire behavior models was addressed, with the aim of supporting wildfire risk assessment and management (Forthofer 2007; Vaillant *et al.* 2013). An important end-product is providing an efficient working environment that allows users to interact with fire behavior models in a geospatial context, and thus gain a better understanding of their limitations and biases. Application of fire behavior modeling continues to grow among planners and researchers alike, especially as land management agencies and policy makers require integrated landscape analyses (Ager *et al.* 2013). The analysis framework proposed contributes to a consistent analytical process for assessing the level of exposure and risk that communities and highly valued resources face from wildland fires. Risk provides a comprehensive index of likelihood, intensity, and potential effects. Burn probability modeling and exposure analyses play an important role in research to address a number of management problems, including analyzing carbon offsets, understanding temporal and spatial tradeoffs of fuel treatments, climate changes impacts, post fire recovery, soil erosion, and wildfire impacts to ecological conservation reserves.

Abstract
The highly erodible ash material that covers the ground after fire is increasingly gaining attention as a potential major contributor to water contamination in fire-affected landscapes.
The recent and severe forest fires near Sydney (October 2013) provided an ideal opportunity to identity and quantify the potential main threats to water quality from pollutants present in the ash. These fires affected forests in the greater Sydney catchment, raising serious concerns about the risk of drinking water contamination from post-fire erosion.
An extensive sampling campaign (sampling points = 120) was carried out in Jan. 2014 along a ridge with homogeneous vegetation and soils, but affected by a range of burn severities. Burn severity was classified based on the differenced Normalised Burn Ratio obtained from satellite imagery, validated by field observations and linked to estimates of fire intensity.
Three burn severities were sampled: extreme (>70,000 kW m-1); moderate (7000-500 kW m 1); and low (<500 kW m-1). At each sampling point, the entire ash layer was collected from a square are of a specified size. The ash layer comprised the loose, charred and wettable material (<1 cm size) lying on top of uncharred water-repellent mineral soil.
Total loads of ash increased substantially with burn severity with averages of 35 16 and 6 t/ha for extreme, moderate and low severity sites, respectively. Notable differences exist in ash composition between fire severities, from comprising mainly charcoal and fine charred particles (derived largely from combustion of litter and vegetation) at low severity sites to a more mineral enriched composition (with substantial contribution from charred mineral soil) at extreme severity sites.
Results in bulk chemical composition of ash and main pollutants availability will be presented and discussed with special focus on potential implications for water quality impacts based on a series of post-fire rainfall and erosion scenarios.

Keywords*: Australia, bushfire, fire severity, eucalypt forest, drinking water, pollutants.*

Introduction

Wildfire enhances the risk of soil erosion and sediment transfer through the removal of vegetation and litter, and changes to soil wettability with associated contamination risks for surface water bodies. Most previous studies on post-fire erosion have focused on soil erosion and associated sediment transfer. The highly erodible ash material that covers the ground after fire and which can be rapidly mobilised and transferred into water bodies by water and wind erosion, however, has been largely overlooked to date. This ash, generated from combustion of vegetation, litter and surface soil, is increasingly gaining attention as a potential major contributor to post-fire water contamination (Bodi *et al*. 2014).
An extensive wildfire near Sydney (October 2013) provided us with an ideal opportunity to determine the quantities of ash produced during wildfire in relation to burn severity and to identity and quantify the main threats to water quality from contaminants contained in the ash. The fire affected parts of the Nepean catchment, which contributes to the greater Sydney water supply system, raising serious concerns about the risk of water contamination from post-fire erosion.

Methods

In October 2013, severe wildfires burnt 10,000 ha of dry sclerophyl eucalypt forest near Sydney (NSW, Australia). Sampling was carried along at a ridge in the Nepean catchment with homogeneous vegetation species composition, fuel load and soil characteristics, but with a range of burn severities, resulting from wind-driven differences in fire behaviour. Burn severity was determined using the differenced normalised burn ratio (dNBR) obtained from satellite images immediately before (1 day) and after (1 week) the fire, supported by on site determination of fuel consumption completeness and linked to estimates of fire intensity. Between the fire and the sampling campaign (early January 2014), rainfall was very limited so that there had been no significant redistribution of material by water erosion.

Three burn severities were sampled: *i) extreme* (>70,000 kW m^{-1}), *ii) moderate* (7000-500 kW m^{-1}), and *iii) low* (<500 kW m^{-1}). For each burn severity, three replicate sites were sampled with 30 sampling points each. At each sampling point, a square of known size was sampled by careful brushing together and collecting the entire ash layer. The ash layer comprised the loose, charred and wettable material (<1cm size) material lying on top of uncharred water-repellent mineral soil. It included residues from the burning of aboveground vegetation and litter, as well as the completely-charred and structureless surface mineral soil. Litter and soil was also samplied at a long-unburned control site on the same ridge.

All samples being analysed for basic parameters (pH, CEC, and total carbon, phosphorous and nitrogen concentrations) as well as total concentrations of trace elements at the time of writing. In addition, leaching tests (Hageman *et al*. 2008) will be also performed on selected representative samples to assess biochemical availability of toxic elements (metals and metalloids) and eutrophication agents (nutrients).

3. Results

Irrespective of burn severity the ash layer was consistently wettable and dark in colour whereas the underlying uncharred soil was highly water repellent and lighter in colour. However, notable differences exist in ash composition between the different fire severities, from comprising mainly charcoal and fine charred particles (derived largely from combustion of litter and understory vegetation) at low severity sites to a more mineral enriched composition (probably with substantial contribution from charred mineral soil) at extreme severity sites.

Total loads of ash increased substantially with burn severity with averages of 35 (±2.0 Standard Error of Mean), 16 (±0.9 SEM) and 6 t/ha (±0.7 SEM) for extreme, moderate and low severity sites, respectively. Ash bulk density also increased with burn severity with values of 58.9 (STDEV 6.4) , 53.7 (STDEV 14.9) and 34.5 g cm^3 (STDEV 16.4) for extreme, moderate and low severity sites, respectively, which supports the increasing contribution from charred mineral soil with burn severity. Results regarding bulk chemical composition of ash and the availability of main pollutants will be presented and discussed with special focus on potential implications for water quality impacts based on a series of post-fire rainfall and erosion scenarios.

Abstract
Accurate information about location and extent of burnt area is required and of particular interest for the scientific communities dealing with meteorological and climate models in what respects to reliable estimations of biomass burned. An automated procedure is here presented that allows identifying and assigning dates of occurrence to burned areas in Portugal using daily reflectance from NIR (near-infrared) and MIR (middle infrared) bands, obtained from the MODIS instrument on-board Aqua and Terra satellites. The algorithm detects persistent changes in the so-called (V, W) Burned Index time series, and the day of maximum change is then identified as the burning day. The procedure was applied to the extreme summer of 2005 and results were validated against a reference map derived from Landsat imagery. Comparison between the burned map as obtained using the developed procedure and the reference map resulted in a Proportion Correct of 96%. Probability of Detection was 63%, meaning that the algorithm was able to identify almost two thirds of the scars occurred in 2005. An assessment of the temporal accuracy of the dating procedure was also conducted. Results show that 75% of burnt pixels were correctly dated by the algorithm with differences to the hotspots dates less than five days.

***Keywords**: Burned areas, NIR and MIR bands.*

Introduction

Portugal is the European country most prone (per unit area) to fire occurrences, which are responsible for many damages, like the emission of greenhouse gases and pollutants, the loss of vegetation and lives, the soil erosion, the proneness to floods in the period following the fire events and the economic impact, among others.
Instituto de Conservação da Natureza e das Florestas (ICNF), the Portuguese authority for forests, has been producing yearly maps of fire perimeters. The fire atlas uses end of fire season Landsat TM/ETM imagery to map all fire perimeters with areas larger than 5 ha. Because it relies on end-of-season imagery, the atlas provides a spatial snapshot of the yearly area burned, and dates of burning for individual events cannot be estimated. However, such information is required to fully understand the fire regime and fire seasonality and to disentangle the complex interactions among fire, land cover and meteorology.
The aim of this work is to apply the so-called (V,W) Burned Index in order to identify and assign dates of occurrence to burned areas in Portugal using daily reflectances from NIR (near-infrared) and MIR (middle infrared) bands, obtained from the Moderate Resolution Imaging Spectrometer (MODIS) instrument on-board Aqua and Terra satellites.

Methods

2.1. Data

Data consist of top of the atmosphere values of MIR radiance, NIR reflectance and thermal infrared (TIR) brightness temperature, acquired by the MODIS instrument on-board Aqua and Terra satellites during July, August and September 2005, together with the respective solar zenith angles. Data were obtained from the Aqua and Terra / MODIS Level 1B 1 km V5 product, MOD021 and MYD021, (MCST, 2006) and respect to channels 2 (centred at 0.858μm), 20 (centred at 3.785μm), and 31 (centred at 11.017μm). Surface values of MIR reflectance are then retrieved by applying the methodology developed by Kaufman and Remer (1994), paying special attention to the possible drawbacks previously pointed out by Libonati *et al*. (2010). Data from Aqua and Terra / MODIS Geolocation Fields Level 1A V5 are also used (MOD03 an MYD03).
Validation of results from the analysis performed on MODIS images is mainly carried out based on the annual atlas provided by the ICNF, based on end of fire season Landsat TM/ETM imagery. Validation of the dates assigned is based on the comparison of estimated dates by the developed procedure and dates of hot spots as identified by Modis.

2.2. The "V,W" Burned Index

Following the procedure described in Libonati *et al*. (2011), the "V,W" burned index is computed for each image based on differences (ξ index) between the reflected component of MIR (middle-infrared, centred at 3.785 μm) and NIR (near-infrared, centred at 0.858 μm) together with the distance (η index) to a convergence point in MIR/NIR space, representative of a totally burned surface. Information of hot spots extracted from the MODIS Fire and Thermal Anomalies Product (MOD14A1/ MYD14A1) is also used.
Coordinate V has a very small scatter for pixels associated with vegetated surfaces and coordinate W covers a much wider range of values, allowing the identification of water content of vegetative surfaces.

2.3. Identification of Burned Areas

Monthly minimum value composites of W are computed and seed points of potentially burned areas are selected based on pre-specified thresholds of W and on temporal differences of W between composites; seed points also have to be located inside a buffer around MODIS hot spots.
Burned areas are identified by expanding the search around selected seed points. Pixels considered as burned are identified based on relative thresholds whose values are contextually derived from the pixels in the neighbourhood. A spatial filter is finally applied to remove outliers.

2.4. Assigning dates to burned areas

The algorithm detects persistent changes in the (V, W) burned index time series, and the day of maximum change is then identified by means of discrimination index S (Giglio *et al*., 2009), which estimates the time separability between two groups of W observations a given day D (the first group consists in the 6 days before D and the second one in the 6 days following D). A large and abrupt decrease in the W values therefore implies positive values of S that is defined as:

$$S(x,y) = \frac{\Delta W(x,y)}{\left[\sigma_{pre}(x,y) - \sigma_{pos}(x,y)\right]/2} \quad (1)$$

$$\Delta W(x,y) = \bar{W}_{pre}(x,y) - \bar{W}_{pos}(x,y) \quad (2)$$

Results

Erro! A origem da referência não foi encontrada. shows the values of W_t and $\Delta W_{t(t-1)}/W_t$ for July, August and September 2005, as obtained by the algorithm. Burned areas are concentrated in pixels with low values of W and/or with negative values of $\Delta W_{t(t-1)}/W_t$ (normalized difference between the value of W in the current and the previous month), namely pixels whose value of W has decreased from one month to another.

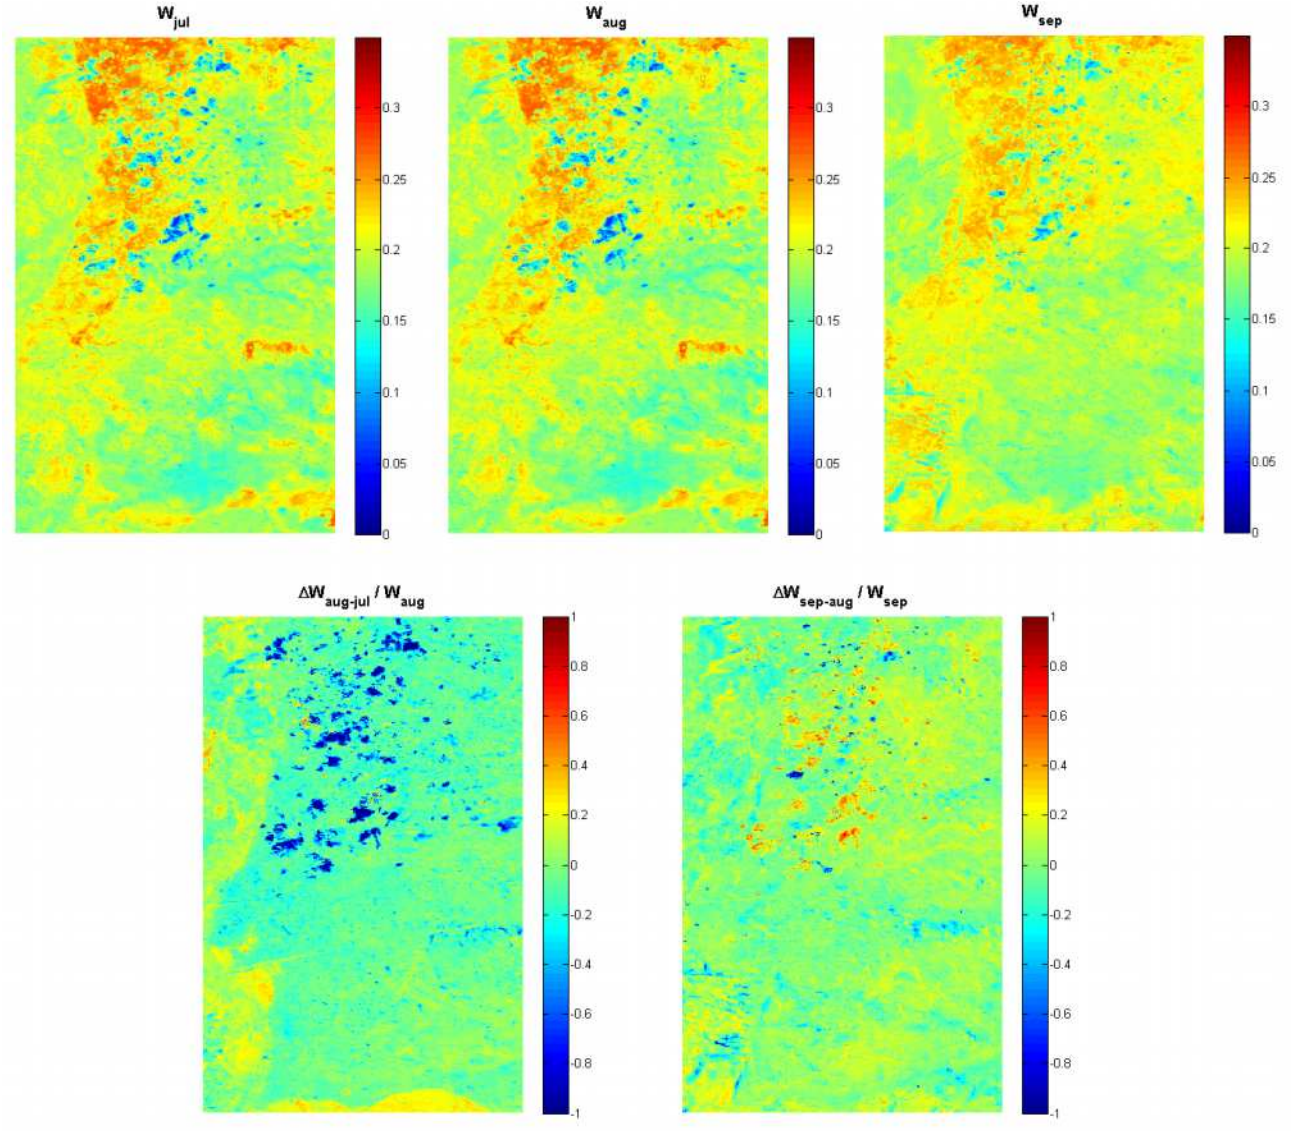

Figure 1. Minimum value composites of W Index for July (upper left panel), August (upper central panel) and September 2005 (upper right panel). Normalized differences between the composites for August and July (lower left panel) and between the composites for September and August (lower right panel).

As mentioned before, fixed thresholds and contextual algorithms are applied to the temporal composites of W_t and $\Delta W_{t(t-1)}/W_t$. This methodology is applied to both August and September 2005, resulting in two scar maps that are on the basis of the burned area map of August and September 2005 (Figure 2).

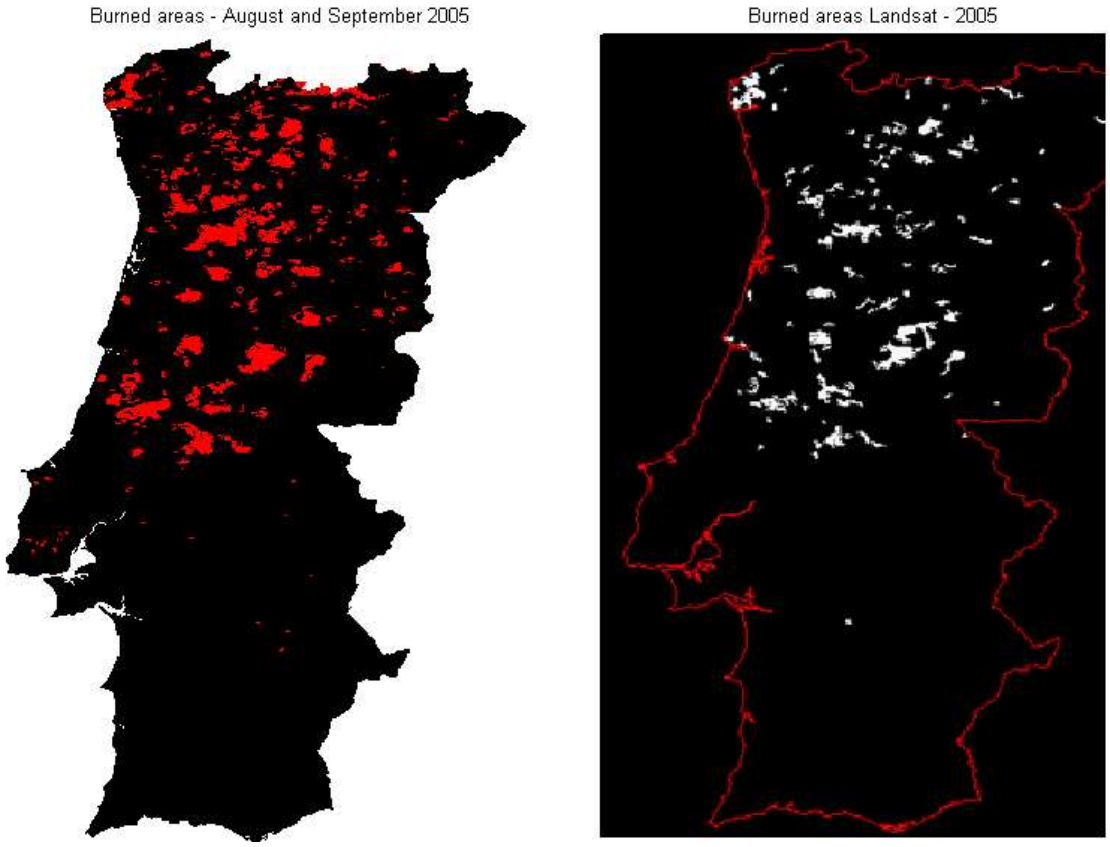

Figure 2. Burned area map for August and September 2005, as obtained by the algorithm based on MODIS imagery (a - left panel) and the reference map for the whole year of 2005, based on Landsat imagery (b - right panel).

Validation of burned area is based on the comparison of the map obtained by the developed algorithm (Figure 2a) with the one derived from scar vectors independently obtained from an end of season Landsat image by ICNF (Figure 2b). For this purpose, the reference map of scar vectors was rasterized to 1 km resolution, the same of MODIS imagery. In this process, however, some pixels, mainly the ones located in the borders of the scars, do not represent totally burned areas. Because of this, each pixel of the reference map have associated to it a value which represents the percentage of burned area (Figure 3).

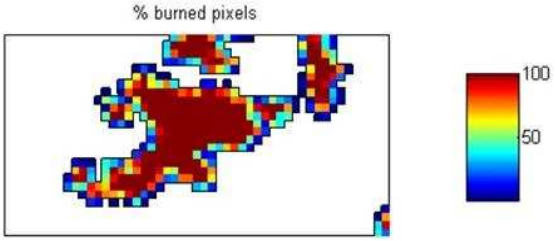

Figure 3. Proportion of burned area in pixels of the reference map, based on Landsat imagery.

Comparison between both maps is performed based on a contingency table (also known as confusion matrix), where all pixels correctly classified are located in the main diagonal, and the incorrect ones, in the remaining cells. The contingency table allows computing a set of accuracy measures, namely Proportion Correct (PC), Commission Error (CE), Omission Error (OE) and Probability of Detection (POD). These measures were computed according to the studies carried out by Binaghi *et al*. (1999), where agreement or disagreement between reference data (with high resolution) and classified data

(low resolution) are calculated taking into account the proportion of burned/unburned area of the reference data inside each pixel of classified data. Tables 1 and 2 present the confusion matrix and the accuracy measures, respectively.

Table 1. Contingency table calculated according to studies carried out by Binaghi et al. (1999). Classification was made based on MODIS instrument data, while reference data were based on Landsat imagery.

		LANDSAT		
MODIS		BURNED	UNBURNED	**Total**
	BURNED	1596.7	3165.0	**4761.7**
	UNBURNED	943.7	87765.6	**88709.4**
	Total	**2540.4**	**90930.6**	**93471.0**

Table 2. Accuracy measures calculated from the contingency table: Proportion Correct (PC), Commission Error (CE), Omission Error (OE) and Probability of Detection (POD).

Accuracy Measures	
PC	96%
CE	66%
OE	37%
POD	63%

The spatial distribution of omission errors, commission errors and hits is presented in Figure 5. Green, red and magenta pixels indicate correctly identified burned areas; commission errors and omission errors, respectively.

According to Table 2, 63% of burned pixels identified by ICNF (based on the end of fire season Landsat imagery) were correctly classified by the algorithm (based on MODIS imagery). This is a very good result, since the algorithm only detects scars corresponding to August and September, while the reference map refers to the whole year of 2005. In other words, using only images of July, August and September, the algorithm was able to detect more than a half of burned area in the year of 2005.

Cases of omission error represent 37% of burned pixels of the reference map. Taking into account hotspots dates, it is found that 23% of all omission errors refer to wildfires occurred in months that are neither August nor September. Therefore, 23% of all omission errors refer to wildfires that occurred outside the period of imagery used, not being detectable by the algorithm. Most of these cases are related to hotspots detected in July (15), namely the largest scar not detected by the algorithm, highlighted in the right panel of Figure 4. On the other hand, almost 30% of omissions have an associated hotspot detected in August or September, and should have been identified by the algorithm (Figure 5). Almost half of omission cases occurred in pixels without the presence of hotspots. This may be due to the following three causes:

a) Hotspots used were restricted to those with confidence over 50%;
b) The MODIS algorithm of detection of hotspots failed;
c) The scar map of ICNF may be incorrect in some cases, presenting scars that do not correspond to wildfires (e.g., deforestation).

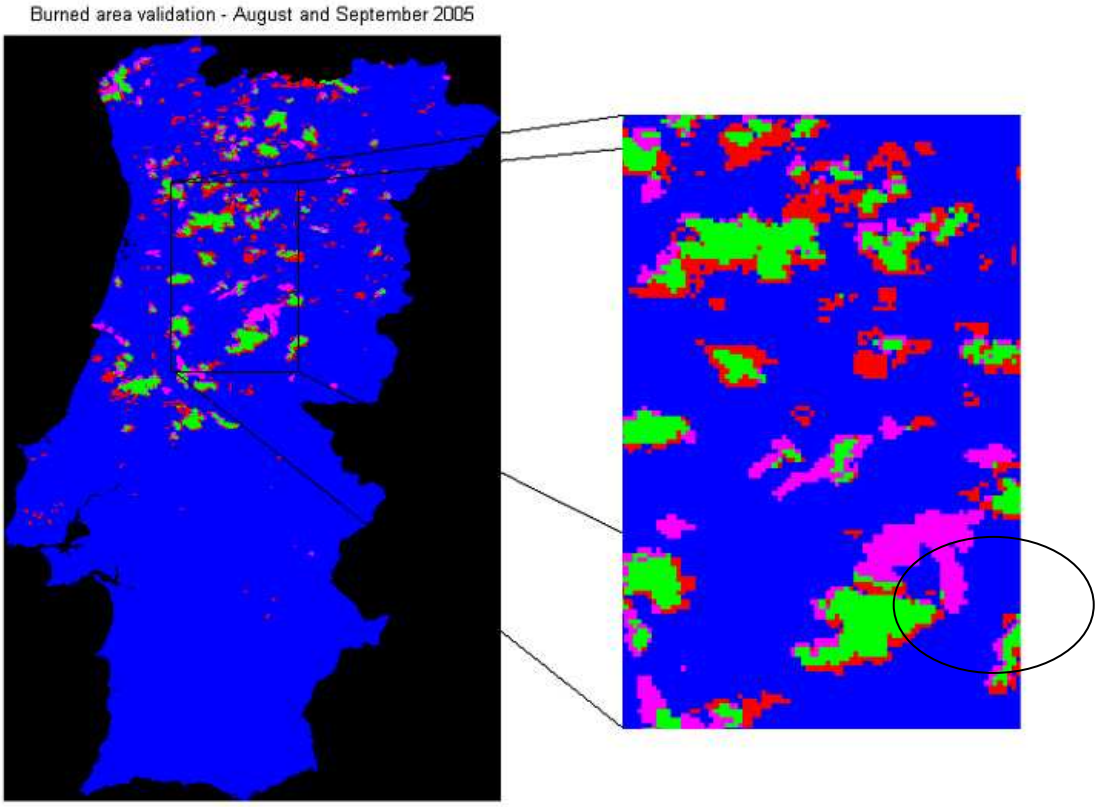

Figure 4. Validation of detection of burned areas. Green pixels indicate agreement between Modis and Landsat; magenta pixels indicate omission errors; red pixels indicate commission errors.

Another important question relates to the proportion of burned pixels area. More than a half (55.4%) of all omission errors refers to MODIS pixels in which only 1-50% of the area is burned (Figure 6). These pixels are, therefore, more difficult to be detected by the algorithm that uses low resolution (1 km) data.

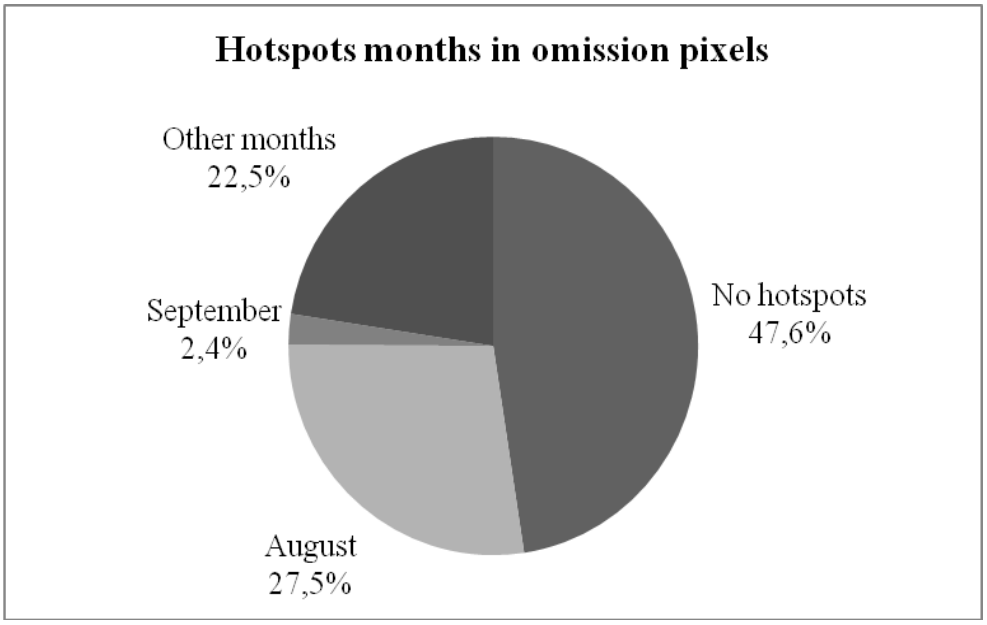

Figure 5. Relative frequency of monthly distribution of hotspots in pixels characterized as omission errors; 62.2% however, do not have associated hotspots.

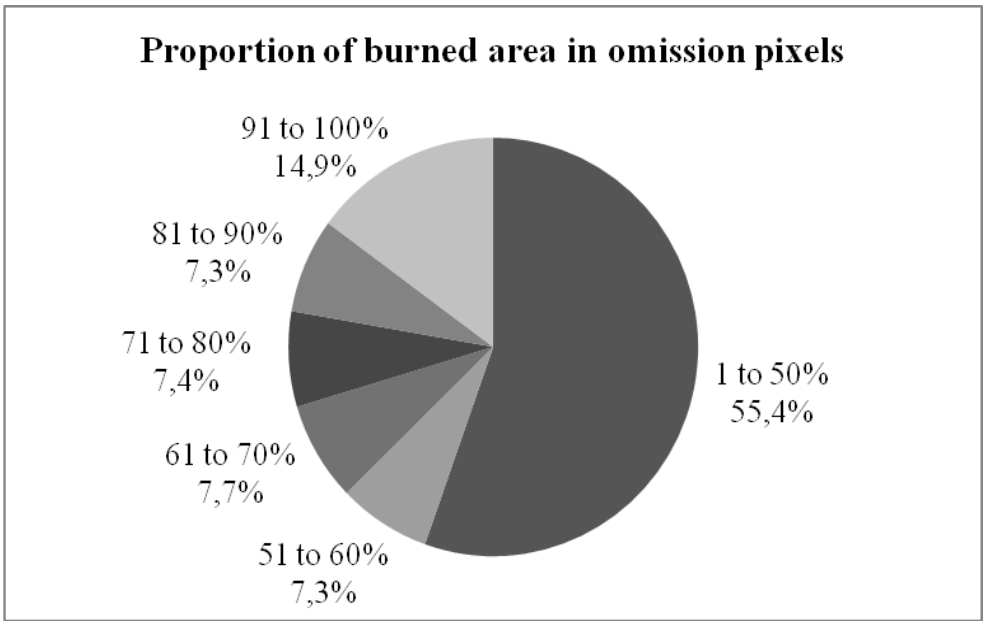

Figure 6. Proportion of burned area of pixels characterized as commission errors. Only 18.4% correspond to pixels in which 90 to 100% of the area is burned.

Two thirds (66.5%) of the pixels detected as burnt by the algorithm were commission errors. However, 14.8% of them have associated hotspots in August and September (Figure 7). Being classified as burned by the algorithm, these pixels are associated to W low values, and since at least one hotspot has been detected it is quite likely that they have burned in fact; the discrepancies may therefore be due to inaccuracies in the reference map, which, despite having a higher spatial resolution and having been prepared with due care, is also subject to errors, mainly because of its lower temporal resolution.

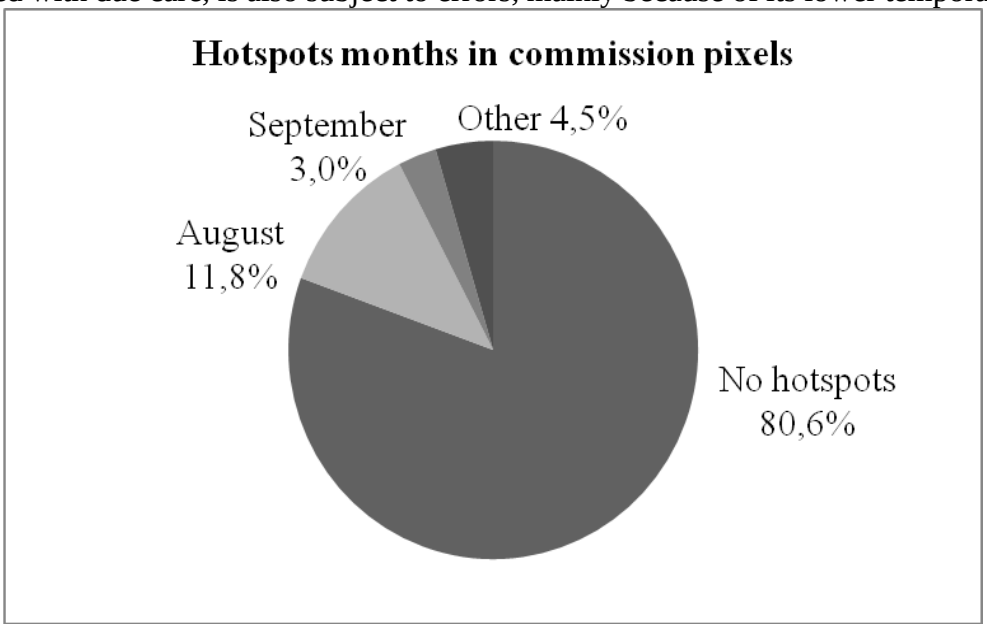

Figure 7. Relative frequency of monthly distribution of hotspots in pixel with commission errors. 20.7% of commission errors have hotspots in August and September, a possible indication of hit of the algorithm and omission of the reference map.

Dates assigned by the algorithm are presented in Figure 8. Attribution of dates was only made for pixels correctly identified as burned (left panel); hotspots dates are also presented for the same pixels, when available (right panel). Validation was performed by comparing these dates (between August 1 and September 30). It may be noted that we opted to restrict to hotspots with confidence higher than 50%, so they are supposed to represent wildfires in fact.

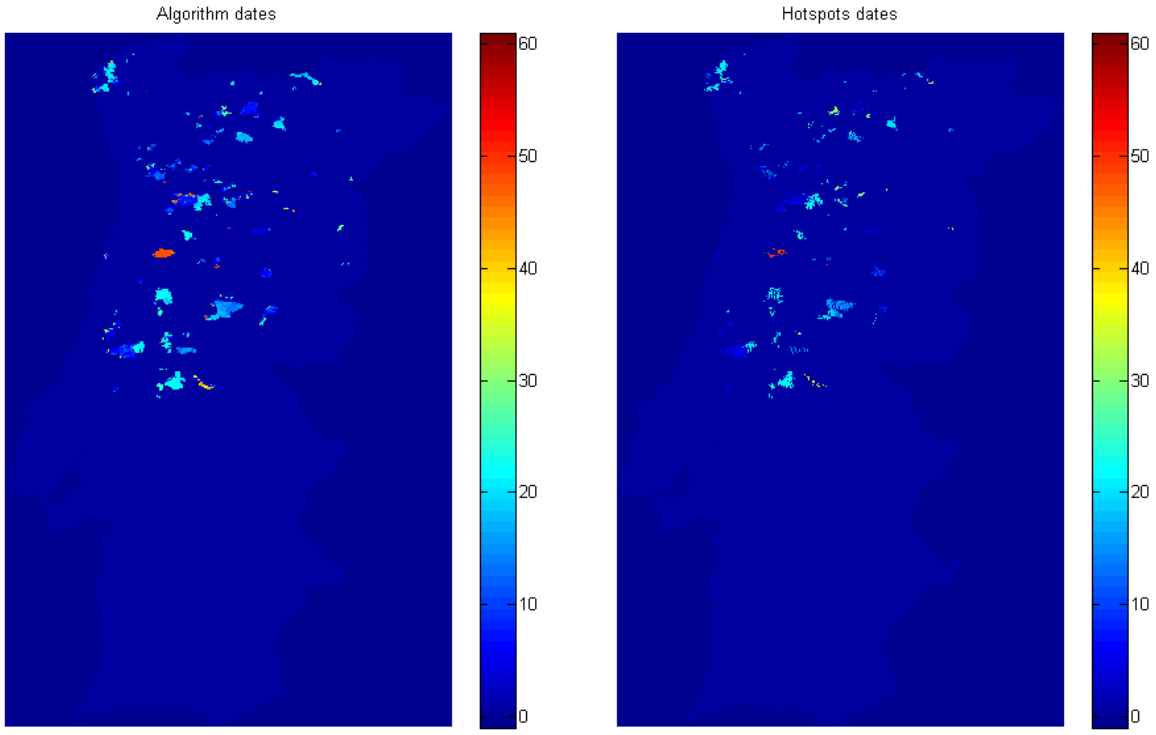

Figure 8. Days of wildfires occurrence. Day 1 refers to August 1, and day 61, to September 30, 2005. Darker blues refer to unburned pixels (zero value) and pixels outside Portugal (negative values) (left panel). On the right panel, are presented days of occurrence of hotspots in the same pixels, when available.

Comparison of estimated dates by our procedure and dates of hotspots as identified by MODIS showed that more than 3/5 of cases (63.5%) have differences between -2 and +2 days and that 3/4 of cases (75.0%) have differences between -5 and +5 days (Figure 9).

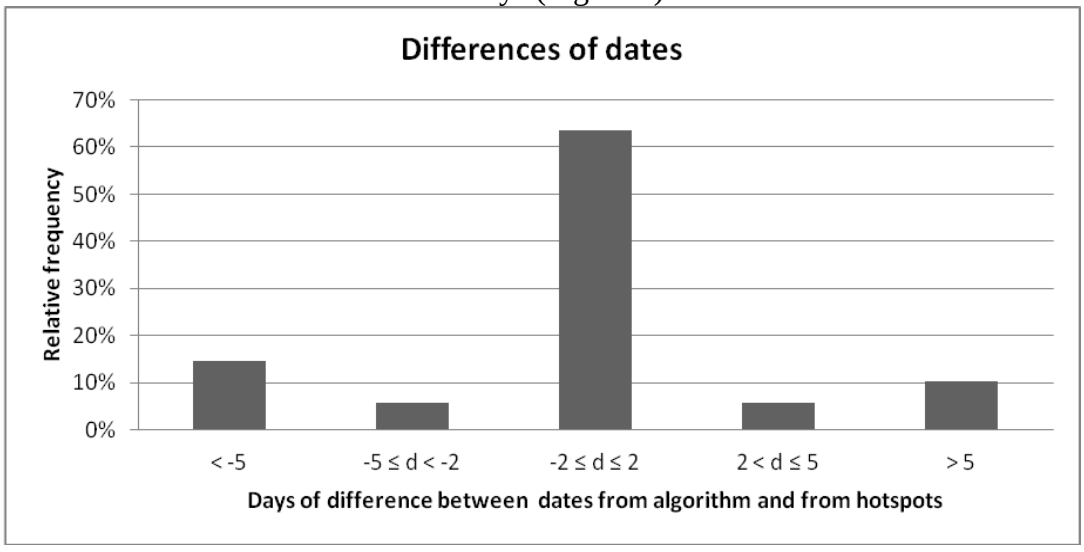

Figure 9. Differences between dates assigned by the algorithm and dates of hotspots occurrence. 75% of dates were correctly attributed.

Discussion

A new automated method of detection and of date assignment to burned areas was applied to Portugal, based on daily reflectances from NIR (near-infrared) and MIR (middle infrared). A total of 170 images from MODIS instrument on-board Aqua and Terra satellites were used during July, August and September 2005, the second worst year in terms of burned area in Portugal.

The algorithm uses MIR and NIR information to calculate the (V, W) Burned Index. Burned pixels are identified by means of fixed and contextual thresholds on monthly composites, and burned area maps are generated. Comparison between generated and reference maps, the latter based on end of fire season Landsat imagery resulted in an agreement of 95.6%, and a Probability of Detection of 62.9%, which means that with only low resolution images for July, August and September, the automated procedure was able to detect almost two thirds of all scars occurred in 2005.

Omission and commission errors were observed mainly on the scars borders, where the proportion of burned area is not so large and the spectral signal on the W Index is not so pronounced. Commission errors were also observed in isolated scars, generally small ones and associated to hotspots. It is possible that these cases are actually omission errors of the reference map and hits by the algorithm. This would be possible given the fact that the reference map is based on end of fire season imagery, when the radiometric signal of some small scars could have been already extinguished. Besides, the lower temporal resolution of Landsat when compared to MODIS, naturally leads to a smaller number of available images.

Omission errors were also observed in isolated scars, generally large ones. Analyzing dates of hotspots in these pixels, when available, it was noted that these undetected scars correspond to wildfires that have not occurred in August and September. Notably the greatest scar, located in the central of the country, in which hotspots indicate wildfires occurred in July. Therefore it was not supposed to be detected by the algorithm.

The attribution of dates to the scars was made based on analysis of W Index values, being the day with the greatest variation (greatest temporal separability) considered the day of burn. Validation shown that 63.5% of the pixels were correctly dated, with differences of the hotspots occurrence between -2 and +2 days. Allowing differences of up to 5 days, the matching score increases to 75.0%.

Results from this work open very promising perspectives towards the operational identification and the assignment of dates to burned areas, therefore contributing to a better understanding of fire regimes.

Characterizing the secondary peak of Iberian fires in March

Instituto Dom Luiz, Faculdade de Ciências, Universidade de Lisboa, 1749-016 Lisboa, Portugal, cdcamara@fc.ul.pt, rmtrigo@fc.ul.pt, mlnascimento@fc.ul.pt

Abstract
Mediterranean Europe is strongly affected by wildfires that burn half a million of hectares of vegetation cover every year causing extensive economic losses and ecological damage. Most studies about fire activity over the Iberian Peninsula (IP) are focused on the summer months, from June to September, as these correspond to the vast majority of BA, but it is important to note the occurrence of a secondary peak during late winter and early spring. This peak is particularly prominent during the month of March, although its relevance changes considerably for different Iberian regions. While the causes of fire activity in March in IP are mainly anthropogenic, either because of negligence or arson, meteorological factors also play an important role in the ignition and spread of wildfires.
The main aims of the present study are threefold: 1) to identify the areas of the IP where fires in March play an important role and have a coherent inter-annual variability; 2) to relate burned areas in March to meteorological danger and 3) to characterize the synoptic conditions that constitute the meteorological background in extreme events (i.e. large burned areas in March).

Keywords*: burned area, meteorological factors, extreme events*

Introduction

Mediterranean Europe is strongly affected by wildfires that burn half a million of hectares of vegetation cover every year causing extensive economic losses and ecological damage (San-Miguel-Ayanz *et al*. 2012). According to reports of the European Commission (European Commission, 2011), during the period 1980-2010 the Iberian Peninsula (IP) has contributed to 60% of the total burned area of 14,620,968 ha that was recorded in five Southern Member States (Portugal, Spain, France, Italy and Greece). As discussed in previous works, e.g. in Trigo *et al*. (2013), this may be attributed to a number of factors that include both natural and anthropogenic factors. Natural factors include geographical location, topography, vegetation cover as well as climate background and extreme meteorological conditions (Pausas, 2004; Pereira *et al*., 2005; Trigo *et al*., 2006). Anthropogenic factors range from land management practices and fire prevention, management and suppression efforts, up to socio-economic and demographic trends (Cueva *et al*., 2006; Costa *et al*., 2010).
Most studies about fire activity over IP are focused in the summer months, from June to September, as these correspond to the vast majority of BA. However, it is important to note the occurrence of a secondary peak during late winter and early spring. This peak is especially conspicuous in the month of March, although its relevance changes considerably for different Iberian regions (Trigo *et al*. 2013). The existence of a secondary peak was known for some northern sectors of IP, but the absence of a pan-Iberian dataset undermined a more thorough analysis on the exact nature and extension of this secondary peak. This caveat was solved to a large extent in Trigo *et al*. (2013) that have used a consistent dataset for the entire Iberian region and applied a k-means cluster analysis to identify large areas characterized by similar fire regimes. The most compelling results were obtained for four clusters (Northwestern, Northern, Southwestern and Eastern) whose spatial patterns and seasonal fire regimes are shown to be related with constraining factors such as topography, vegetation cover and climate conditions. Interestingly, two of the identified clusters present two maxima, with the Northwestern cluster revealing a much larger peak in August and a smaller one in March. The northern most areas of Iberia are concentrated in the Northern cluster that presents two peaks, both comparable in

magnitude (although relatively small), in early spring (March) and late summer (September). Finally, the two remaining clusters (Southwestern and Eastern) are characterized by a single summer maximum in either July or August. Therefore, considering the fact that these March fires affect not only ecosystems but also local populations, they should not be neglected, and deserve to be further investigated. While the causes of fire activity in March in IP are mainly anthropogenic, either because of negligence or arson, meteorological factors also play an important role in the ignition and spread of wildfires. The main aims of the present study are threefold: 1) to identify the areas of the IP where fires in March play an important role and have a coherent inter-annual variability; 2) to relate burned areas in March to meteorological danger and 3) to characterize the synoptic conditions that constitute the meteorological background in extreme events (i.e. large burned areas in March).
For that purpose, monthly amounts of BA are analyzed for each administrative region of Portugal and Spain, covering the period 1980-2005. The study area is first identified based on a ranking of relative BA in each region (i.e. in terms of percentage of the total area of the region) and two regions with distinct inter-annual variability are defined based on cluster analysis performed on time series of BA. The impact of meteorological danger is then assessed by means of the so-called Daily Severity Rating (DSR), an indicator of fire danger which is part of the Canadian Forest Fire Weather Index System (CFFWIS). Finally, meteorological charts of sea-level pressure, 500 hPa height, 2m-temperature and zonal and meridional components of the wind are analyzed for extreme years of BA during the period of study.

Data and methods

Burnt area data

Fire data were supplied by the Autoridade Florestal Nacional (AFN, 2011) and by the Dirección General de Biodiversidad, the national authorities for Portugal and Spain, respectively. The datasets cover the period from 1980 to 2005. Following Trigo *et al*. (2013), data for both countries were merged into a single dataset of monthly amounts of BA, spatially organized into administrative regions, respectively *distritos* for Portugal and *provincias* for Spain. Therefore, the database spatial domain is constituted by a total of 66 regions, 18 for Portugal and 48 for Spain.

Meteorological data

Following Pereira *et al*. (2013) meteorological danger of fire was evaluated based on DSR which integrates the Canadian Forest Fire Danger Rating System (CFFDRS). This system is composed of a set of quantitative indices of fire potential, which are used as guides in a wide variety of fire management activities. For instance, DSR is considered to be a good indicator about the expected efforts required for fire suppression and was specifically designed for averaging either in time or in space (Van Wagner 1987).
Daily values of all components of CFFWIS, in particular DSR, were computed based on ERA-interim reanalysis data at 12 UTC for the period 1979-2012. DSR fields are defined in a 0.05º by 0.05º grid covering the region delimited by latitude circles 35° and 45° N, and by meridians 10° W and 5° E which encompasses IP as well as a part of France and North Africa.

Synoptic conditions

Information about synoptic conditions associated with extreme events was obtained using the Koninklijk Nederlands Meteorologisch Instituut (KNMI) Climate Explorer tool. Synoptic information consists of maps of monthly anomalies defined as departures from climatological normal of 1981-2010 of sea-level pressure (SLP), 500 hPa geopotential fields (Z500), 2m-temperature (T2). Besides the aforementioned anomalies, monthly means of zonal and meridional wind magnitudes at 10 meters (U10 and V10, respectively) were also used. Maps of SLP and Z500 are defined on a large window, centred over IP and covering Europe and North Africa, delimited by latitude circles of 30° and 70° N

and by meridians of 45° W and 45° E, whereas maps of T2, U10 and V10 are defined on a smaller window covering the North of IP, defined between 40° and 45°N and between 10°W and the Greenwich meridian.

Results

Spatial analysis of BA in March

The total amount of BA in March, for each region, was sorted in descending order. However, because the considered regions have quite different surface areas, the analysis was performed on relative values of BA for each region, which were obtained by dividing the total amount of BA of each region by the total area of the region. All but one region that rank in the first 24 are spatially contiguous, spreading over the North and Northwest of IP. The exception is the region of Castellon (located over the East of IP) that ranks 19. This suggests considering the 23 contiguous regions as the study area for March BA over IP.

Inter-annual variability of BA in March

In order to identify regions of consistent inter-annual variability within the study area, a k-means clustering analysis was performed on time series of March BA for each region.

The k-means clustering analysis was applied to the 23 regions that constitute the study area, each one viewed as a point in a 26 dimensional space, each axis being the value of BA (normalized in time) for a specific year during the 26-year period 1980-2005. The k-means clustering analysis is performed by pre-specifying a given number *k* clusters (*k* was set to 2) and by successively assigning each point to the nearest centroid of the clustering, computing the centroids of obtained new clusters, and repeating the process until the assignment of members does not change. As shown in Fig 1, the two clusters obtained, hereafter referred to as East cluster and West cluster, present spatial continuity and are separated from each other by the Cantabrian mountain ranges.

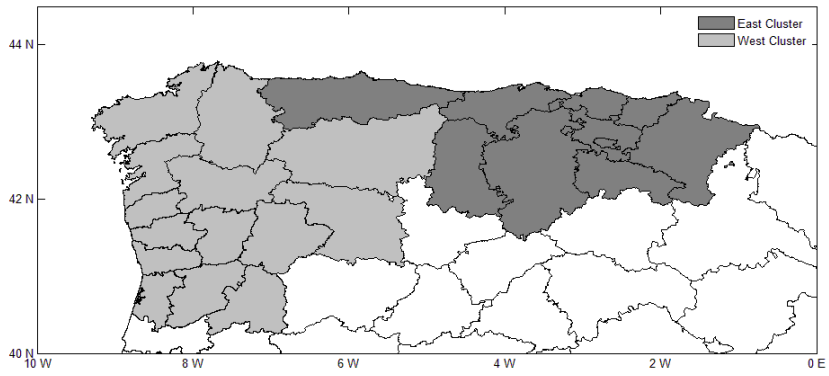

Figure 1. The k-means determined clusters of Northern Iberia

As shown in Figure 2, the time series for the two clusters of normalized burnt area present distinct behaviour, especially in terms of years of extreme BA. The years of 1981 and 1989 correspond to high values of burnt area for the East cluster, whereas the years of 1997 and 2000 are the ones of higher values of burnt area for the West cluster. The year of 1997 is especially conspicuous since both regions present high values of burnt area.

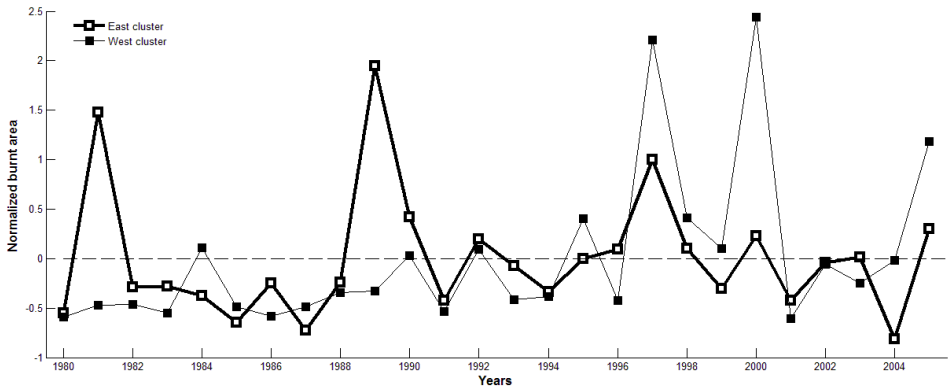

Figure 2. Time series of normalized BA for East and West clusters

Using polygon shapefiles for the administrative regions, a spatial mask for each cluster was defined and spatial means of daily values of DSR in March were accordingly computed. Then, for each year and for each cluster, the average of these DSR daily values above the monthly median was assigned to each year. This value, hereafter referred to as DSR+, is expected to reflect (at the monthly level) the presence of the usually small number of days that have high values of DSR and are associated to large fire activity that virtually explain the monthly amounts of BA. This is illustrated in Figure 3, where high values of DSR, for the West cluster in 2005, concentrate in a period of 5 days, from March 16th to 20th.

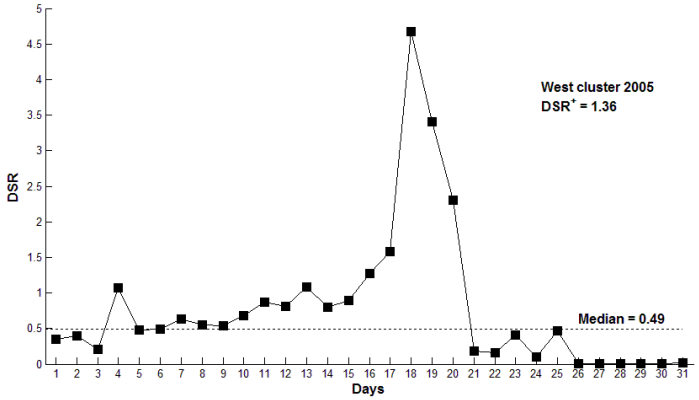

Figure 3. Time series of daily values of DSR for March 2005, for the West cluster

The time series of DSR$^+$ for both clusters are shown in Figure 4. As expected, because of the magnitude of the spatial scale associated to synoptic conditions, the two time series present a coherent temporal behaviour which reflects on the value of the correlation between the two (r = 0.88). The peak in both series occurring in 1997 is worth being noted since it corresponds to a year of high values of NBA in both East and West clusters. The same happens in 2005 which is associated to high values of NBA in both clusters and to high values of DSR$^+$ in both time series. The year of 2000, associated to a high value of NBA in the West cluster is also associated to a high value of DSR$^+$. However, the years of 1981 and 1989, where peaks of NBA may be identified in the East cluster, are associated to relatively low values of DSR$^+$.

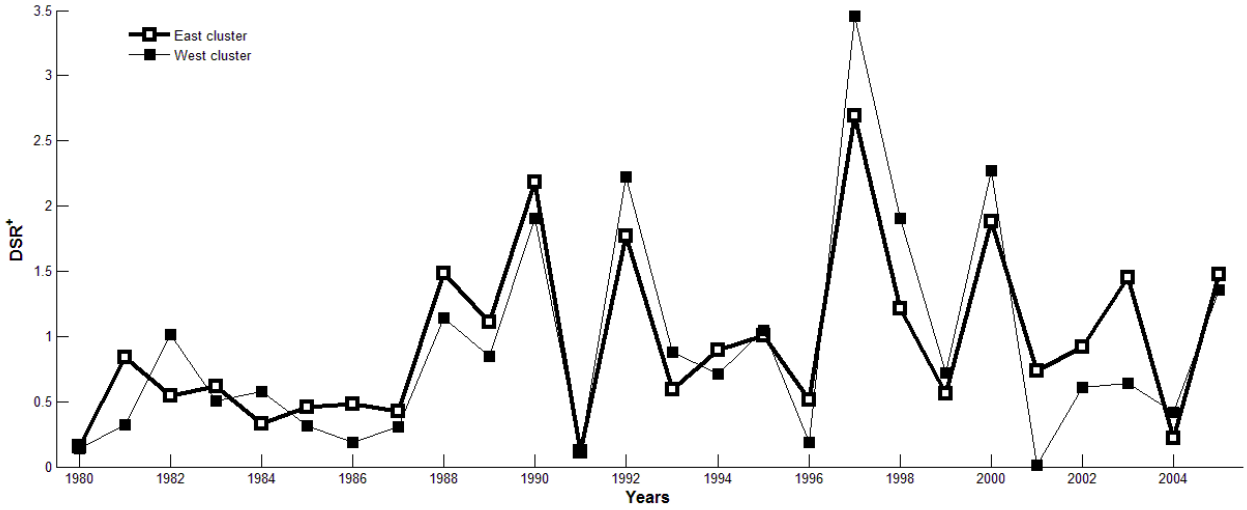

Figure 4. As in Figure 2 but for time series of DSR+.

3.3. The role of meteorological danger

Results from the previous sections suggest that the relationship between DSR+ and NBA in each cluster should be further investigated. Figure 5 presents scatter plots of DSR+ versus NBA for the West cluster (left panel) and the East cluster (right panel). In the case of the West cluster, results provide evidence of a linear relationship between the two analyzed time series. A linear model was fitted by least square regression which explains almost two thirds (65%) of the total variance.

In the case of the East cluster the above-mentioned year of 1981 and 1989 appear as outliers from a distribution that again suggests a linear relationship between DSR+ and NBA. These two outliers were disregarded and a linear regression model was fitted to the data, with good results, explaining three quarters (75%) of the total variance.

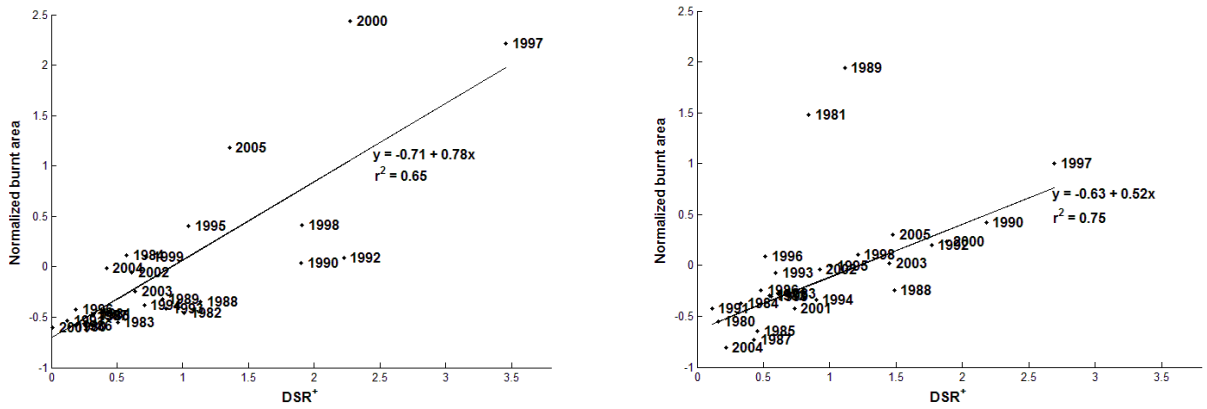

Figure 5. Scatter plots of NBA vs. DSR+ for the West (left panel) and East (right panel) clusters. Straight lines were obtained by linear regression that was applied to all years in the case of the West cluster and to all years but 1981 and 1989 in the case of the East cluster.

Results suggest that inter-annual variability of March NBA in the two clusters is linked to meteorological conditions that induce meteorological danger of fire ignition and fire spread. Nevertheless, the two highest years of BA in the East cluster present a different behaviour that deserves

to be further investigated. However, and as to be expected, even for all remaining cases in both clusters there is still a substantial amount of inter-annual variability that is not explained by such a simple model (about one third and one fourth of total variability for West and East clusters, respectively).

3.4. Atmospheric patterns associated to extreme years of burnt area

The linkage between DSR^{+} and NBA was further investigated by analyzing the synoptic circulation patterns that prevailed for years characterized by very large amounts of March NBA for each or both clusters. Figure 6 presents the values of NBA in descending order for the West cluster (left panel) and the East cluster (right panel). The four (six) highest years for the West (East) cluster are labelled.

First a detailed analysis will be presented for the year of 2000, associated to the highest value of NBA in the West cluster. Then a similar analysis is provided for the year 1989, associated to the highest value of NBA in the East cluster and finally for the year 1997 associated to high values of NBA in both clusters (ranking 2nd and 3rd in the West and East clusters, respectively).

As shown in Figure 7 (top panel), the extreme event of 2000 covers the majority of the area of the West cluster, with all regions ranging from the top to the 5th position, half of the 14 regions occupying the 1st rank in BA.

In the case of the extreme event of 1989 (Figure 7, central panel), the large majority of regions that form the East cluster occupy the first three positions, the exception being the provinces of Asturias and Cantabria, located in the northwest coast of the East cluster.

In the case of 1997 (Figure 7, bottom panel), 19 regions out of the 23 regions that form the East and West clusters occupy the first five positions, 12 of them ranking 1st and 2nd. The exceptions are the easternmost regions of Guipúzcoa, Vizcaya, Navarra and La Rioja that rank in positions 12, 13, 15 and 19.

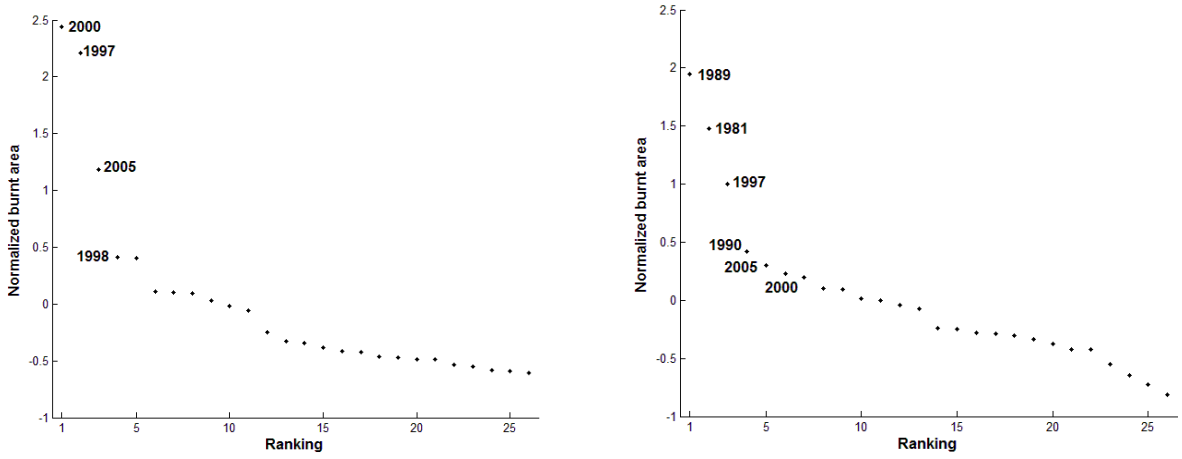

Figure 6. Values of NBA sorted in descending order for the West (left panel) and East (right panel) clusters.

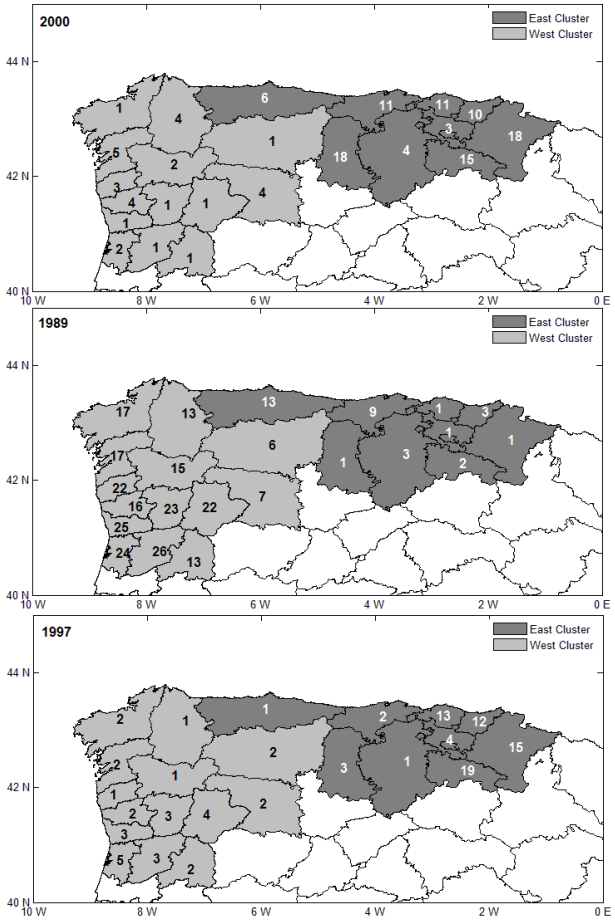

Figure 7. Ranking of administrative regions in the study area according to the amount of BA for the extreme events of March 2000 (top panel), March 1989 (middle panel) and March 1997 (bottom panel).

3.5. The extreme cases in the West cluster (March 2000), the East cluster (March 1989) and both clusters (March 1997)

The atmospheric circulation relative to March 2000 is characterized by the presence of an intense anticyclonic pattern centred just west of the British Islands (Fig 8, top panel). This structure is characterized by positive anomalies of SLP (Figure 8, top left panel) and geopotential height at the 500hPa level, which are characteristic of a hot quasi-barotropic anomaly. The location of such patterns, farther North than usual, corresponds to a typical Winter-Spring blocking pattern (Trigo *et al.*, 2004) that disrupts the usual path of low pressure systems from the Atlantic towards Europe. The negative values of zonal and meridional winds for the West cluster point to a North-eastern continental air flow which results in negative temperature anomalies along the northern coast of Spain as a consequence of the advection of cold air from northern Europe (Trigo *et al.*, 2004). Positive temperature anomalies may however be observed for Northern Portugal and Galicia (Figure 8, top right panel), as a result from an intense Föhn effect over the Cantabrian mountains with warmer and drier air descending the southern flank. The warm temperatures and downwind are associated to meteorological conditions favouring the onset and spreading of fires, which translates into an increase of meteorological danger of fire. This is clearly shown in the daily time series of DSR for March 2000 where a steady increase may be observed since the 7th until the 20thof March (Figure 9, top left panel).

When compared with March 2000, the atmospheric circulation of March 1989 presents an almost inverted pattern, with an intense low pressure system crossing the Atlantic with its centre placed just south of Iceland (Figure 8, central panel). The presence at high latitudes of highly negative anomalies of SLP (Figure 8, central left panel) and geopotential height at the 500 hPa level associated with

positive anomalies in the lower latitudes induce stronger than usual westerly winds, with the advection of warm and moist being responsible for the positive anomalies that are observed over the study area. Warming of air is further enhanced by the Föhn effect when the flow crosses the Cantabrian mountain ranges, resulting in hot (and dry) anomalies close to the Basque country and Pyrenees that could induce fire activity (Figure 8, central right panel). This is supported by the behaviour of time series of DSR that presents a sequence of three small peaks of increasing amplitude in the first 17 days of March, the third one centred on March 16th, followed by a very large peek centred on March 27th (Figure 9, top right panel). The fact that extreme values of DSR are concentrated on this last very short period of time makes it very difficult to perform an analysis of the events at the monthly scale and explains the apparently anomalous behaviour of March 1989 when looking at scatter plots of DSR^{+} versus NBA (Figure 5, right panel).

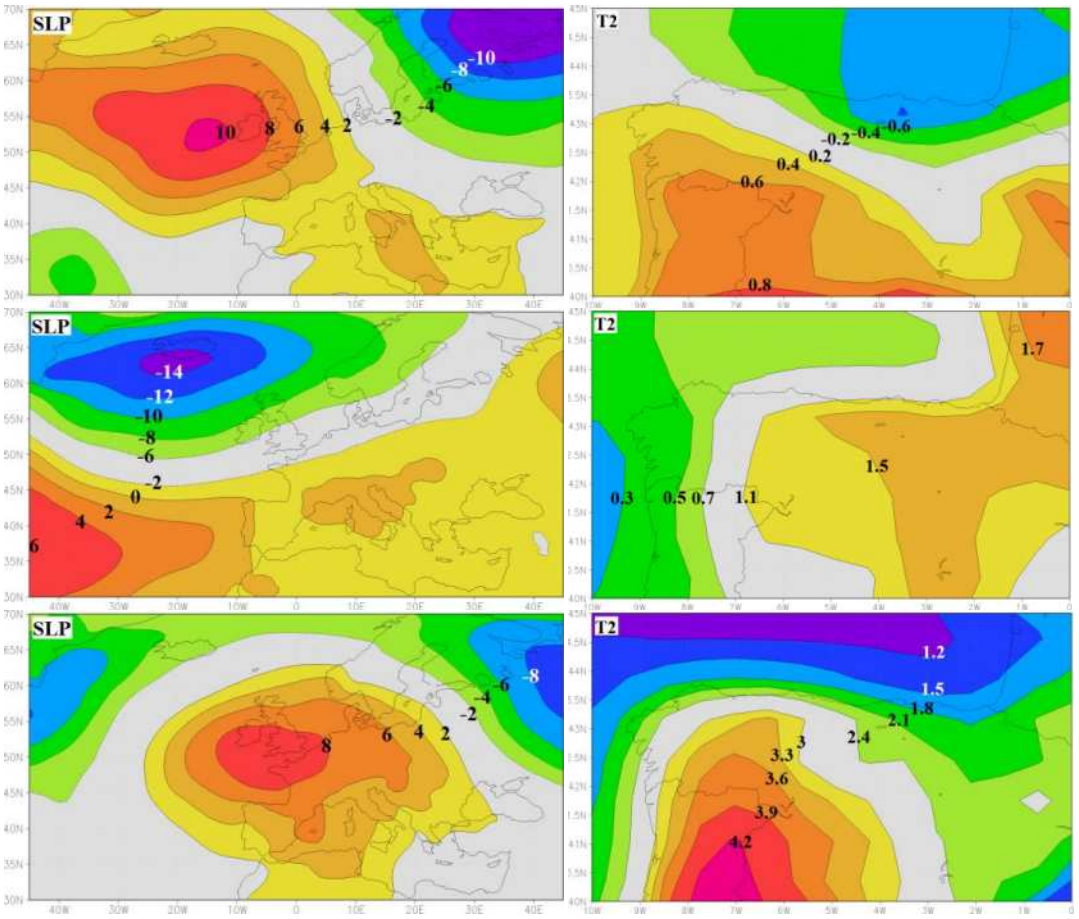

Fig 8 –Monthly anomaly charts for the West cluster of March 2000 (top panel), the East cluster of March 1989 (central panel) and for both clusters of March 1997 for two atmospheric fields. Contour lines delineate anomaly fields of SLP (hPa), and T2 (°C)

The atmospheric circulation of March 1997 is very similar to the one of March 2000, being dominated by a strong anticyclonic pattern centred above the English Channel (Figure 8, bottom panel). Two intense positive anomalies of both SLP (Figure 8, bottom left panel) and Z500 may be again identified, suggesting a hot barotropic anomaly, typical of a blocking pattern. The resulting Northeastern winds induce a small positive anomaly over the easternmost regions of the East cluster and the air is further warmed by the Föhn effect when crossing the Cantabrian Mountains into Galicia and Northern Portugal. This effect is clearly illustrated by the daily time series of DSR over the West and East clusters (Figure 9, bottom panel), where two large peaks may be identified in the last ten days of March, the peaks in the time series of the West cluster being substantially higher than the

corresponding ones in the East cluster. The two time series present a coherent variability during the month, especially during the last 10 days, a feature that explains the high values of burned area that were registered in both clusters.

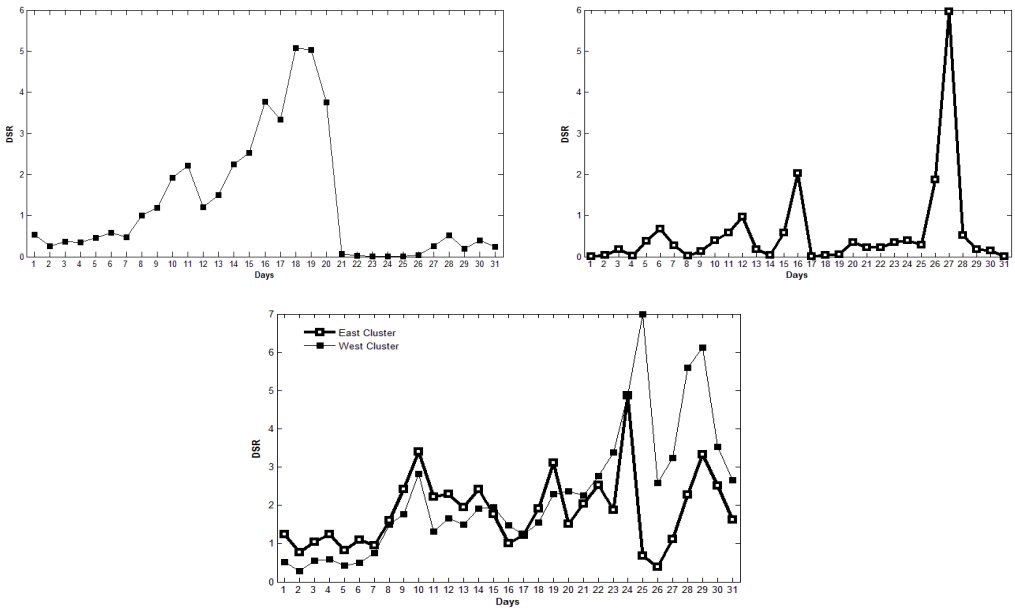

Fig 9 – Daily values of mean DSR for the West cluster of March 2000 (top left panel), for the East cluster of March 1989 (top right panel) and both clusters of March 1997 (bottom panel)

3.6. The role of large-scale atmospheric patterns

The role played by large scale atmospheric patterns in the establishment of meteorological conditions favouring the occurrence of fire events may be put into evidence by analyzing the atmospheric patterns of 1989, 1997 and 2000, associated to these three extreme events. As shown in Figure 8, in all three events the study area is crossed either by Northeastern flow (cases of March 2000 and of March 1997) or by Southwestern flow (case of March 1989); in all cases the flow crosses the Cantabrian mountains and the associated Föhn effect induces warm and dry conditions downstream where fire activity is observed.

Such large scale flow is induced by well-defined anomalies west of the British Isles, with a barotropic structure which are either positive anomalies (of blocking-type) or negative. These barotropic anomalies tend to be stationary for several days and together with the Föhn effect are on the origin of the observed peaks of daily DSR (Figure 9), i.e. of meteorological danger.

This simple conceptual model was applied to the seven cases where amounts of BA ranked in the top four positions in the case of the West cluster and in the top six positions in the case of the East cluster (i.e. the two outliers of 1981 and 1989 and the following four years of higher BA). The chosen years are identified in Figure 6 and in Table 1, the latter showing the ranks and the type of anomaly located in the Atlantic Ocean near the British Isles.

It may be observed that the two extreme cases in the East cluster (March 1981 and 1989) are associated to an intense negative anomaly that steers Southwestern flow and that all remaining 5 cases are associated to a blocking-type positive anomalies that induces Northeastern flow. It may be further noted that 3 out of these 5 cases (i.e. March 1997, March 2000 and March 2005) correspond to high values of BA in both clusters.

Table 1. Extreme years, West and East ranking and occurrence of blocking event.

Year	Large-scale pattern	West cluster rank	East cluster rank
1981	Negative anomaly	19	**2**
1989	Negative anomaly	13	**1**
1990	Positive anomaly	9	**4**
1997	Positive anomaly	**2**	**3**
1998	Positive anomaly	**4**	8
2000	Positive anomaly	**1**	**6**
2005	Positive anomaly	**3**	**5**

Conclusions

A study was performed on BA in the IP associated to fire activity in March. The study relies on monthly values of BA for a set of 66 regions covering the period 1980-2005 (Trigo *et al*., 2013). The annual cycle of BA for the entire IP was determined, showing two peaks of BA, a first large peak centred in August and spreading over summer and a secondary one centred in March and spreading over late winter-early spring.

The 66 regions were sorted by decreasing order of relative BA, which was obtained by dividing the total amount of BA for each region by the corresponding total area, therefore ensuring equal weights from the regions. The ranking procedure allowed defining a spatially contiguous study area formed by 23 regions that ranked in the first 24 places; the region of Castellon, that ranked 19th was discarded because of the spatial location, out of the area covered by the remaining ones.

Time series of BA for each of the 23 regions were normalized by subtracting the respective time mean and dividing by the standard deviation and a cluster analysis was performed on time series of NBA leading to the identification of two clusters, each one presenting a characteristic inter-annual variability. The two clusters, the so-called West cluster and East cluster, are formed by contiguous regions and are separated by the Cantabrian Mountains. Extreme events were identified in each or both clusters, namely March 1997 for both clusters, March 2000 and March 2005 for the West cluster, and March 1981 and March 1989 for the East cluster.

For each cluster, the associated meteorological conditions were analyzed by inspecting time series of DSR, an index of meteorological danger, i.e. of meteorological conditions that might induce fire onset and fire spread. Because fire events tend to be associated to a small number of days with higher meteorological danger, the monthly values of meteorological danger were assigned in terms of DSR^{+}, i.e. on time means performed on days with DSR above the monthly median. Time series of DSR^{+} for each cluster show peaks in March 1997 for both clusters, as well as in 2000 and 2005 for the West cluster. These results indicate that high levels of meteorological fire danger are associated to large values of NBA; however, the years of 1981 and 1989, associated to the highest values of NBA in the East cluster, present rather low values of DSR^{+} in that cluster.

In order to further investigate the relationship between fire danger and monthly burned area, linear regression models were developed relating DSR^{+} and NBA in each cluster. The models were able to provide good results in both the West and the East clusters, but in the case of the latter cluster the extreme years of 1981 and 1989 had to be disregarded. Results suggest that inter-annual variability of March NBA in the two clusters may be partly understood in terms of the prevalence of meteorological conditions that induce meteorological danger of fire ignition and fire spread.

The role of meteorological conditions was further investigated by analysing the synoptic atmospheric circulation that prevailed during March of the extreme events in the West cluster (March 2000), in the East cluster (March 1989) and in both clusters (March 1997). Results indicate that in all cases, there is an intense prevailing atmospheric flow over the Cantabrian Mountains, either from the Northeast

(March 2000 and March 1997) or from the Southwest (March 1989), which are driven by the presence of barotropic anomalies located near the British Isles. These steady anomalies are negative in the case of northwestern flow over the study region and positive in case of northeastern flow, being in this associated to blocking-type patterns. The prevailing NE-SW or SW-NE directions are essential since they allow the establishment of a Föhn effect when the air flow crosses the Cantabrian Mountains originating warm and dry air downstream that favours the onset and spreading of fire events.
This simple conceptual model was finally successfully applied to seven cases where amounts of BA ranked in the top four positions in the case of the West cluster and in the top six positions in the case of the East cluster. Results obtained provide a conceptual framework that may assist in developing warning systems of fire danger in March over IP.

Abstract
The present paper considers, on the basis of the available data and experimental studies, a variant of deepening of the combustion site with account for the botanical composition. After analyzing the thermocouple data, the experiment have shown that there is a steady transition of combustion from a ground forest fire to the deep layer of peat at a low humidity content and sufficient stock of forest fuel.
The presence of combustion conductors and their chaotic arrangement promote combustion propagation in both the horizontal and the vertical planes.

Keywords*: combustion process, peat, botanical composition, combustion conductors.*

Introduction

According to different estimates, the world′s deposit of peat varies from 250 to 500 billion tons (counting moisture content). Peat is widely used in various branches of national economy, in agriculture, medicine, biology, power engineering, etc. Peat is valuable due to the fact that its deposits can regenerate. So, in the world up to 3 billion square meters of peat deposits are formed yearly, which is about 120 times more than used. Peat is characterized by a high natural moisture content of up to 96%, and its porosity amounts to 96% with an average diameter of water-conducting pores of the order of 8.2 μm (Grishin *et al.* 2013).
It should be noted that in determining the kind of peat the most important index is also the degree of decomposition (Nikitin *et al.* 1986). Since peat is an organic compound, under certain conditions its combustion takes place. Peat combustion under natural conditions depends on a complex connected with climatic, meteorological, and topographical factors. This dependence shows up most clearly in a prolonged droughty period when it is necessary to take into account the solar radiation intensity, the air temperature, the time of the day, the ground water level, and many other factors (Belozerov 2010). Peat ignition sources may be different: the sparks from the wires, electrical sparks produced during short-circuit current-carrying wires and cables to the units, careless use of fire, the heat of the sun. Ignition of peat may be due to one of many different causes: sparks from wires, electric sparks produced by short circuit of current-carrying wires and cables to assemblies, careless use of fi re, and the heat of sunbeams. Most often peat beds catch fire from ground forest fires. Three stages of development of a peat fire are distinguished. The first stage has a small area of the site and a low temperature in the combustion zone. It has been established that in the first 1.5–2 hours a peat layer of thickness $(2-4)\cdot 10^{-2}$ m burns up. The second stage is characterized by an increase in the burning velocity and an increase in the zone temperature. The area of the fire increases to several thousands of square meters, and the combustion becomes stable. Acrid fume propagates for a long distance. The third stage is characterized by a large combustion area, a high temperature in the combustion zone, a high smoke content, and a high fi re propagation velocity (Grishin *et al.* 2013).The fire area is calculated by the formula:

$$F_n = \frac{\Pi \cdot V_n^2 \cdot t_p^2 \alpha}{360} = 0{,}00873 V_n^2 \cdot t_p^2 \alpha$$

The approximate change with time in fire areas at various wind velocities is presented in paper (Grishin *et al.* 2013).
It should be noted that the burning of peat in natural conditions is carried out with an excess moisture content and lack of oxidant decay mode (Grishin 1986). Combustion has a diffusive character as limited intake of oxidant environment.
It should be noted that all the well-known works do not consider a botanical composition of peat to be a factor for penetration of the combustion front in the mass of peat. The influence of the botanical composition on ignition of peat is given in the work (Grishin *et al.* 2006) that provides the results of experiments for determination of the minimum ignition energy, and in the work (Loboda 2012) that provides the results of experimental studies to determine the depth of the combustion front in the peat layer. The samples represented four types of peat with different characteristics (botanical composition, density, humidity content and degree of decomposition). We have found that the depth of the combustion front in peat is varied in the range of 10-28 mm, depends on the type of peat, the degree of decomposition, the density and is weakly dependent on the changes of humidity content in the range from 2.6 to 17.3% and does not depend on the size of the sample in the range from $0.3 \times 0.3 \times 0.3$ to $0.35 \times 0.15 \times 0.15$ m.
In this work we suggest an explanation of self-penetration of the combustion front, taking into account the botanical composition of peat. Peat is characterized by the bimodal particle size distribution connected, on the one hand, with the presence of coarse particles of plants and, on the other hand, with a finely-dispersed fraction consisting of the decomposition products. Coarsely dispersed residues, forming a carcass grid or representing a «filler», have an average particle size from 0.1 to 4.5 mm (Churaev 1961).

Technique of the experiment

We assume that peat fire occurs due to the ground forest fire initiated by needle and leaf litter. In the work, the mechanism for penetration of combustion is investigated and evaluated in the peat layer of a different botanical composition.
When the ignition takes place on the surface, combustion (smouldering) will be propagated in the mass of peat. In order to check this assumption, in the laboratory we conducted a series of experiments for modeling the ignition of peat from ground forest fire (Figure 1) using a test complex (Grishin *et al.* 2009).

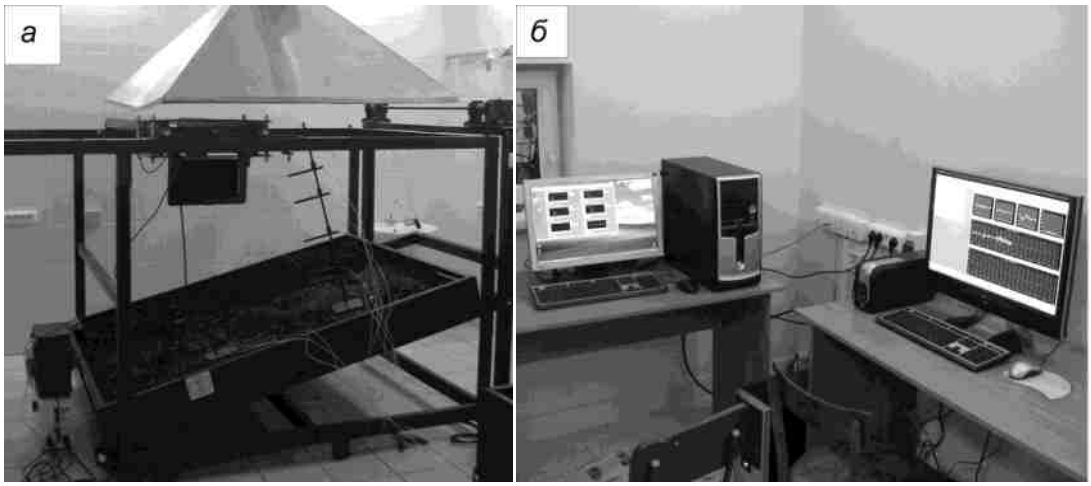

Figure 1. Facility for physical modeling of ground and steppe fires (a); system of data input and registration (б) (Grishin et al. 2009).

There are a complex of measuring equipment and an automated data acquisition and recording system based on a computer and three five-channel ADCs with chromel-alumel thermocouples. The input data recording program was developed on the basis of the Labview program complex. The humidity content of peat is determined using a humidity analyzer A&D HX-50 with an accuracy up to 0.01%. The weight of the samples was determined using an electronic balance A&D HL-400 with an accuracy of 0.1g. Forest fuels (FF) was ignited using a linear source of ignition in the form of a spiral. Combustion temperature was measured by a thermocouple method using chromel-alumel thermocouples.
The scheme of the experiment is presented in Figure 2. A peat sample (2) with sizes $(0.08 \times 0.065 \times 0.05) \cdot m^3$ is placed on the bottom of the metal box (1). Four thermocouples were set in the peat sample: one in the near-surface layer closer to the FF (3), one on the axis inside the peat layer at a distance of $1 \cdot 10^{-2}\ m$ (4), one on the axis at a distance of $2 \cdot 10^{-2}\ m$ (5), and thermocouple (6) was set below thermocouple (3) at a distance of $1 \cdot 10^{-2}\ m$ from it and at a distance of $2 \cdot 10^{-2}\ m$ from the peat surface adjoining the FF. Ignition was realized by means of a point source.

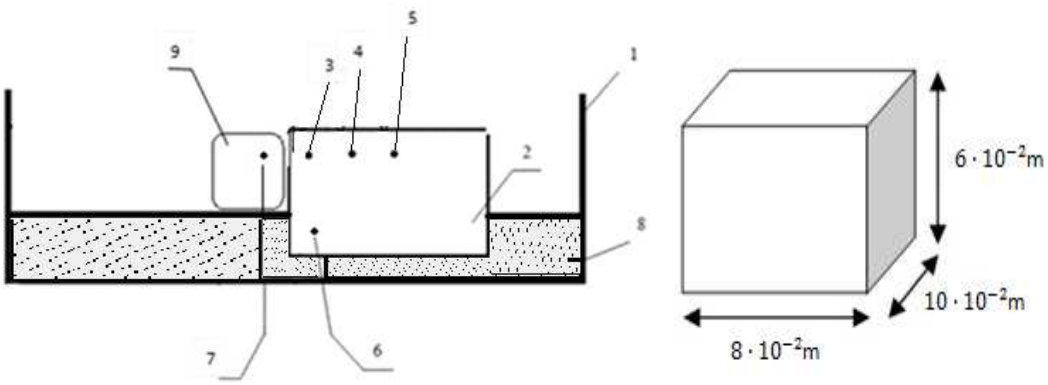

Figure 2. The scheme of the experiment (side view) and dimensions of peat samples (right one). 1 - metal box-testing area; 2 - peat sample; 3,4,5,6 - thermocouple in the peat sample, 7 – thermocouple in the FF layer; 8 - ground substrate; 9 - FF layer.

Since the underlying surface is over peat in the nature, we modeled two variants for the development of underground fire (Figure 3):

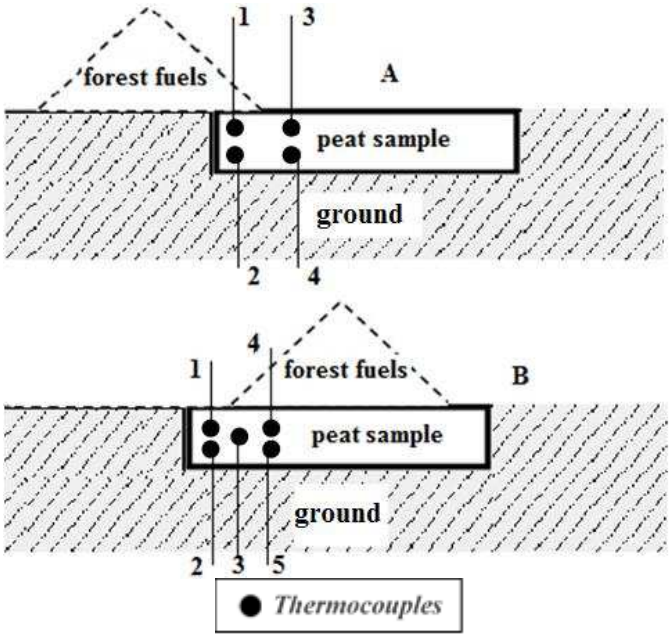

Figure 3. The scheme of experiment: A – Ground forest fire front coming to peat layer, buried in the ground; B - Initiation of ground forest fire occurs directly above the peat, buried in the ground;

The main parameters:
$M_{peat} = 27{,}3$ г, $M_{FF} = 20$ г, $W_{peat} = 4{,}7$ %, $W_{FF} = 5{,}7$ %, $T_{initial} = 17^0 C$.

We studied the samples with a different botanical composition of peat (Grishin *et al.* 2013).

Analysis of the structure of peat samples

To analyze the structure of the peat layer, peat samples with a different humidity content were photographed using the microscope. Figure 4 shows the photographs with a vertical section of peat samples (deposit in the settlement of Plotnikovo, Tomsk region) with a magnification of 200 times. Plant residues ***A*** and water-conducting pores ***B*** are clearly observed.

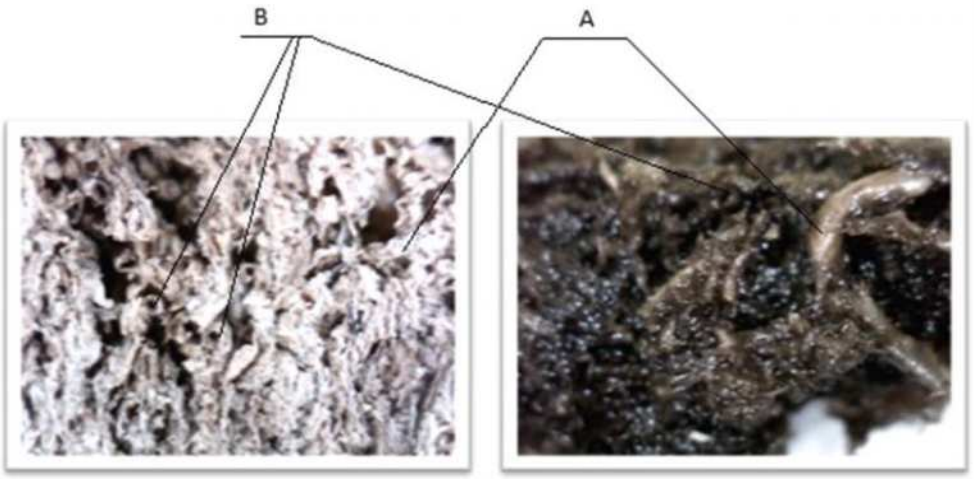

Figure. 4. Vertical slice of peat sample: $W = 4{,}7$ % (left one) u $W = 57{,}7$ % (right one).

Taking into account the properties and the role of initiation and propagation of fires, the components of the ground layer forming peat are unequal and divided into three classes: conductors of combustion, materials supporting combustion and retarding combustion propagation (Grishin *et al.* 2013).

The conductors include the materials that quickly become wet and then quickly become dry. Therefore, they are the materials that ignite very fast and provide a continuous propagation of flame over the ground cover.

Materials supporting combustion include live plants regulating evaporation, with a constant high humidity (more than 70%) and a small volume weight of the layer. This fact does not allow combustion to propagate spontaneously. They can burn only together with the conductors of combustion, increasing the total intensity of the fire line.

Materials retarding propagation of combustion are the materials which can not burn naturally due to the high humidity. They significantly reduce the total intensity of combustion, since the ignition and combustion requires a large amount of heat.

Analysis of experimental data

Figure 5A shows time dependence of the temperature change for the humidity content of the peat $W =$ 4.7% according to the first scheme of the experiment (Figure 2).

Figure 5B shows time dependences of the temperature change for the humidity content of the peat $W = 57.7\%$ according to the same scheme of the experiment.

.

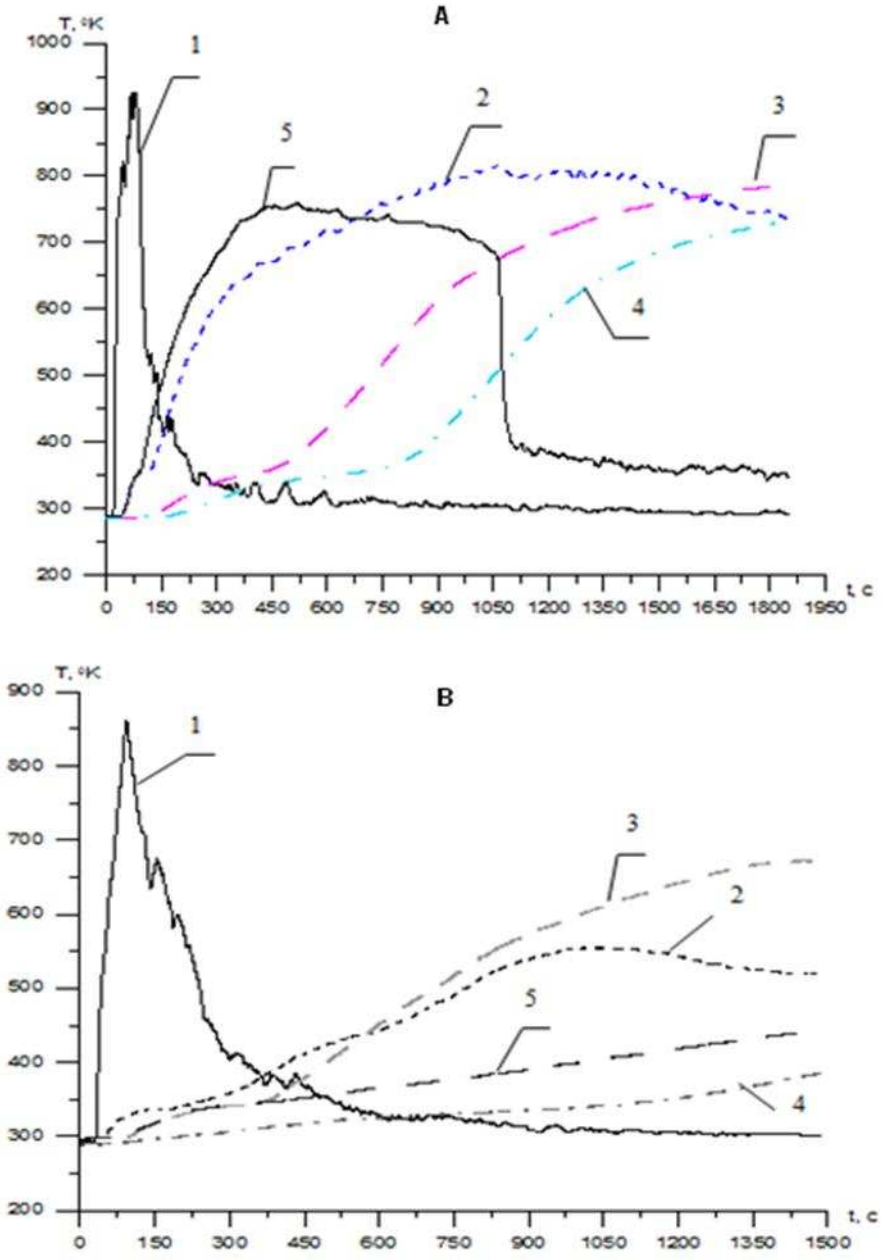

Figure. 5. Time dependences of the temperature change (A-moisture of peat samples $W = 4.7\%$, B-moisture of peat samples $W = 57.7\%$): 1- temperature in the FF layer, 2- temperature change at the boundary between the layer of peat and FF, 3- temperature change on the axis in the layer of peat at the distance of $1 \cdot 10^{-2}$ m from the thermocouple 3 (Figure 3), 4- temperature change on the axis in peat at a distance of $2 \cdot 10^{-2}$m, 5-temperature change in the lower part of peat layer.

Thus, combustion (smouldering) propagates in the mass of the peat sample (2) faster than in the horizontal direction. The rate of the fire front is approximately 0.19 mm/s at a distance of $1 \cdot 10^{-2}$ m between the thermocouples.

Analyzing the plots, it is seen that the transition of combustion from FF to peat is slower for the more wetted sample of torus. In general, combustion has a focal character, which is consistent with the different works (Reardon 2007; Ohlemiller 2002). Thus, combustion (smouldering) propagates in the mass of the peat sample (2) faster than in the horizontal direction. The rate of the fire front is approximately 0.19 mm/s at a distance of $1 \cdot 10^{-2}$ m between the thermocouples (Grishin *et al*. 2013).

Time dependences of the temperature change in accordance with second scheme of experiments (Figure 3A) are shown on Figure 6.
Figure 7 shown the time dependences of the temperature change for the case where the seat of the fire was initiated immediately above peat layer (Figure 3B).

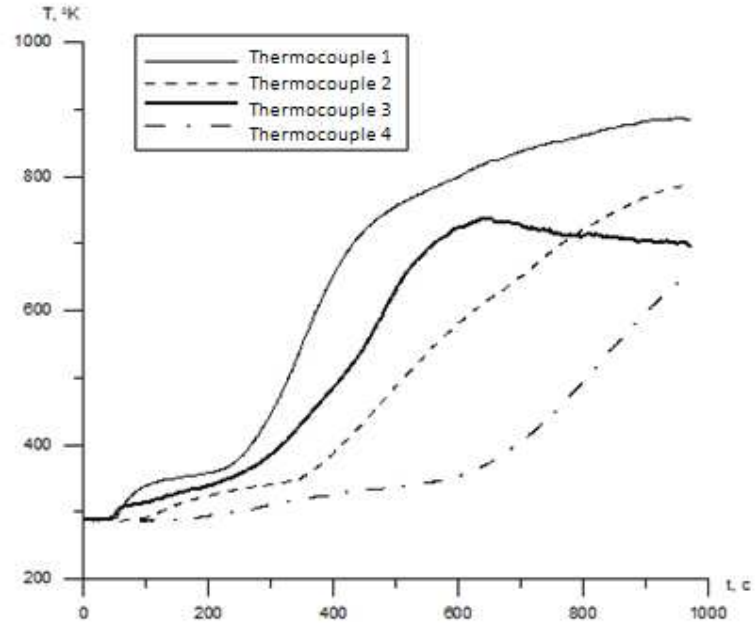

Figure 6. Time dependences of the temperature change. The numbering of the curves corresponds to the numbering of thermocouples in Figure 3A.

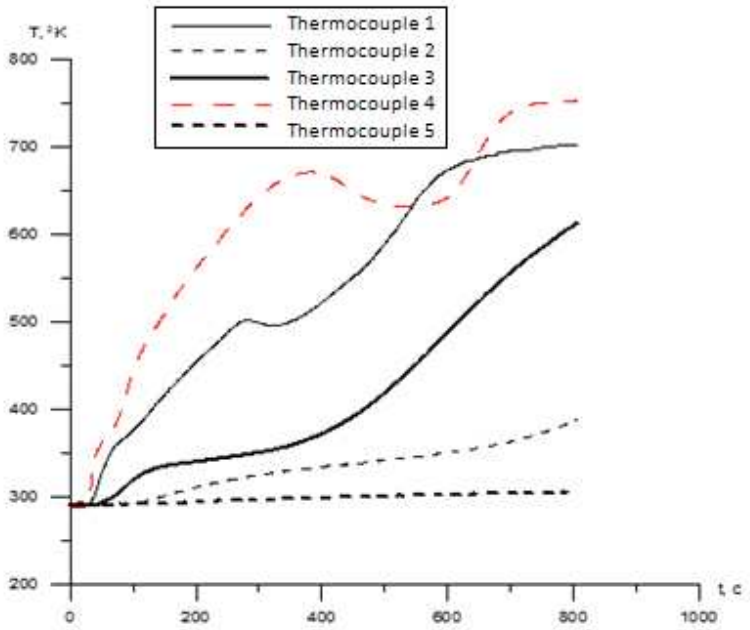

Figure 7. Time dependences of the temperature change. The numbering of the curves corresponds to the numbering of thermocouples in Figure 3B.

After analyzing the thermocouple data, the experiment have shown that there is a steady transition of combustion from a ground forest fire to the deep layer of peat at a low humidity content and sufficient

stock of forest fuel. The mechanism of penetration is mainly dependent on the botanical composition of peat. The presence of combustion conductors and their chaotic arrangement promote combustion propagation in both the horizontal and the vertical planes.
Complete understanding of the mechanism of penetration of combustion in peat layer requires additional investigations involving IR-methods, as well as mathematical modeling and comparison with the existing data.

Results

1. The experiments to study the deep of combustion in the peat layer from the front of a ground forest fire have been prepared and conducted.
2. The rate of peat burning has a value of about 0.19 mm/s.
3. The combustion has a site character, which agrees with the data of (Reardon 2007; Ohlemiller 2002).
4. Analysis of the structure of peat samples has been conducted. It has been noted that the characteristic of peat structure is the presence of burning conductors and water conveyance pores. The penetration of combustion may occurs on them.

Abstract
The study contains an evaluation of the occurrence of forest fires caused by rail transport and the effectiveness of the firebreaks beside railway lines. Analysis was conducted on the basis of information given in a questionnaire completed by forest administration units, inspection of the actual condition of equipment and maintenance of firebreaks and data are obtained from Polish State Railways and the State Fire Service. Analysis showed that approximately 65% of firebreaks are located in forests most subject to forest fires, 90% of firebreaks are made in pine stands, mainly of over 30 years of age (81.8%). Most forest fires occur in coniferous forest habitats (58.3%). Over 60% of all fires occurred in pine stands. Most frequently stands aged from 30 to 60 years (28%). From analysis of the effectiveness of the application of firebreaks beside railway lines it is shown that the first furrow of the firebreak was crossed by 27.3% of all fires. The conduct of extinguishing operations in the case of forest fires adjacent to railway lines is significantly hindered primarily by the late discovery of the fire, difficult access and initiation of burning along a significant length. The conducted investigations indicated the necessity of making and maintaining firebreaks in order to reduce the risk of fire to adjacent forest areas, which appropriately maintained are capable of reducing the risk of fire. The accuracy of this statement is also confirmed by the fact that such a method of protection is applied in many European countries. On the basis of the analysis conducted, a modification proposal has been drawn up for the existing firebreaks also with guidelines, concerning forest fire prevention in forest areas.

***Keywords**: Firebreaks, forest fire risk, railway transport*

Introduction

Rail transport, despite technical progress, still constitutes a significant fire risk to forest areas. It is true that over the last 30 years[1] a trend of reduction of the number of fires beside railway lines has been observed (in the years 1981–1990 rail transport was the cause of 5.92% fires, in the years 1991–2000 – 2.1%, and in the years 2001–2010 – 0.81% of all fires recorded), the greatest forest fire disasters occurred beside railway lines (Forest District: Rudy Raciborskie – 9060 ha and Potrzebowice – 5130 ha). Among the established causes of fires, those, which occurred because of rail transport, are seventh out of nine in statistical classification. The frequently compared cause - road transport - in the years 2001-2010 constituted the cause of 0.34% of forest fires, which is under half of the number of fires caused by rail transport.
According to the analysis of the Railway Scientific-Technical Centre[2] over 90% of forest fires were caused by sparks from brake blocks, or as a result of their friction. In such a situation, where fire embers are caused, the role of passive fire protection is filled by the firebreak, executed alongside the railway line, the role of which is to prevent or limit the possibility of the spread of fire to the adjacent

[1] Statistical data of the Forest Research Institute
[2] Prevention of fires beside rail routes. Rail Scientific-Technical Centre, Warsaw 1994

forest area protection. This method of fire prevention protection of forests against the risk caused by rail transport has been known since the mid-19th century and with certain modifications is currently applied also in countries other than Poland. Appropriately prepared and maintained, a belt of land is capable of preventing the spread of fire and limiting its speed and area.
Refraining from the making of firebreaks beside railway lines was the reason for undertaking the study, which was intended to assess the risk of forest fire from rail transport and the effectiveness of fire prevention protection in the form of firebreaks executed beside railway lines. The study was also required because of the lack of a complete insight concerning the cause of forest fires as a result of rail transport, concerning not only the number of fires caused and their surface area, but also fire risk development tendencies, spatial occurrence of fires in relation to firebreaks, evaluation of their effectiveness in the instance of occurrence of fire, the costs of execution and maintenance of firebreaks and also occurrence of fires in relation to habitat factors.
Obtaining reliable and complete data would provide the basis for assessment of activities, concerning protection of forests against fires and its adequacy with regard to the existing risk from rail transport and possible proposals for changes.

Methods

In the research information was used concerning the occurrence of fires beside railway lines and equipment and the maintenance of firebreaks from the State Forests, State Fire Service, Polish State Railways (PKP) and the Forest Research Institute.
The sources of this information are:

1) questionnaire information about the principles of fire prevention protection beside railway lines in Europe and analysis of the legal situation in Poland,
2) questionnaire information from 314 forest district offices from the years 2000–2010,
3) information from the incident registration system of the State Fire Service (EWID), from the years 2006–2010,
4) information from Polish State Railways Polish Railway Lines (PKP PLK) from the years 2002–2011,
5) information from terrain inspections conducted in selected forest districts.

Analysis of the fire risk from rail transport and the effectiveness of firebreaks consisting of the following stages. The first analysis stage was assessment of the conditions of performance of firebreaks. It was composed of analysis of the results of questionnaires and assessment of the execution of firebreaks on site. The basis for assessment of location of firebreaks maintained beside railway lines was information obtained through research questionnaires from forestry districts in the year 2010, containing information about all firebreaks maintained beside railway lines in the territory of Poland. In this stage, inspections were made of existing methods of creating firebreaks in other European countries and in Poland. In the second stage the hypothesis was verified, that forests lying beside railway lines are subject to a greater degree of fire risk, in comparison to other forests. Verification was based on the density of occurrence of fires and the average size of single fire. For this purpose was calculated the density of occurrence of fires and the average area per single fire beside railway lines in the years 2000–2009, on the basis of data are obtained from research questionnaires. The data was compared with data concerning the remaining forests. The third stage was detailed analysis of the occurrence of fires beside railway lines conducted according to the number of fires, area burnt, causes, place of occurrence and type of fire. Because only data for fires occurring as a result of two causes (faults of means of transport – code 26, incorrect use of means of transport - code 27) is available from the information system of the State Fire Service (EWID), the analysis was performed on the basis of information from the State Forests from the years 2007–2010, which is available in the National Forest Fires Information System. The fourth stage of the analysis was the assessment of the effectiveness of

firebreaks in the limitation of the spread of forest fires. It included the number of fires occurring in front of the first furrow of the firebreak, which crossed that furrow, the number of fires occurring between furrows, which crossed the second furrow and the number of fires that crossed both furrows. These analyses were conducted with regard to the type of forest, age of stand and prevalent species of trees.

Results

Legal status of fire prevention protection of forests beside railway lines in Poland

3.1.1. *Current situation in Poland*

According to statutes currently valid in Poland railway managements and hauliers and also users of rail sidings are obliged to fulfil technical and organisational conditions assuring fire prevention protection and environmental protection (art.17. point 1.3 of the Rail Transport Statute of the 28th of March 2003 – Journal of Laws no. 16 entry 94). The principles for the execution of firebreaks beside railway lines are regulated by the *Ordinance of the Minister for Internal Affairs and Administration of the 17th June 2010 concerning the fire protection of buildings, other building structures and land areas (Journal of Laws no. 109 entry 719) and the Ordinance of the Minister of Infrastructure of the 7th of August 2008 concerning the requirements in the extent of distance and permissible conditions of situation of trees and bushes, acoustic elements and the performance of earthworks adjacent to railway lines and also the manner of execution and maintenance of snow protection shields and firebreaks (Journal of Laws 2008 no. 153 entry 955).*

According to these regulations, beside railway lines on which traffic is conducted a firebreak shall be executed in the form of two furrows of a width of at least 2 metres, at a distance from each other from 10 to 15 m and connected with each other every 25 to 50 m by transverse furrows of the same width.

3.1.2. *Protection of forests in Europe*

Analysis concerning execution of firebreaks beside railway lines in particular European countries conducted on the basis of questionnaires, which were sent to services and institutions concerned with fire prevention protection. Countries/regions, which did not declare the execution of firebreaks beside railway lines running through forested areas are: Austria, Bulgaria, the Czech Republic, Germany (landers (provinces): Baden-Wurttemberg, Bavaria, Hesse, Rhine-Westphalia), Norway, Great Britain and Sweden. Respondents justified the lack of firebreaks by the slight risk of fire in those territories. From the questionnaire it is plainly shown that in a decided majority of states the responsibility for protecting forested areas against the risk of fire caused by rail traffic is borne by the managements of railway lines. This responsibility is regulated legally or constitutes a type of agreement between railway line management and the manager of afforested land (e.g. Turkey). The costs of these measures are borne by the railway line management or are divided between the rail management and the forest management (Slovakia).

The majority of the replies obtained from representatives of German landers indicated Deutsche Bahn Ag.DB, as the entity responsible for fire prevention protection. Only in one case (Mecklenburg-Pomerania) were the entire costs of fire prevention protection of forests borne by the private owners or managers of forests. The determining factor of the location of firebreaks is mainly the intensity of rail traffic and the susceptibility of afforested areas to the spread of fire. In the case of Switzerland and France the location of the so-called spark barriers was emphasised in places, in which trains frequently brake (downward gradients, curves), where obviously there is an increased risk of sparking from brake blocks. In Greece, Romania Portugal and in Lithuania firebreaks are executed along the entire length of rail routes running through afforested areas.

As a result of the information collected concerning methods and frequency of renewal of firebreaks, in the majority of cases they are renewed at least annually before the beginning of the fire season (April-September). Some questionnaire respondents also declared repetition of this activity in the

autumn. The main methods of renewal of firebreaks include clearing vegetation from the specified area measured from the external edge of the tracks by mowing or application of chemicals (herbicides). Use of chemical substances in order to prepare firebreaks was emphasised in information obtained from Greece and Spain. In the countries where questionnaires were sent the assessment of the effectiveness of firebreaks was mainly specified as good and very good.

3.1.3. *Assessment of execution of firebreaks beside railway lines*

Assessment of preparation and maintenance of firebreaks based on information from 1879 enquiries. The enquiries indicated that the combined length of firebreaks in Poland amounted to 5926.6 km, and that the decided majority of them (90.4%) were maintained by PKP PLK. The State Forests maintained 248.1 km of firebreaks, and other entities maintained 322.3 km. The majority of the land (66%), on which the firebreaks were situated was maintained by the State Forests, 29% were the property of PKP, and the remainder (5%) were managed by other entities. The annual cost of maintenance of firebreaks in the State Forests amounted to approximately 60,000 PLN. Whereas the Company PKP Polskie Linie Kolejowe [Polish Railway Lines] spent on average annually approximately 2,000,000 PLN, with the exclusion of the year 2011 when execution and renewal of firebreaks was limited. The results of analyses are presented in tables or directly in the text.

The results of analysis of the establishment of firebreaks along railway lines depending on the habitat type of forest are shown in table 1. Close to 65% of firebreaks are located in forest habitats, being the most subject of fires, 90% of the firebreaks executed are in pine stands, of over 30 years old (81.8%). Site terrain inspections, for the purpose of assessing the means and conformity with regulations for creating and maintaining firebreaks along railway lines were conducted at 67 selected locations. Among them, 46 were places where fires had occurred in the area of the railway track in 2010. The remaining 21 inspections were made in average places for the whole length of firebreaks in forestry districts, in which a significant number of fires have occurred beside railway lines. Evaluating the distance of the first furrow from the railway embankment it is confirmed that only in 48% of cases was the distance according to the regulations. In 19% instances the distance was less, and in 33% greater. Conformity of distance between the furrows was confirmed in 44% of cases, in 14% the distance was less, in 42% the distance was greater. The width of furrows was confirmed in the case of the first in 84% of instances, and in the case of a second in 93% of instances. At 7 inspection locations it was confirmed that firebreaks had not been renewed for a year or maybe two years.

Table 1. Firebreaks length according to the forest habitat types

Forest habitat type	Lenght [km]	Share [%]
BMśw	2093,4	35,6
Bs	20,3	0,3
Bśw	1509,3	25,6
Bw, BMw, Bb, BMb	297,3	5,0
Ł, Ol, OlJ, Lw	88,9	1,5
LMśw	1146,3	19,4
LMw, LMb	202,8	3,4
Lśw	267,4	4,5
other	228,9	3,9
mountain	2,7	0,0
upland	47,8	0,8

3.2. Occurrence of forest fires beside railway lines

In the years 2000–2009 in State Forests on the belt of ground 50 m wide beside railway lines there were 599 fires that burnt a combined area of 350.9 ha w. In the incident registration system (EWID) the State Fire Service registered 757 fires in forests, including all forms of ownership, which occurred

by railway lines in the years 2006-2010. Whereas according to the information of PKP Polskie Linie Kolejowe S.A. in the years 2002–2011 28 fires were noted involving an area of 84.19 ha. The information obtained from PKP PLK is grossly disproportionate to the information provided by the State Forests and the State Fire Service. The discrepancy probably results from internal instructions of PKP, that only incidents of fires that constitute a significant threat and the existence of which might be a liability to PKP PLK are recorded. With regard to the completeness of information, further analysis was conducted on the basis of information obtained from the State Forests. In order to verify the hypothesis stating that forests lying beside railway lines are at a greater risk of fire than the remaining afforested areas, the density of occurrence of fires was calculated and also their average surface area with regard to the category of forest fire threat (kzpl). The results shown in table 2 indicate that the density of occurrence of fires beside railway tracks (2.0 fires /1000 ha) was almost threefold greater in comparison to forests classified as I and II kzpl (0.7 fires/1000 ha).

Table 2. Density of forest fires occurrence and average burnt area in the relation to localization of the forest fire

Place of the fire occurrence	Forest fire risk category	Average annual density of the fire occurrence [fires/1000 ha]	Average burnt area [ha]
I and II forest fire risk category (kzpl)	I	1,1	0,28
	II	0,3	0,32
	I i II	0,7	0,31
Forests area along the railway	I	2,5	0,65
	II	1,3	0,41
	I i II	2,0	0,59

Comparing individual density in particular categories of fire risk it is shown that in afforested areas I kzpl is over twice as great in comparison to the remaining areas included in this category. Whereas in areas II kzpl this difference is over four times as great. The density of occurrence of fires beside railway lines in areas classified as I kzpl was almost twice as great as that of areas classified as II kzpl. Evaluating the average area of single fire and for forests lying beside railway lines in comparison to the remaining forests classified as I and II kzpl it may be seen, that beside railway lines it is almost twofold greater.

3.3. The occurrence of forest fires beside railway lines in relation to stand conditions and the size of the burnt area.

Analysis of the occurrence of fires beside railway lines in relation to forest habitat type is shown in table 3.

Table 3. Number of forest fires along the railway in the relation to the forest habitat type

Forest habitat type	Total forest fire		Ground cover forest fire		Together	
	number	share[%]	number	share[%]	number	share[%]
BMśw	38	50,0	139	26,9	177	29,8
Bs			3	0,6	3	0,5
Bśw	12	15,8	122	23,6	134	22,6
Bw,BMw,Bb,BMb	6	7,9	26	5,0	32	5,4
Ł, Ol, OIJ, Lw	2	2,6	10	2,0	12	2,0
LMśw	10	13,1	76	14,7	86	14,5
LMw, LMb	4	5,3	8	1,5	12	2,0
Lśw	3	4,0	14	2,7	17	2,9
undefined			116	22,7	116	19,6
upland	1	1,3	3	0,6	4	0,7

Most forest fires occurred in forest habitats (58.3%), including fresh mixed coniferous forest (BMśw) 29.5% and fresh coniferous forest (Bśw) 22.6%. 21.4% of fires occurred in forest habitats, including fresh mixed broadleaved forest (LMśw) 14.5%. There is a lack of clear difference of combined number of forest fires between stand age categories. Most fires (28%) occurred in stands aged from 30 to 60 years. Over 60% of all fires occurred in pine stands, and next (at a similar level) in stands, in which the principal species were birch and oak. Information presented in the above tables enables one to state that the flammability of forests beside railway lines is typified with a certain variability in comparison to the remaining forests. Apart from "particularly flammable" (Bs, Bśw, BMśw) attention is drawn to the significant flammability of stands growing in moist and boggy habitats (Bw, BMw, Bb, BMb, Ł, Ol, OlJ, Lw), which may arise from the presence on track side shoulders of a strongly developed grass cover, which during times of drought and in spring-autumn periods constitutes a high fire risk.

Size of burnt area

Analysis conducted on 553 fires since the remaining 46 fires did not spread to the forests, including within its reach exclusively the tracks and therefore omitted. Most fires were germinal, the area of which did not exceed 0.05 ha, and then small (from 0.06 do 1 ha). With regard to percentage share by size of fires occurring in all forests the results were similar. This however does not apply to large fires (from 10.1 to 100 ha), 1.6% of which occurred beside railway lines, and only 0.1% in remaining forests. This indicates that the probability of occurrence of a large fire beside a railway track is significantly greater.

The most frequent cause of forest fires according to information from the National Forest Fires Information System was rail transport, which caused 39.9% of all fires. Next in order were: arson (7.3%), carelessness of adults (5.2%), spread of fire from non-forested areas (1.6%) and electric power line malfunction and carelessness of children accounting for 0.5%. It was not possible to establish the cause in the case of 44.6% of all fires. Quite different information is given by PKP PLK, according to which arson is the dominant cause (39.3%), and followed by: blocked brake blocks (21.4%), sparks from locomotive funnel, electrical equipment faults and starting fire from train at 3.6%. Fires for which no cause was established constituted 28.5%.

3.4. Assessment of the effectiveness of firebreaks in limiting the spread of fires in forest

Analysis of the effectiveness of firebreaks along railway tracks in the limitation of the spread of fires was conducted on the basis of questionnaire concerning 417 forest fires in.

In the assessment were considered:

- the number of fires occurring in front of the first furrow, which crossed that furrow,
- the number of fires which crossed both furrows,
- the number of fires occurring between furrows, which crossed the second furrow.

Results with regard to stand conditions are shown in tables 4–6.

Table 4. Number of forest fires occurred before the first firebreak furrow and which crossed the first firebreak furrow according to the forest habitat type

Forest habitat type	Number of fires which crossed the first firebreak furrow	Total number of fires	Share[%]
BMśw	33	112	29,5
Bs	2	2	100,0
Bśw	30	96	31,3
Bw, BMw, Bb, BMb	15	20	75,0
Ll, Ol, OlJ, Lw	5	10	50,0
LMśw	14	55	25,5
LMw, LMb	3	9	33,3
Lśw	4	9	44,4
undefined	5	95	5,3
mixed	2	7	28,6
upland	1	2	50,0
together	114	417	27,3

Presented in table 4 information confirming significantly greater threat to forests by fires, in more fertile and moist habitats. They are places, in which on nonforested areas an abundant grass cover growth may occur and certainly for that reason a greater number of fires crossed the first furrow. Analysing the effectiveness of limiting the spread of fire by the first furrow in relation to the age of the stand it may be stated that its effectiveness increases together with the age of the stand. However similarly to the assessment conducted with regard to habitat type of forest is the situation in the case of prevailing species. From the data analysed it is shown that the first furrow was crossed by 27.3% of all fires.

The next aspect of information analysis was the assessment of effectiveness of the first furrow depending on the place of occurrence of fire (table 5).

Table 5. Number of forest fires occurred before the first firebreak furrow and which crossed the first firebreak furrow according to the place of the fire outbreak

Place of the fire outbreak	Number of fires which crossed the first firebreak furrow	Total number of fires	Share[%]
Between railway and the edge of embankment or ditch	68	227	30,0
Between the edge of embankment or ditch and first firebreak furrow	46	190	24,2

Approximately 6% more was the number of fires, which crossed the first furrow in the case of fires, which occurred within the vicinity of a railway line (to the edge of embankment or ditch) in comparison to the fires, which occurred from the edge of embankment or ditch to the first furrow. This probably results from the time of free spread of these first fires until the moment of reaching the first furrow was longer, and because of that attained a greater intensity, which facilitated overcoming obstacles.
In the case of fires, which crossed both furrows, the analysis included fires occurring in front of the first furrow, which crossed this furrow and analysis of what proportion of them cross the second furrow – table 6. Of the fires, which crossed the first furrow 22.8% also spread beyond the second furrow. The spread of fires, which occurred in more fertile, though moist habitats in deciduous stands, was

significantly more effectively stopped by the second furrow than by the first furrow. This is probably connected with the significantly weaker spread of herbaceous soil cover inside the stand in comparison to the sunlit part in front of the first furrow. Investigating the age of the main stand the least fires crossed the second furrow in stands with an age of 30–60 years.

Table 6. Number of forest fires occurred before the first firebreak furrow and which crossed the second firebreak furrow according to forest habitat type

Forest habitat type	Number of fires which crossed the second firebreak furrow	Total number of fires	Share[%]
BMśw	6	33	18,2
Bs		2	
Bśw	10	30	33,3
Bw, BMw, Bb, BMb	5	15	33,3
Ł, Ol, OlJ, Lw		5	
LMśw	1	14	7,1
LMw, LMb	1	3	33,3
Lśw	2	4	50,0
undefined		5	
mixed	1	2	50,0
upland		1	
together	26	114	22,8

According to questionnaire data only 98 fires occurred between furrows, and only 1 fire, which occurred in a pine stand aged >60 growing in a BMśw (fresh mixed coniferous forest habitat) crossed the second furrow, which constituted 3.8% of all analysed occurrences. Attention should be drawn to the fact that the conduct of fire extinguishing operations in the case of forest fires by railway lines is significantly hindered primarily by late discovery of fire, impeded access and initiation of burning along significant distance. From reports in the EWID State Fire Service system it is shown that burning on a section from 100 to 500 m occurred in 5.4% of all occurrences, on a section from 500 to 1000 m in 2.1%, and 7.3% of incidents were noted when the section was longer than 1000 m.

Summary

The conducted research showed the necessity of creating firebreaks beside railway lines, which appropriately maintained are capable of reducing the fire risk to adjacent areas of forest areas. The correctness of this statement is equally confirmed by the fact of the application of such a means of protection in many European countries. Also in those, in which the rail rolling stock used is significantly more modern than in Poland and creates less fire risk. In the majority of states in which firebreaks are executed beside railway lines, they have a mineralised form, or vegetation free belts of a width from 2 to 20 m. The factor, which is considered in making the decision of location of firebreak, is primarily the density of rail traffic, the level of risk and the susceptibility of afforested terrain to fire. Firebreaks are renewed at least once a year prior to the forest flammability season, by removal of vegetation by mowing or by application of chemical substances.
Considering the research results, from which it is shown that approximately 54% of forest fires beside railway lines occurred in front of the first firebreak furrow and of these fires almost 27% crossed this belt, drawing up a modification of the means of executing firebreaks one is guided primarily by the need to halt or limit the spread of fire of relatively low burning intensity. This may be achieved, if the

barrier belt shall be situated as close as possible to the railway line, thereby limiting the time of unimpeded fire development of fire, fire loading shall be reduced and a mineralised belt shall be wider. For these reasons the proposed firebreaks beside railway lines should have the form of one mineralised belt of a width of a least 4 m placed as close as possible to the line (Fig.1). Additionally it is recommended that the belt section be extended to public or fire access road executed in such a way that it might simultaneously fulfil such a role. Firebreaks should be situated in forests, through which railway lines pass and that are classified as having I and II category fire risk.

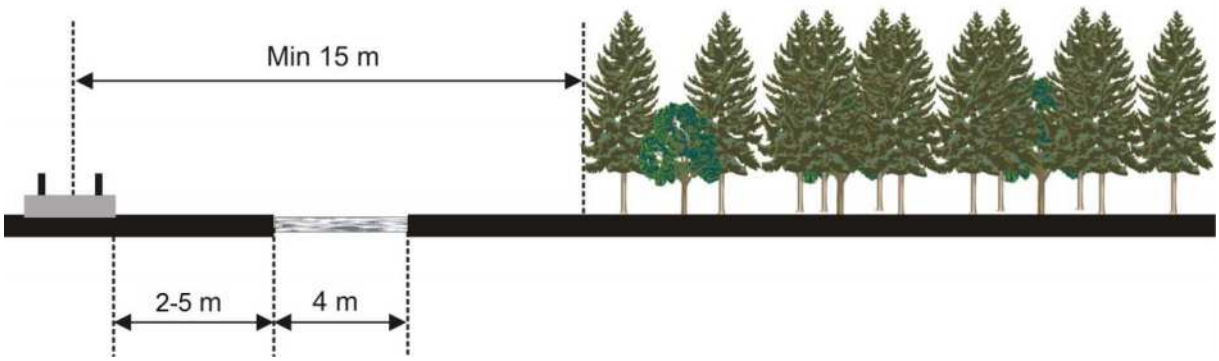

Figure 1. Scheme of the modified firebreak beside the railway

Figure 2. Modified firebreak beside the railway

In the case of modernisation of existing firebreaks it is recommended to use the existing first furrow, executing widening of this furrow to the required width from the side of the tracks, as the ground conditions permit. In connection with the above it has become essential to change the regulations currently in force through agreement of the ministers responsible for supervision of rail traffic, forests and fire prevention protection.

The amendment of the regulation became legally valid through the *Ordinance of the Minister of Transport, Building and Marine Economy of 15 March 2013.*

Forest fire severity in NW Spain: a case of study

Fernández-Alonso, J.M., Vega Hidalgo, J.A., Jiménez Carmona, E.

Centro de Investigación Forestal de Lourizán. PO Box 127. 36080, Pontevedra. Spain.
txema182@gmail.com

Abstract
Wildfires have become a main forestry concern for pine stands in Galicia (NW Spain). Burned forested areas have patterns of varying burn severity as a consequence of various topographic, vegetation and meteorological factors. Determining the relative importance of these factors is necessary to predict fire severity in the canopy, and therefore, base decisions on fuel management. A spatial study of fire severity for a large wildfire (Oia, Pontevedra) is presented here. Pine stands within the fire were classified according to the fire severity. The effect of meteorological (simulated wind speed and direction), topographic (aspect, slope and combined variables) and canopy fuel structure (LIDAR data) variables was described and then modeled. The presence of high fire severity patches was significantly linked to areas of higher simulated wind speed, to lower height stands and to sunny slopes. Simulated wind speed was the most important variable determining the high intensity areas in the rank order of importance analysis, meanwhile slope and aspect were the second and third most important variables. Canopy structure presented low variability in the studied area, which leads to a low importance in classifying fire severity. Variables evaluating alignment of forces, slope and wind direction, have not been found to be important predictors.

Keywords*: Random forests model, Pinus pinaster Ait., fire severity, landscape-base*

Introduction

Fire severity reflects the impact of heat pulses aboveground and belowground and it can be assessed as the degree of organic matter consumed (Ryan and Noste 1985, Keeley 2009). Crown fire is considered as extreme fire behavior (Alexander and Cruz in Werth *et al* 2011) and it is generally considered as one of the highest degrees of fire severity, where tree canopies are killed and needles are consumed (Key and Benson 2006; Lentile *et al* 2006; Keeley 2009; Holden *et al* 2009; Lecina *et al* 2014). That type of stand replacement fires means a challenge for fire managers: they pose an important risk to population and firefighting crews due to difficulty to suppress them. They also are a threat to forest production by removing much or the entire tree canopy in a particular area, and resulting in considerable C emissions (Jimenez *et al* 2013). They reset the successional and growth processes of stands and forests (Graham *et al*, 2004) and can change post-fire dominant vegetation type (Holden, 2009). Moreover that type of fire by consuming all canopy needles leave soil unprotected and prone to post-fire degradation and erosion (Robichaud *et al* 2000, Alexander *et al* 2006, Jain and Graham 2004).
Predicting high severity fire is essential to define areas to apply fuel treatments for severity mitigation or forest restoration works (Lentile *et al* 2006, Holden *et al* 2009, Amato *et al* 2013), nevertheless spatial patterns of burn severity over time remain poorly understood to date (Alexander *et al* 2006; Fernandes *et al* 2010; Sikkink and Keane 2012). Topography, vegetation and weather vary over space and time and they interact in complex ways to influence fire extent and fire occurrence (Turner and Romme, 1994, Odion *et al* 2004; Holden *et al*, 2009). Understanding the relative importance with which these factors contribute to fire severity is critical information for land managers of fire-prone landscapes (Graham *et al* 2004; Holden *et al* 2009 Sikkink and Keane 2012) since they may permit to prioritize investments in fuel treatments or to plan suppression tactics.
Despite the relevance of this topic, most of the studies published to date on fire severity are focused in the USA (Turner *et al* 1994, Lentile *et al* 2006, Alexander *et al* 2006, Collins *et al* 2007, Holden *et al*

2009, Dillon *et al* 2011, Amato *et al* 2013). Fire severity studies in Europe were carried out mainly in Mediterranean forests (NE Spain) (Broncano and Retana 2004, García-Martín *et al* 2008, Oliveras *et al* 2009, Roman-Cuesta *et al* 2009, Alvarez *et al* 2013, Lecina-Diaz *et al* 2014). Most of the studies assess fire severity using medium resolution satellite imagery data (Turner *et al* 1994, Lentile *et al* 2006, Collins *et al* 2007, Holden *et al* 2009, Dillon *et al* 2011, Bradstock *et al* 2010, García-Martín *et al* 2008, Oliveras *et al* 2009, Roman-Cuesta *et al* 2009, Lecina-Diaz *et al* 2014), whereas less studies used a field sampling-based approach (Broncano-Retana 2004, Holden 2009, Fernandes *et al* 2010, Alvarez *et al* 2013). Information from satellite imagery allows assessing fire severity patterns across a large scale and over time. This is useful to reflect the complexity of the interaction among topography, vegetation cover and weather (Amato *et al* 2013). However field data –based studies supply with more detailed information on that interaction and at finer scale.
In Galicia (northwestern Spain), a territory of about 30,000 km2, more than 10,000 fires occur annually (D.X. Montes 2010). That represents about than half of fires in Spain (MARM 2010). In that area, suitable conditions for biomass growth, summer drought and abundant ignition sources coincide (Vazquez 2006; Moreno and Chuvieco 2013), favoring high severity fires. Most of these fires occur in very continuous and productive conifer stands frequently resulting in stand replacement crown fires. These fires cause important economical losses and severe ecological impacts. Given the dominance of rainy climate and the steep terrain in the area, the main undesirable post-fire consequence is the soil erosion. This problem is more dramatic in crown fire-affected areas where soil losses measured following this type of fire in Galicia are considered the highest rates after wildfire in the Southern Europe, requiring costly rehabilitation treatments (Fernandez *et al* 2011; Vega *et al* 2014).
Despite of the tremendous impact of the high severity fires in Northwestern Iberian Peninsula, not a single study has been carried out on this topic in that area. Therefore, we considered essential to gain knowledge in how fine scale variables, used as inputs from empirical fire behavior models (Rothermel 1972, Rothermel 1991, Van Wagner 1977, Cruz *et al* 2004) and their spatial and temporal variability during the occurrence of a wildfire, can affect the severity patterns in a landscape scale. In the present paper we used fire related variables (topography, weather and fuel structure parameters) to evaluate their importance on high severity fire patterns in Oia fire in Galicia. More specifically we addressed: (i) assessing the differences of these variables between high-severity crown fire areas and low severity areas (ii) fitting statistical models to determine their capability to predict high-severity fire occurrence and the relative importance of each predictor variable.

Methods

Study area

Our research focused on the Oia wildfire (area > 500 ha) occurred during the summer of 2013 in the coastal area of Galicia (Northwestern Spain) (Fig 1). This wildfire affected mainly *Pinus pinaster* Ait. (maritime pine) pole-size stands.

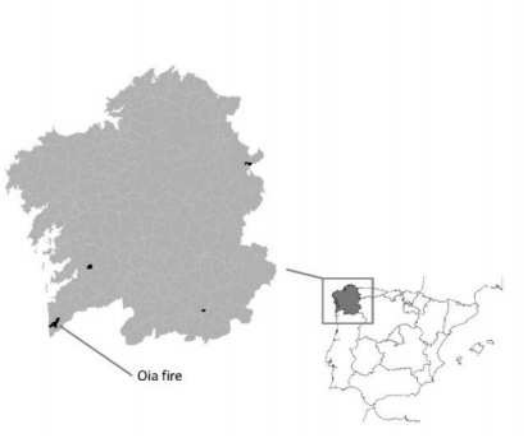

Figure 1. Location of the study area, in Galicia (NW Spain)

The Oia fire occurred in the municipalities of Oia and O Rosal (Pontevedra province). The elevation of the study area ranged from 30 to 515 m. The aspect was generally southeast, with slopes between 0 and 65%. Maritime pine and *Eucalyptus globulus* Labill. (blue gum) were the dominant tree species and the main shrub species were *Ulex europaeus* L., *Pteridium aquilinum* (L.) Kuhn, and *Pterospartum tridentatum* (L.) Wilk. The fire was human-caused and started in 26th August 2013. It was brought under control two days after the ignition. It burned 1810 ha. According to Spain Lithological Map 1/50.000 (http://www.igme.es/internet/cartografia/cartografia/magna50.asp, accessed on 21st June 2014), the soils in this area are developed from schist, slates and granite.
Meteorological conditions during the wildfire are presented in Table 1.

Table1 - Meteorological conditions during the wildfire. Variables from Canadian Forest Fire Weather Index (Van Wagner 1987): FFMC: Fine Fuel Moisture Code; DMC: Duff Moisture Code; DC: Drought Code; ISI: Initial Spread Index; BUI: Buildup Index; FWI: Fire Weather Index. Data from meteorological station located at 4 km from the burned area (Meteogalicia, Xunta de Galicia)

Variable	26th August	28th August
Temperature (ºC)	18.8(13.4-26.1)	20.6(15.3-26.7)

FWI	21	23

Field sampling and spatial data

Wind speed and direction, fuelbed load and structure, slope, fuel moisture content, distance from the surface fuelbed to the lower limit of the canopy stratum and crown bulk density are the input variables determining crown fire occurrence (Van Wagner 1977, Cruz *et al* 2004).
Fieldwork was carried out in the following weeks after the fire. Areas affected by crown fire were visually identified as the patches where the crown fine fuel consumption was complete. The perimeters were tracked using a Trimble Juno 5B GNSS to delimit these areas from where tree crown were totally or partially scorched in the same stand. The areas of interest for the present study were delimited in a Geographic Information System (GIS) as continuous stands where the high-severity fire (crown fire) occurred and surface or low severity fire was observed in the surrounding area. In this way, two contrasted fire severity levels were considered: high and low.
A grid of 100 m was overlaid on a map of the areas of interest. The starting sample point was randomly chosen and 41 sample points were selected. Circular plots of 10 m radius were established on each point. In each plot, all trees with diameter at breast height (Dbh) >5 cm were tagged. Diameter at breast height, total height and post-fire crown base height were measured for each tagged tree. Descriptive characteristics of the plots are presented in table 2. Fire direction was determined observing the char patterns on the tree trunks and the stuck pine needles.

Table2. Mean characteristics and range of monitored plots. Dbh: diameter at breast height; Ht: total height; CBH: crown base height, G: basal area. Minimum and maximum observed values of means per plot between brackets

Type of fire	Density (trees.ha^{-1})	Dbh (cm)	Ht(m)	CBH(m)	G(m^2.ha^{-1})
High-severity	1364(265-2487)	16.4(11.2-22.9)	12.4(8.8-15.8)	6(1.9-9.7)	29.4(9.9-56.7)
Low-severity	881(368-1741)	21.5(14.9-36.6)	15.3(9.4-29.6)	8.4(2.5-23.1)	32.4(7.9-53.8)

Given the landscape-scale and spatial characteristics of a large wildfire, we used the methodology proposed by Stratton *et al* (2006) for wildland fire spatial analysis of the fire environment (weather, fuel, topography) variables.

Grid-based digital elevation model (DEM) at horizontal resolution of 25 m was obtained for the study area from the Spanish Geographic National Institute (http://www.ign.es/ign/layoutIn/modeloDigitalTerreno.do, accessed on 21st June 2014). The DEM was used to calculate the slope and aspect (topography variables) within each fire digital perimeter in ArcGIS v. 9.3 (ESRI 2008).

The same DEM was utilized to simulate the wind fields within the fire perimeters with WindNinja (Forthofer, 2007). WindNinja is a mass-consistent fluid flow dynamics models that estimates the modifying effects of topography on synoptic winds. Although presumably local wind field could be significantly affected by the fire itself, obtaining direct information on wind field within fire perimeter was not an operational option. Wind and temperature data were obtained from Meteogalicia weather stations network (http://www2.meteogalicia.es/galego/observacion/estacions/estacions.asp, accessed on June 21, 2014). The two closest weather stations were selected to supply with the information necessary for the corresponding wind simulations. Characteristics of weather stations are shown in table 3. Wind simulations were made for the wildfire at ignition time and at different moments of the fire run by dividing burned area in function of the approximated position of the fire front, by using the information provided by the suppression crews. Vector files (point geometry) containing wind speed and wind direction were generated and clipped for the study area.

Table3 - Characteristics of weather stations used in the wind simulation (Meteogalicia, Xunta de Galicia)

Station name	Elevation (m)	Distance to study area (km)
Castro Vicaludo	440	4
Aloia	480	15

A database was created including topography (aspect and slope) and simulated wind variables (wind speed and direction) for each pixel within the fire perimeter. With the aim of evaluating if the concurrent effects of the simulated wind and slope is determinant for the occurrence of high-severity crown fire in the same way it is for fire behavior (Weise and Biging, 1997) two combined variables were calculated and included:

a) Terrain slope in the wind direction (fig 2), ranging from positive value of maximun slope (wind vector aligned with upslope vector) to negative value of maximum slope (wind aligned downslope) and

b) the difference between upslope direction and wind direction (fig 3) vectoring as described in Rothermel (1983), where 0º is complete alignment of slope and wind blowing upslope, and 180º means alignment of slope and wind blowing downslope.

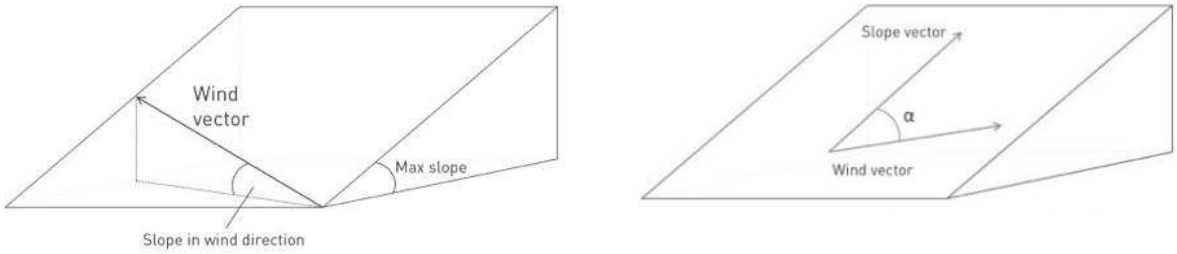

Figure 2 and 3. Sketches of: slope in wind direction calculation, referenced to maximum slope (left) and degree of alignment between slope and wind vector (α), referenced to the slope vector (maximum slope) (right)

National Aerial Ortophoto Program (PNOA) LIDAR data (http://www.ign.es/PNOA/presentacion.html) was used to account for the effect of vegetation structure on fire severity. Light Detection and Ranging (LIDAR) technology has proven its capability to measure canopy and surface fuel structure and to generate landscape-scale maps of these variables (Riaño *et al* 2004, Andersen *et al* 2005, Skowronski *et al* 2011, Mutlu *et al* 2008,van Aardt *et al* 2011, Jakubowski *et al* 2013; Gonzalez-Olabarría *et al* 2012). In fact, these studies have shown that LIDAR data allow to fit models to estimate variables directly linked with crown fire behavior, such as canopy bulk density (CBD), crown fuel load (CFL), canopy base height (CBH), and also understory stratum. In this area of study the LIDAR flights were carried out in the year 2009. Values of the laser height distribution (mean, minimum, maximum, mode and percentiles) and canopy cover above 2 m were added to the statistical analysis as a potential predictor for fire severity on canopy, given the above relationship between these variables and the vegetation variables that drive crown fire initiation (CBH, surface fuel structure) and spread (CFL, CBD).

2.3. Statistical analysis

Two statistical tests were applied to the variables distribution to assess significant differences between the two severity categories considered. The Kruskal-Wallis one-way analysis of variance was used to examine significant differences for each potential continuous variable. Fisher's Exact Test was applied to the contingency table to examine the significance of the association between fire severity and aspect class.

Random Forests (RF) (Breiman, 2001) is a variant of Classification and Regression Trees (CART). This technique is an ensemble method that fits many classification trees to a data set and then combines the predictions from all the trees. Approximately 66% of the data are used in a classification tree with the remaining data used as a validation data set (called out-of-bag observations). An estimate of the error rate is obtained based in this out-of-bag, or OOB, data. RF has shown its power in the analysis of ecological data in a landscape base in the Cutler *et al* (2007) study, in which RF showed higher classification accuracy than four other commonly statistical classifiers. Holden *et al* (2009) used Random Forest to assess the ability of landscape variables to predict severe fire occurrence and Pierce *et al* (2012) also used RF for modeling and mapping four canopy fuel variables at a landscape level.

We used this statistical approach to assess the ability of topography, fuel and wind variables to predict fire severity on forest canopy layer. We used the Random Forest Package developed for R (R Core Team, 2013) by Liaw and Weiner (2002). A first RF model was adjusted containing weather and topographic variables (6 variables) and all the LIDAR variables (67 variables) into the dataset to compare the goodness-of-fit of each model and to select the most relevant variables. For a suitable evaluation of the variable importance, multicollinearity between variables was analyzed using the Pearson's correlation coefficient: the threshold of 0.75 was applied as criteria for removal any of the correlated variables. The final RF models were adjusted with the dataset containing the remaining variables (6 or 7 variables). Sampsize option was used to account for the lack of balance in the datasets.

High-severity observations were less than the low-severity ones, so sampsize was set up in order to RF select the same number of observations for each type of fire severity by randomly decreasing the sampling size of scorched fire observations.
Model error stabilized after 2000 bootstrap replicates. The m parameter (number of predictors randomly selected at each tree node as potential variables to base the split on) was optimized with 3 of the 6 explanatory variables. Variance plots were used to identify the relative strength of each predictor variable.

Results

Variables related to fire severity

Mean value of terrain slope was higher in low severity-affected stands than in high severity patches (table 4), but the difference was less than 4%. Mean wind speed was higher for high-severity patches than for low-severity ones, with a difference of 2.2 km.h-1 between them. Minimum wind speed values were also higher for high-severity patches. Mean values for simulated wind direction were very close between fire severity levels: 66 and 67 degrees for high and low severity respectively. Mean values for slope in wind direction were very close, with a difference of 2.4% between fire severity levels and very similar ranges for both. Angle between maximum slope and wind direction showed a higher mean value for high severity patches, 109 degrees, and the difference with low severity patches was 9 degrees.
Kruskal-Wallis one-way analysis of variance test determined that only the distribution of terrain slope, wind speed, and angle between maximum slope direction and wind direction values were significantly different ($p<0.05$) between fire-severity levels.

Table 4- Mean and range for topography and weather variables values in the studied area. SD = standard deviation. Obs = number of observations

Fire type	Statistics	Slope (%)	Wind Speed (km/h)	Wind direction (º)	Slope in wind direction (%)	Max.slope-wind direction (º)	Obs
High severity	Min.	4.0	12.6	55	-44.7	1	3335
	Max.	60.6	27.6	81	58.7	180	
	Mean	26.4	20.3	66	-3.4	109	
	SD	12.5	2.5	4	18.1	45	
Low severity	Min.	0.3	8.7	53	-48.7	0	7781
	Max.	65.8	27.6	109	65.5	179	
	Mean	30.2	18.1	67	-1.0	100	
	SD	14.7	3.1	8	23.6	48	

Table 5 shows the observed percentage distribution, in aspect class, for each severity level. High severity fire was significantly more frequent in S, SE and SW aspect classes (sunny slopes) (Fisher's Exact Test; p-value < 0.01). Conversely, E, N, NE and NW aspect classes showed more low-severity points.

Table 5- Percentage of pixels by aspect class in the studied area. Obs = number of observations

Fire type	Flat	N	NE	NW	E	S	SE	SW	W	Obs
High-severity	0.0%	1.8%	2.7%	7.2%	7.5%	20.9%	26.9%	16.1%	17.0%	335
Low-severity	0.0%	5.0%	7.0%	14.3%	9.5%	15.9%	19.1%	9.6%	19.6%	781

RF model

Table 6 shows the statistics for the only relevant LIDAR variable in classifying high severity fire after fitting the RF model. According the RF classification, maximum elevation (Elev max) of LIDAR pulse appeared to be the only important variable, and it was significantly different (Kruskal-Wallis test, $p<0.05$) between high and low severity areas. Mean value of LIDAR maximum elevation was higher for low severity patches than for high severity ones.

Variable	Type of fire	Mean	SD	Minimum	Maximum
Elev max	High-severity	8.00	3.27	0.61	18.93
	Low-severity	9.27	4.54	0.46	33.59

Table 6. LIDAR variable used for determining severity crown fire occurrence. Elev max = maximum elevation of LIDAR pulse.

Table 7 shows the out-of-bag (OOB) estimate of error rate for the classification of fire severity. Total OOB estimate was 18.46%. For high severity estimations the number of misclassified observations was 23.72%.

Table 7. Confusion matrix for the Random Forests model predicting severity crown fire occurrence in each severity level. Obs = observed fire, Pred = predicted fire, OOB= out-of-bag estimation of error.

	Pred.		
Obs.	Low-severity	High-severity	
Low-severity	700	137	16.37%
High-severity	79	254	23.72%
		OOB estimate:	**18.46%**

Figure 4 shows rank orders of variable importance for the RF model. The most important variables classifying fire severity are at the top of the y-axis. A weather variable, wind speed, was the most important one for this fire. Slope and aspect class, both topography variables, were the second and the third most important variables. Maximum elevation of LIDAR pulse, a fuel variable, was the less important variable in classifying fire severity.

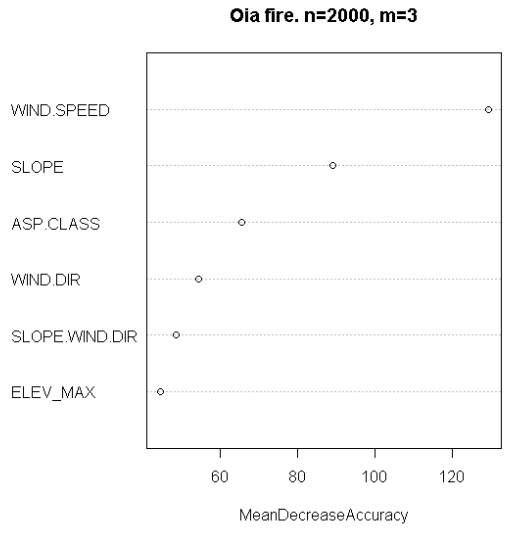

Figure 4. RF variable importance rank plot for the studied area. The most important variables predicting crown fire severity are at the top of the y-axis. n= number of trees in the RF model and m = number of predictors randomly selected at each tree node as potential variables to base the split on.

Discussion and conclusions

4.1. Variables related to fire severity

The effect of slope on severity is dissimilar in literature. Some authors have found positive correlations between fire severity and slope (Jimerson and Jones 2003, Alexander *et al* 2006, Holden *et al*, 2009). Contrarily, Bradstock *et al* (2010) found a negative correlation between fire severity and slope, which is explained by the authors as a possible effect of rocks outcrops, common in slopes, lowering the fire intensity. Although the slope was significantly different between severity levels in our study, difference in mean values was less than 4%, which we consider not having a large effect on fire behavior.

Few studies have taken into account the effect of wind speed on fire severity and all of them have followed different approaches to the one we used in this study. Dillon *et al* (2011) used mean and maximum values of wind speed for a 10-days period starting on the detection date of each fire and number of days with wind speed above 20 miles/hour. These wind variables were positively related to fire severity in only one of the six studied regions. Collins *et al* (2007) used mean wind speed values for each burning period in two fires and they observed contrasting associations between wind speed and fire severity. Bradstock *et al* (2010) found a positive association between high severity and extreme weather, variable that includes the effect of wind speed. Our approach, in which wind speed was simulated taking into account the effect of topography, seems hardly comparable. However, the positive association we found between high severity fire and wind speed seems consistent with the results in the above studies.

Alignment of wind and slope did not seem essential for high severity occurrence. Statistical difference was found for the variable angle between slope and wind direction between fire severity levels. Despite of these results, difference for mean values between fire levels was only 9 degrees. This scarce difference between fire severity levels may point out that was not determinant for high severity occurrence in the studied area.

Studies in fire severity have found dissimilar results regarding the effect of aspect on fire severity. Weatherspoon and Skinner (1995) and Alexander *et al* (2006) have found that patterns of severity were associated to the aspect, underlining that south-facing slopes or flat terrains tended to burn with higher severity than other aspects. Holden *et al* (2009) found that at lower elevations, north-facing slopes were proner to have high intensity fire likely because a higher vegetation growth than in south-facing slopes, whereas at higher elevations solar insolation would increase drying of surface fuels in south-face slopes, which are associated to higher burn severity. Dillon *et al* (2011) also found north-facing slopes to focus high severity fires for five of six ecoregions studied. Nevertheless, in the Pacific ecoregion the probability of high severity fire was highest in the warmest aspects, which may be explained because aspect is not a limiting factor for productivity in these areas with high precipitation. In our study, given that the elevations were relatively low and the annual rainfall is high, we consider that the fuel availability is not limited by the aspect. Summer drought is common during the fire season in Galicia, which could act drying the sunny slopes and leading to an increased probability of severe fire in those aspects.

ELEV_MAX variable was positively correlated to canopy height (Andersen *et al*, 2005), so looking at table 4 one can say that, under the same under conditions, high severity fire tended to occur more frequently in lower (i.e younger) stands. Studies in maritime pine stands for the same area (Jimenez *et al* 2013, Fernandez-Alonso *et al* 2013, Gomez-Vazquez *et al* 2013) have shown that there is a positive correlation between mean stand height or dominant height and canopy base height (CBH). Thus, higher stands may have also higher CBH values and therefore, lower possibilities of crown fire occurrence.

4.2. RF model

Despite of the correction for the unbalanced dataset, since the number of high severity observations was lower than low severity observations, results showed that RF had more difficulties to correctly

classify high severity observations. A possible explanation for such phenomenon is that less information on high severity occurrence was available for RF, which complicated its correct classification. Anyway, RF model was a useful tool to determine which variables were related with high severity occurrence and which was the relative importance of each of them.

This case of study was a good example of wind-driven fire. Meteorological station data (not shown) presented a constant wind conditions during the fire and the fire shape (Anderson, 1983) was narrow and elongated, with an approximated length to width ratio of 4:1. Information provided by fire fighting services described the fire as driven by strong winds, with high spotting activity and the most of the fire runs occurring during the first night. Our results seem compatible with these observations. High wind gusts were observed for the closest weather station and mean wind speed was considerably high during the fire. Under these conditions it seems reasonable that wind speed played a determinant role in the fire behavior in this area and, hence, controlling fire severity, as it was shown by the RF model. Fuel variables were the last in the importance ranking determining high severity occurrence for this fire. A possible explanation is the homogeneity of canopy fuel structure within this area: mean values for LIDAR maximum elevation of canopy layer were very close between fire severity levels. This fact supports that studied stands were considerably similar for this fire and canopy structure did not play an important role in high severity occurrence.

Regardless of the favorable results, some limitations of our approach are evident. We used driver variables of fire behavior to estimate fire severity, but we acknowledge that fire behavior models do not necessarily provide good predictions of fire severity (Alexander *et al* 2006). Nevertheless, studied variables here are well-known for affecting fire intensity, and in the case of a tree stand, a higher intensity can lead to crown activity and to a higher canopy fuels consumption (Alexander, 1982).

The effect of wind speed explaining high severity occurrence must be taken with caution. Windninja simulation only accounts for the effects of topography, but obviously there was an interaction between fire and the atmosphere surrounding fire that affects the crown fire activity (Coen *et al* 2004). In cases with moderate wind conditions, these interactions may become more important for fire behavior than local winds as convective plume created by the fire modifies notably its surrounding atmosphere (Potter, 2012) and fire -induced turbulence can be critical to understand apparently inexplicable fire behavior (Seto *et al*. 2013).

Results regarding the variable importance should be taken in the context of the studied area. In our study most of the stands had similar ages and all of them were pure and even-aged, which means that canopy fuel structure was quite similar within each stand. Moreover, fuel treatments aimed at reducing fire severity on canopy were not identified in the studied area. Under those conditions is understandable that weather variables were the most important predictors of high severity in two of the fires because their higher variability within the perimeter.

However our results seem reasonable and consistent with the current knowledge on fire severity phenomenon. In despite of the limitations of the wind simulation approach used, wind speed emerged as the most important variable predicting high severity occurrence. That agrees with the central role the current models give to wind in fire intensity and rate of spread, and accordingly, to fire severity. Our results also suggest that slope and aspect class, the latter likely as a surrogate of fuel moisture, seemed to play an important role in determining crowning occurrence and fire severity on canopy. Having into account the rate of accuracy of the RF model, this methodology may be helpful for fire managers to delimitate and plan fuel treatment works for severity mitigation, in areas where fire events recur under a fixed synoptic wind condition and post hoc case study

Acknowledgments

The research was funded by the agreement between the Spanish Ministry of Agriculture and INIA, Project RTA2009-0153- C03-01.

Abstract
The effect of two post-fire stabilization treatments (seeding and mulching) on some selected physical, chemical, biochemical and microbiological properties as well as the efficacy of these treatments on post-fire erosion control was investigated. The study was performed in two scrubland areas of Galicia (N.W. Spain), susceptible to suffer post-fire erosion (slope 30-50%) after an experimental fire and a wildfire, respectively. Soil samples were taken from the A horizon at different sampling times over one year after the fire event as well as from the corresponding unburnt soil located in an adjacent plot used as control; the sediments from the burnt soils, with and without different post-fire stabilisation treatments, were periodically collected after precipitation events. The results showed that initially the wildfire induced important changes in most properties measured and that these effects persisted 12 months after the fire; in contrast, the experimental fire provoked slight changes in the physic-chemical and chemical properties but moderate changes in the biochemical properties. They also indicated that both stabilisation treatments had no effects on the soil properties analysed and then on soil quality, but reduced significantly the sediments yield compared to the control burnt soil. The mean efficiency of the seeding and mulching treatments in preventing soil erosion was 21-31% and 85-88%, respectively, showing that, in the short- and medium-term (12 months), the straw mulching was the most effective treatment for reducing the post-fire erosion in both burnt areas.

Keywords*: experimental fire, wildfire, soil quality, post-fire soil erosion, post-fire rehabilitation.*

Introduction

High severity forest wildfires are common in the N.W. of Spain and the risk of post-fire erosion is very high due to the presence of forest ecosystems located in pronounced relief terrains, in combination with abundant precipitations (Carballas 2014; Carballas *et al.* 2009; Vega *et al.* 2013). It is well known that post-fire stabilisation treatments such as seeding, mulching and erosion barriers can reduce surface runoff and keep post-wildfire soil in place and thereby prevent sediment deposition in unwanted areas, being regarded as a defensive first line against post-fire erosion and sediments movement (Robichaud *et al.* 2005). Therefore, the implementation of post-fire stabilisation techniques in burnt forest ecosystems could reduce post-fire erosion; however, studies on this topic are scarce and have been mainly performed in USA. Since post-fire stabilisation treatments are expensive they should only be applied where and when they are required; therefore, studies on monitoring the efficacy of these techniques are necessary to compare their effectiveness and determine if they should be implemented in burned areas of the N.W. of the Iberian Peninsula. The aim of this investigation was to evaluate the effectiveness of two stabilisation techniques, seeding and mulching, in reducing soil erosion as well as their effects on the soil quality.

Methods

The study was performed on two scrubland hill slopes areas located in Galicia (N.W. of Spain), one affected by an experimental fire of low severity (Monte Cabalar, Pontevedra; E soil), and the other affected by a high severity wildfire (Laza, Ourense; W soil) and highly susceptible to suffer post-fire erosion (slope 30-50%). In both areas, experimental plots (E soil, 30 m long x 10 m wide; W soil, 20 m long x 5 m wide) were installed by triplicate (W soil) or quadruplicate (E soil) and four treatments were established: unburnt control soil (U); burnt control soil (B); burnt soil with seeding (B+S; a mixture of seeds at a rate of 45 g m^{-2} in the E soil; and rye seeds at a rate of 10 g m^{-2} in the W soil); and burnt soil with straw mulch (B+M; straw at a rate of 250 g m^{-2}) (Figs. 1. 2, 3). For the different soil treatments, the sediments production (Figure 4) as well as the analysis of different physical, chemical and microbiological properties of the soil samples collected from the A horizon (0-5 cm) was performed over an one year period. A detailed description of the experimental set up as well as the methods used for the sediments and soil characterization are given in Fontúrbel *et al.* (2012) and Díaz-Raviña *et al.* (2012). Soil characterization included a wide range of physical (texture, water retention, water repellence, aggregate stability), physic-chemical (pH, electric conductivity), chemical (total C, soluble C, soil carbohydrates, total N, ^{13}C, ^{15}N, inorganic N, macro- and micro-nutrients) and biochemical and microbiological (microbial biomass, soil enzymes of C, N and P, bacterial activity, soil respiration, microbial biomarkers such as phospholipids fatty acids –PLFA pattern) properties, as well as sediment characterization, performed at different sampling times over one year period. However, to facilitate the interpretation of data, only 11 soil properties measured 1 day and 365 days after the application of the treatments were here used for evaluating the soil quality status in the two experimental burned areas.

In order to evaluate the effect of the fire and the post-fire stabilisation treatments, the values of three-four plots with the same treatment were averaged (mean ± SE). The data were analyzed by a standard analysis of variance (ANOVA1) and, in the cases of significant F statistics, the Turkey's minimum significant difference test was used to separate the means. In addition, a principal component analysis (PCA) was carried out on the physical, chemical and biochemical data for the evaluation of the soil status. All statistical analyses were made using SPSS 15.0 statistical package.

Results and discussion

The main topsoil characteristics of the unburnt and burnt soil samples 1 day and 365 days after the wildfire are showed in Figures 5 and 6. The soils studied had an acid pH, elevated content of organic matter and microbial biomass C and low nutrient availability and microbial activity values, these results being representative of forest soils under shrub land vegetation in the Atlantic humid temperate zone of the N.W. of the Iberian Peninsula. Compared to the corresponding unburnt soil samples (U), significant positive or negative effects in most physic-chemical, chemical and biochemical properties were observed immediately after the wildfire (W soil) and less marked or even no significant changes in the soil affected by the experimental fire (E soil). These results can be explained by the temperatures reached during the fire event; the prescribed fire was of low severity, reaching temperatures of 153ºC in the mineral soil surface and 34ºC at 2 cm soil depth (Fontúrbel *et al.* 2012) whereas the uncontrolled fire was of moderate to high severity as it was indicated by the presence of black and white ashes and the total consumption of the ground plant communities (Vega *et al.* 2013). The microbial biomass and the activity values were lower in the burnt soils than in the corresponding unburnt soils, indicating that the fire had negative effects on the microbial population (death of microorganisms by soil sterilization). It should be noticed that for both soils, the fire induced more marked changes in the biochemical properties (microbial C, glucosidase activity, urease activity) than those observed in the physic-chemical and chemical properties. This is consistent with earlier studies performed with soils from the same region showing the usefulness of the more labile and active fraction of the soil organic matter, the microbial component, to detect the impact of prescribed fires (Barreiro *et al.* 2010; Basanta *et al.* 2004) or wildfires of medium and high intensity (Prieto *et al.* 1998; Villar *et al.* 2004).
One year after the wildfire, except for the electric conductivity, the burnt soils showed values for the physic-chemical, chemical and biochemical parameters different from those reported for the corresponding unburnt soil, indicating that the adverse fire impact persisted over time. This behaviour can be explained by the high temperatures reached during the fire as well as the low recovery of the vegetation.

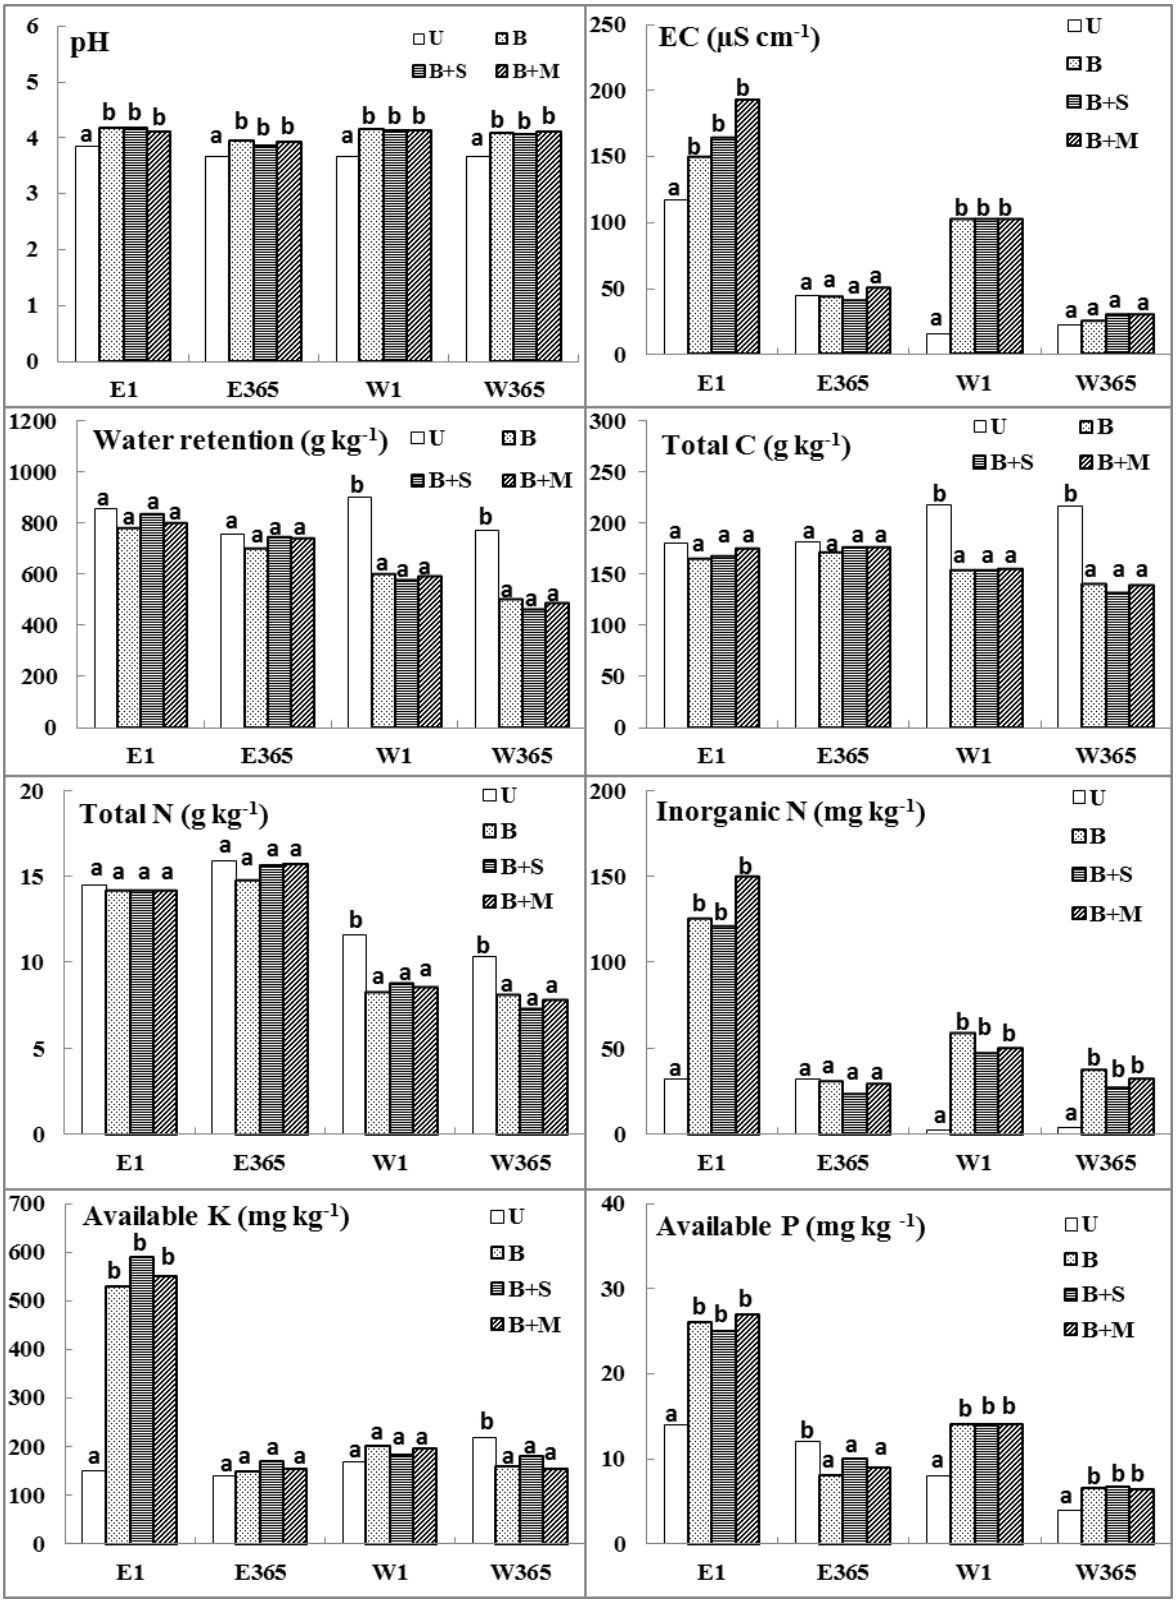

Figure 5. Soil physical and chemical properties for the different soil treatments 1 day and 365 days after the experimental fire (E) or the wildfire (W) (mean values of 3-4 replicates). Treatments: U, unburnt soil; B, burnt soil; B+S, burnt soil plus seeding; B+M, burnt soil plus straw addition. For the same soil and sampling time different letters denote significant differences ($p<0.05$) among treatments. Available nutrients were taken from Gómez-Rey et al. (2013) and Gómez-Rey and González-Prieto (2014).

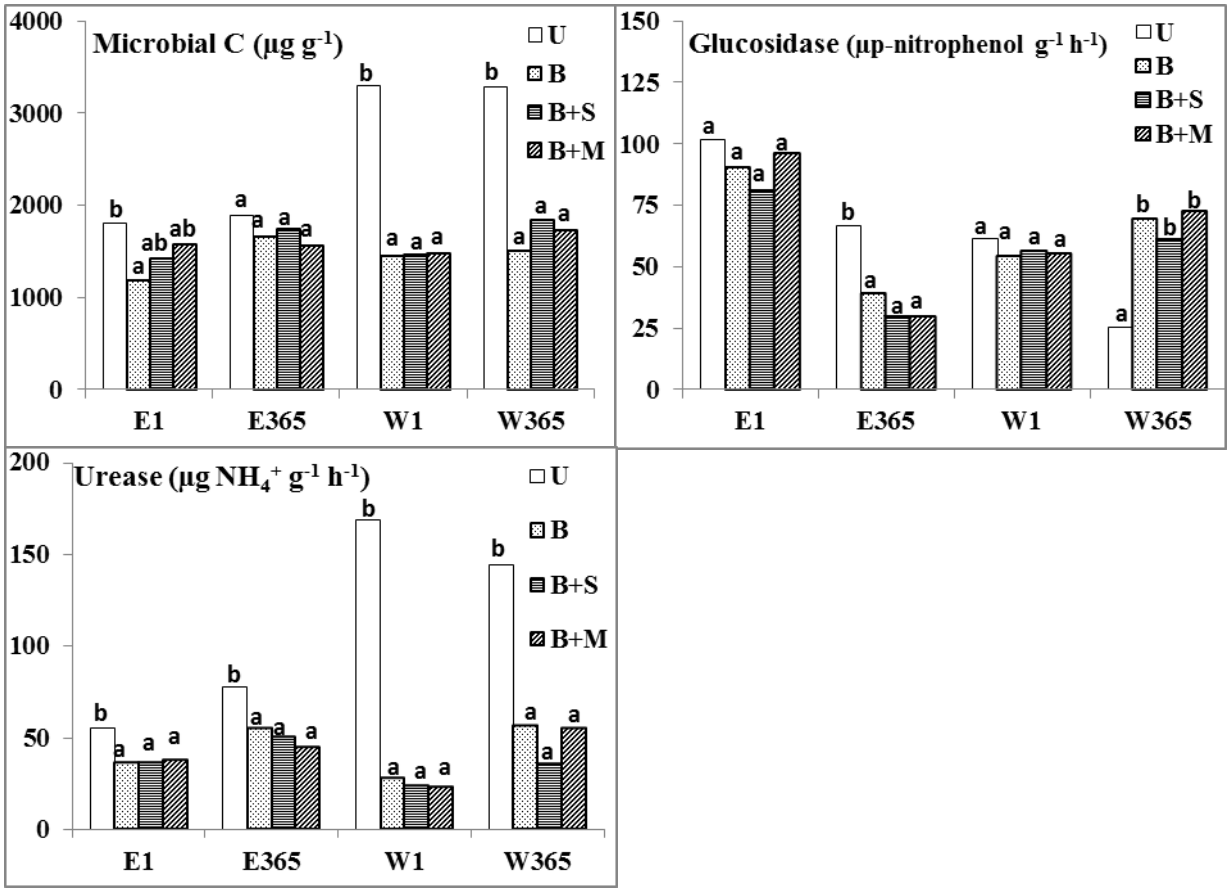

Figure 6. Soil biochemical properties in the different soil treatments 1 day and 365 days after the experimental fire (E) or the wildfire (W) (mean values of 3-4 replicates). Treatments: U, unburnt soil; B, burnt soil; B+S, burnt soil plus seeding; B+M, burnt soil plus straw addition. For the same soil and sampling time different letters denote significant differences ($p<0.05$) among treatments.

With regard to the experimental fire, a positive fire influence on pH and a negative effect on the glucosidase and the urease activities were still maintained after 365 days.

The comparison of the values obtained for the selected soil properties analyzed in the burnt plots under seeding and mulching treatments (B+S, B+M) 365 days after the fire with those of the corresponding untreated burnt soil (B) allowed us to determine the effect of these two post-fire stabilisation treatments on the soil quality. Likewise, the analysis of the sediments corresponding to the above treatments allowed us to determine their effectiveness on the control of soil erosion. The results clearly indicated that, independently of the fire event, there were no significant differences between the B+S and B+M treatments and the corresponding burnt control (B) for any of the soil properties studied, which showed that at least after one year these two stabilisation treatments did not modify the burnt soil quality (Figures 5 and 6).

In order to compare the soil quality in the unburnt and the burned samples collected in the two experimental areas, all physic-chemical, chemical and biochemical properties should be used together. Consequently, a Principal Component Analysis (PCA) was used to analyse the 11 soil properties of the whole data set of the samples analyzed (n = 16 samples) (Figure 7). The main two factors identified accounted for 68% of the variance. The factor 1, which accounted for 42% of the variance, is defined at its positive extreme by the pH, the electric conductivity, the inorganic N and the available P; and at its negative extreme by the microbial biomass C and the urease activity. The

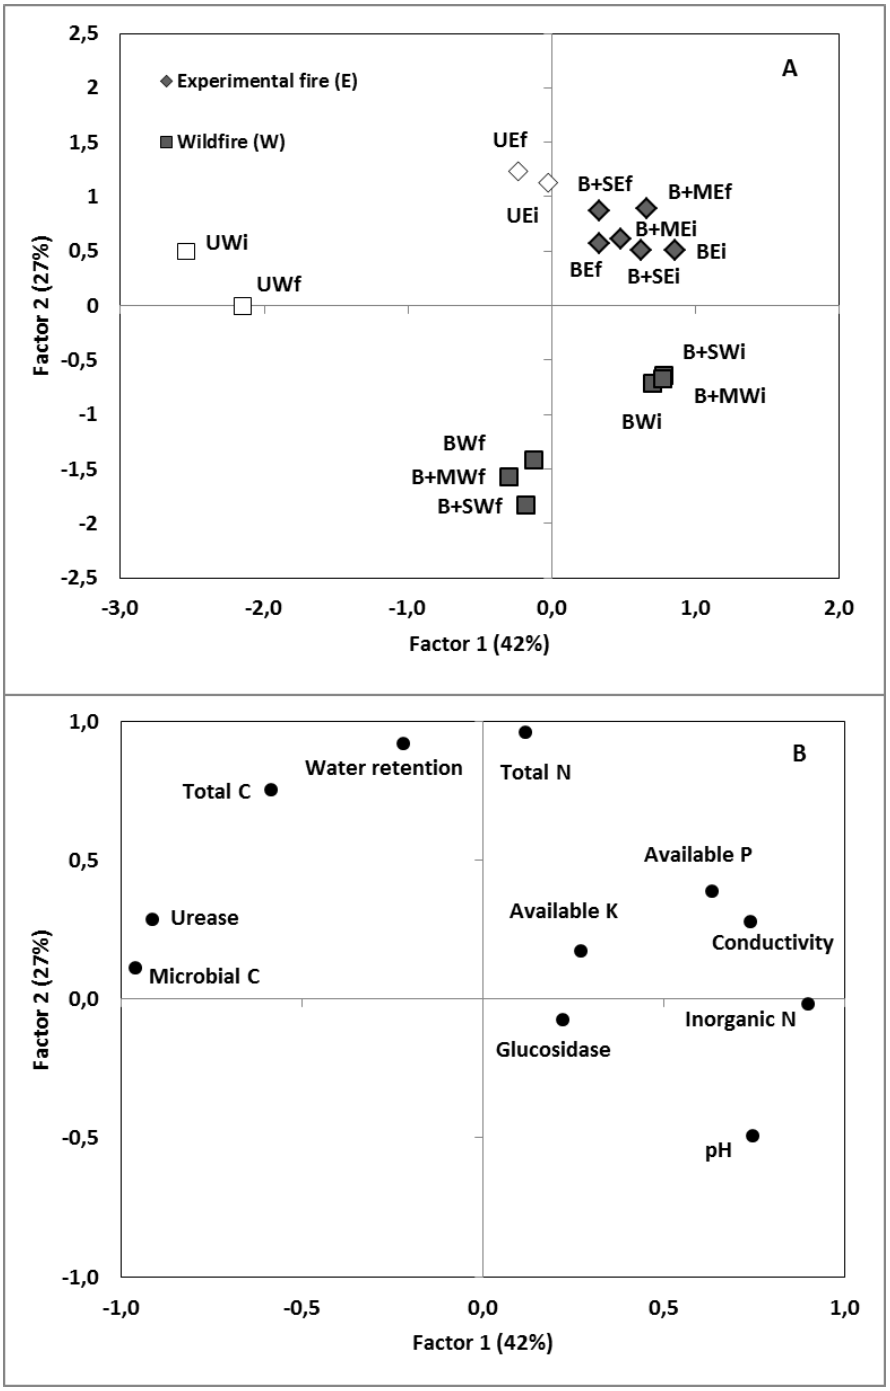

Figure 7. Score (A) and loading plots (B) from principal component analysis performed on the physical, chemical and biochemical properties of the studied soil treatments 1day (i) and 365 days (f) after the experimental fire (E) or the wildfire (W). Treatments: U, unburnt soil; B, burnt soil; B+S, burnt soil plus seeding; B+M, burnt soil plus straw addition.

factor 2, which accounted for 21% of the variance, is defined at its positive arm by variables related to the organic matter (total N, total C and water retention). The distribution of the samples in the plane defined by the Factors 1 and 2, make it possible to separate clearly the unburned samples of the soil affected by the wildfire from the corresponding burnt samples and even the burnt soil sample from the two treatments collected at different soil sampling time (1 day and 365 days); and, in a lesser extent, the burnt samples of the soil affected by the experimental fire from the corresponding unburnt control soil, suggesting that the factors 1 and 2 are related to the fire impact. The results showed that the fire

provoked a decrease in the microbial C, the urease activity and the organic matter content; and an increase in the available nutrients, electric conductivity and soil pH. These findings are consistent with the results obtained in previous studies performed in the same region (Carballas *et al.* 2009; Martín *et al.* 2012). Likewise the data indicated that the effect of the wildfire on the soil quality was much more accentuated than that observed for the experimental fire (the unburned samples of the E soil were grouped closer to the corresponding samples from the burnt treatments, whereas the unburned samples of the W soil were clearly separate from the samples corresponding to the burnt treatments).

With regard to the soil stabilisation treatments effects, it should be noticed that, independently of the experimental area considered, the burned treatments of the same soil (B, B+S, B+M) are grouped together, indicating that the post-fire stabilisation treatments did not change at medium-term (1 year) the quality of the burnt control soil.

The total loss of soil in the soil affected by the experimental fire and the wildfire within 12 months, without and with two different post-fire stabilisation treatments, is showed in Figure 8. The values were 3,628 kg ha^{-1} in the burnt E soil and 1,206 kg ha^{-1} in the burnt W soil, with 60-80% of sediments production in the 2-5 months following the treatments application. The soil loss values obtained lied in the reported range given for burnt soils of the temperate humid zone (Vega *et al.* 2013); however, it should be noticed that the area affected by the wildfire (W soil) exhibited lower values than those observed in the area subjected to the experimental fire (E soil). This behaviour can be explained according to the rainfall amount and intensity that differed notably between the two experimental areas, the rain events and the erosive power being higher in the E soil than in the W soil. The results clearly indicated that important post-fire erosion processes can occur following a low severity fire and that the climate rather than the fire intensity can be more determinant for the production of sediments under specific environmental conditions such as those in the present study (N.W. of the Iberian Peninsula).

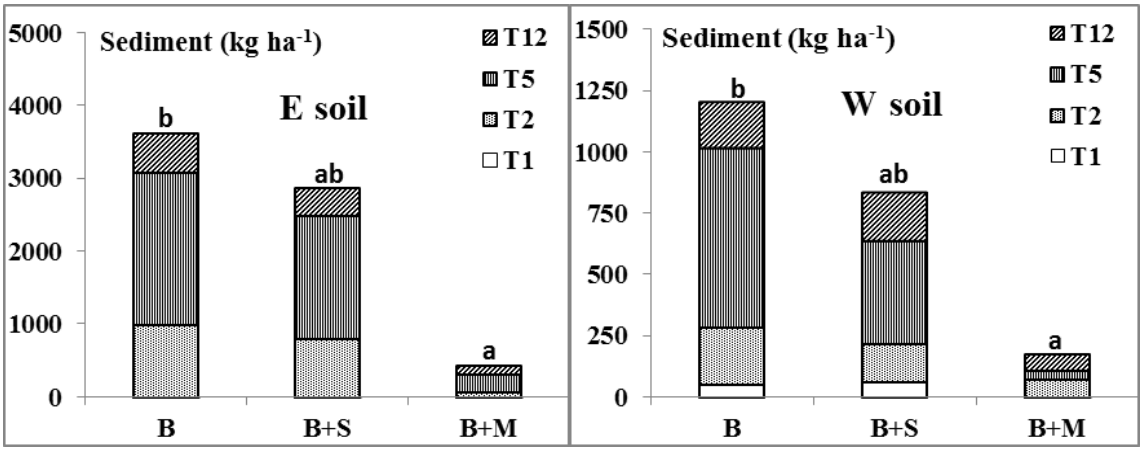

Figure 8. Accumulated sediment yield during the first 1, 2, 5 and 12 months following the experimental fire (E) or the wildfire (W) (11 variables, n = 16 samples). Treatments: U, unburnt soil; B, burnt soil; B+S, burnt soil plus seeding; B+M, burnt soil plus straw addition.

The soil losses accumulated during the study period from the plots with post-fire stabilisation treatments were much lower than those registered for the burnt control. The sediment yield data indicated that the mulching treatment was the most effective to control the post-fire erosion since compared to the control the soil losses were reduced by 75-95% in the four evaluation dates, whereas the seeding reduced the soil losses by 20-42%. At the end of the experiment the efficiency of the seeding was 21% in the E soil and 31% in the W soil, whereas the mulching reduced the erosion by 88% in the E soil and 85% in the W soil; therefore the mean efficiency of the treatments were similar independently of the fire severity. The efficiency values of these soil stabilisation treatments differed

notably from the values obtained in the NE of Spain (Badía and Martí 2000) but are in accordance with those observed in recent studies performed in the NW of the Iberian Peninsula (Prats *et al.* 2013; Vega *et al.* 2013).

Conclusions

The results showed that initially the wildfire induced important changes in most properties analyzed and that these effects persisted 12 months after the fire; in contrast, the experimental fire provoked slight changes in the physic-chemical and chemical properties but moderate changes in the biochemical and microbiological properties. They also indicated that both stabilisation treatments had no effects on the soil properties analyzed and then on the soil quality, but reduced significantly the sediments yield compared to the control burnt soil. The mean efficiency of the seeding and mulching treatments in preventing soil erosion was 30-40% and 70-90%, respectively, showing that, in the short- and medium-term (12 months), the straw mulching was the most effective treatment for reducing post-fire erosion in both burnt areas. Therefore, taking into account their effects on soil quality as well as their effectiveness, treatments such as seeding and mulching are recommended to control the post-fire erosion in this temperate humid region. However, since post-fire stabilisation techniques are expensive, the straw mulching rather than seeding should be implemented due to its lower cost/benefits ratio.

Abstract
ArcFUEL [1] is a LIFE+ Project that involves six European Partners with the objective of producing updated fuel maps to be used in forest fire management operations and geoplatforms. The ArcFUEL project delivers a complete, up-to-date, methodology for Fuel Classification Mapping (FCM on a Web-Geodatabase) based on "readily available" data, harmonized, accessible and interoperable according to INSPIRE principles, for the Mediterranean Region. This paper outlines the: (i) history of the Fuel Classification Maps (FCMs), (ii) the problem targeted in fuel mapping, (iv) the significance of FCMs for Forest Fire (FF) Management, (v) the ex-novo ArcFUEL methodology developed within the project, (vi) two case studies applied in Spain and Portugal, (vii) the field validation process and (viii) the final results derived from the project.

Keywords*: wildland, forest fire management, fuel maps, fuel types, LIFE, ArcFUEL, ESRI ArcGIS, QRASS GIS*

History

Fuel Classification Maps (FCMs) production started in the 90's when experts used the reclassification vegetation type's method to produce Fuel Maps from Forest & National Maps based on assumptions [2]. In the last decade established forest fuel catalogues (NFFL, Scott & Burgan, and PROMETHEUS) were used in several FCM projects in combination with Remote Sensing Techniques [3] [4] [5] [6] [7] [8]. A number of projects on fuel mapping for operational purposes have been accomplished in several European countries [9]. However, with some exception [10], these efforts concentrated at local or regional scale, and no maps at national scale are produced. Fuel type mapping was also approached at a pan-European within the FUELMAP Project [11]. This project derived a novel fuel classification adapted to European environments that enables a high level harmonization of the different fuel mapping initiatives. Yet, the JRC's fuel map was not meant for local scale applications.

ArcFUEL compiles information from past FCM efforts, utilizes ancillary data, and delivers a new era of FCMs, an ex-novo methodology and workflow.

The problem targeted

Effective Forest Fire (FF) Management requires knowledge of Fuel Classification Maps (FCMs) that are poorly available in Mediterranean countries since they are produced only at local or regional scale, without any regular updates and/or using standardized methodologies. Therefore available FCMs cannot support the systematic use of FF modelling at operational levels (prevention, suppression planning) of FF management.

Why FCMs for FF Management?

Forest vegetation is considered as a "fuel" and its structure and status govern the dynamics of a fire. This is the reason why Fuel Models and their spatial patterns (i.e. FCMs) are significant for FF Management Actions during all four phases of the FF lifecycle: 1 (Awareness phase - prior to the fire), 2 (Emergency phase - during the fire), 3 (Impacts phase - after the fire), 4 (Dissemination phase - lesson learnt). Moreover, fuel models are dynamic; either due to natural or anthropic causes (mostly because of the latter), the composition and loading of forest fuel changes and hence the need for up-to-date forest fuel information.

The ArcFUEL methodology

The ArcFUEL methodology consists of cascaded steps based on the use of multi-temporal LANDSAT [12] Thematic Mapper (TM) images for the distinction of fuel classes with different seasonal characteristics and further refinement based on ancillary data, such us burned areas, and canopy cover density data [13] derived from satellite observations. In more details, the ArcFUEL methodology is accomplished in 2 major blocks: (i) pre-processing of Landsat satellite imagery and (ii) forest fuel classes mapping.

The pre-processing of Landsat scenes involved:

1. Searching, selecting, ordering / downloading Landsat scenes (5TM or 7 ETM+ SLC-) of interest via the official sources (USGS' Landsat archive, GloVis and EarthExplorer web-services). The selection criteria are strict in the sense to get as much as possible cloud free acquisitions which, in addition, were timely as close as possible. All Landsat scenes in a geospatial database
2. Trimming scene border fringes
3. Converting Digital Numbers (DNs) to Top-of-Atmosphere Reflectances (ToAR) by normalizing either a statistical approach for most cloud-free scenes, or the 6S algorithm for scenes that were significantly cloud-contaminated (as per the cloud cover percentage estimation given in the metadata, as well as after visual control).
4. Detecting clouds and cloud shadows
5. Topographically correcting Imagery by using the Minnaert method (insert reference?) based on the ASTER GDEM2 dataset.
6. Relatively normalizing images (separate handling for each spectral band and season) to balance up seasonal radiometric variations based on the Histogram Matching technique.
7. Creating a large surface reflectance mosaic (for each band) for the whole study area.

The forest fuel classes map production comprised the following steps:

1. Extracting major vegetation classes from existing land data bases, i.e. (i) forested areas (Broadleaved, Coniferous and Mixed) from JRC's Forest Type Map (2006), (ii) surface fuels from JRC's Forest Fuel Type Map (2006), (iii) ground and azonic fuels (and non-fuels) as the remaining areas from the Corine Land Cover 2000/6.
2. Separating deciduous and evergreen vegetation (and, similarly, grasses and shrubs) is done via a bi-temporal classification approach, i.e. clustering and classifying the seasonal vegetation index difference inside the two main vegetation categories (forest and surface fuels) [14] [15]. Clustering is performed by implementing a modification of the K-Means algorithm.
3. Sub-classifying the above vegetation classes based on forest density criteria [16]. This is done by using JRC's up-to-date Tree Cover Map.
4. Filtering spatially and temporally relevant burned areas extracted from JRC's [17] Burnt Area Perimeters data base [18].

5. Additionally, sub-classifying the fuel type classes can be achieved by incorporating JRC's Environmental Zones [19] (Eco-Regions) classification.

Figure 1 below presents the whole ArcFUEL methodology.

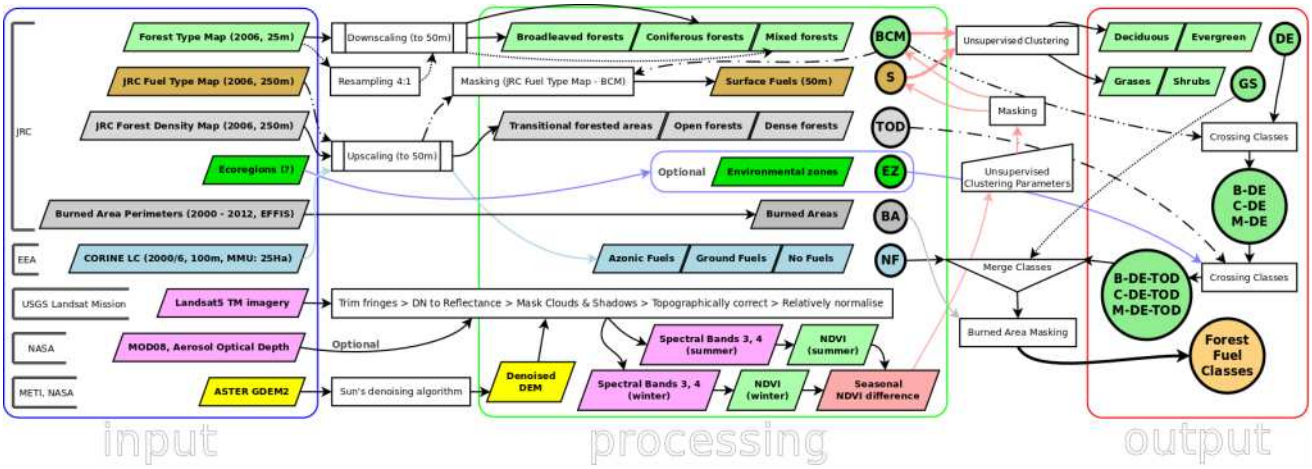

Figure 1. ArcFUEL methodology

Case Study

Two case studies are presented, one in Portugal and the second in Spain. In both cases the study consisted on two phases, a prior testing of the methodology in a smaller pilot area, and the implementation of the refined methodology over a larger area of interest.

Phase I: The pilot area chosen was located in Central Portugal in the area of the Lousã Mountains, part of the NATURA 2000 Network (Figure 2). The most representative species of forest stands and shrublands for Portugal occur in this region. It is an area of 10000 ha delimited by the coordinates 40º7'N – 40º13'N and 8º15'W – 8º7'W, and with altitudes ranging 80-700m. The region, falls inside the "Lusitanian" Ecorregion.

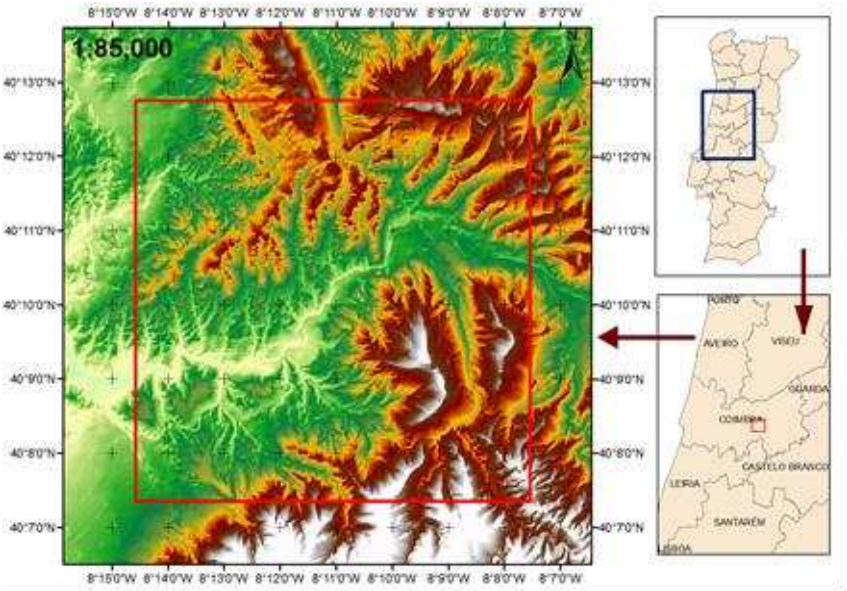

Figure 2. Portuguese pilot area (red box) (Phase I)

The application of the methodology in this first phase produced the map shown inFigure 3. It was proven to be an easy to use procedure although some fine tunings had to be done, particularly regarding the definition of the density parameter. A couple of methodologies were tested and it was finally decided to use the density cover map produced by JRC [20] and freely available.

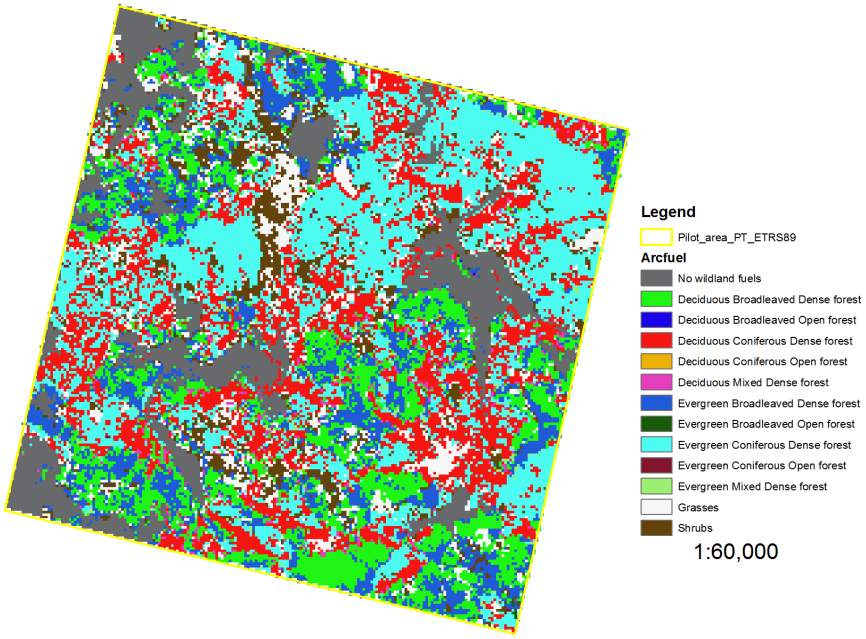

Figure 3. Phase I PT Pilot Area fuel map (reprojected to ETRS 89))

Phase II: After tuning the methodology the ArcFUEL fuelmap was produced for the entire Portuguese (islands excluded). The work was performed with the GIS tools ArcMap 10.1 [21] and Grass GIS 7.0 [22]. The workflow consisted of the following general steps of the production chain:

- Mapping of the main ArcFUEL vegetation classes
- Multi-temporal analysis
- Refinement of the produced fuel classes based on density cover
- Merge of all the produced map layers in a single one
- Combination of the fuel classes with Ecoregions data

A crucial part of the methodology application was the selection of good clear Landsat images. For Portugal we had to go back to 2007 and use Landsat 5 images as they were the only acceptable ones covering the entire country. The new Landsat 8 should provide new up to date images that will allow us to update the maps. All areas burned in 2007 were masked from the final map (Figure 4).

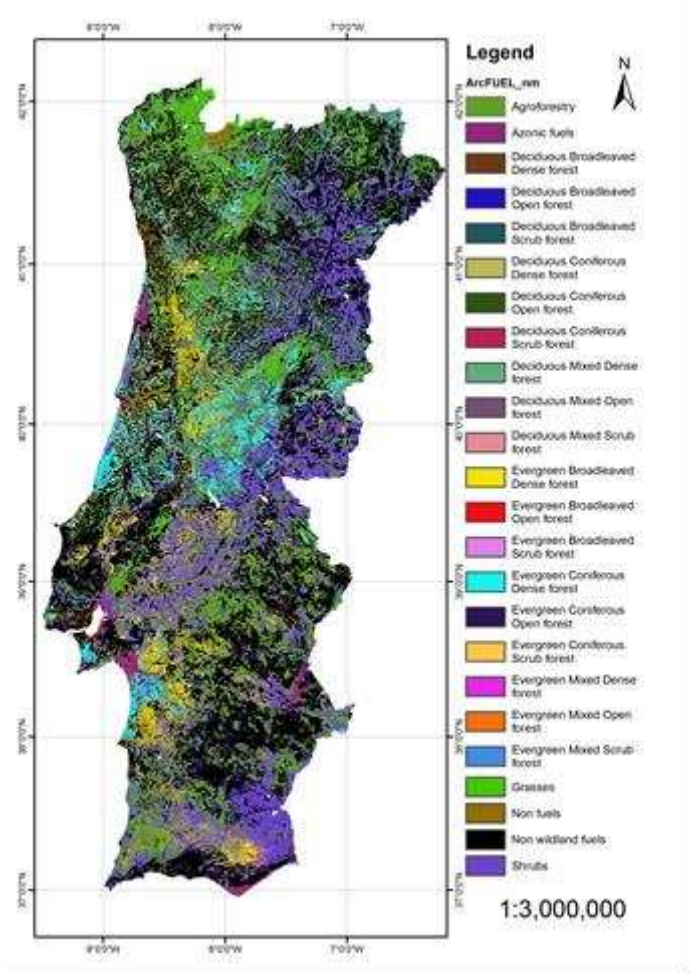

Figure 4. Final ArcFUEL map for Portugal mainland

The accuracy assessment of the produced map is currently being performed. A predefined number of control points is being directly checked in the field in order to check for the map consistency and reliability. At the moment, and after slightly more than 2/3 of the field campaign finished, the matching between the produced map and the reality can be considered visually satisfactory. Further statistical analysis will allow us to define a more reliable accuracy percentage.

5.1. Case study in Spain

The pilot area chose for Phase I was the Sierra de Las Nieves Natural Park, located west of Málaga province (Andalucía region), inside a Biosphere Reserve of the same name, showing very high terrestrial biodiversity. The area covers 20.163 ha and shows a high elevation gradient, raging in few km, from near the sea level to circa 2000 m (highest elevation peak at 1.919 m).

The area of interest (AOI) selected for Phase II in Spain was made up by the provinces of Málaga and Córdoba (north of Málaga), both in Andalucía region.

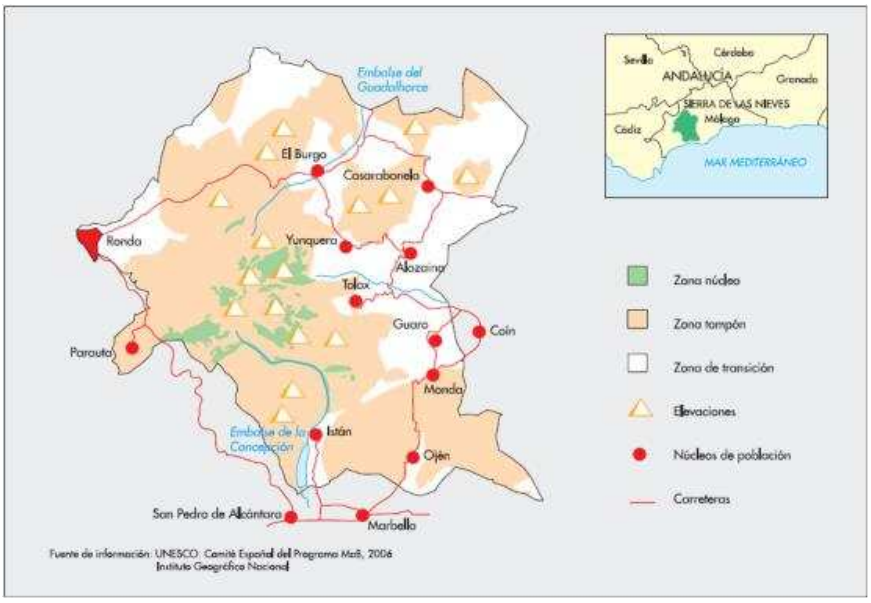

Figure 5. Biosphere Reserve of Sierra de las Nieves (Phase I)

Six Landsat 5TM images were used to cover the entire area in spring-summer, and another six to cover it in winter. Images date from year 2009, 2010 and 2011.

Erro! A origem da referência não foi encontrada. below shows the ArcFUEL fuel types derived over the entire area of study in Spain. The map shows a clear predominance of a few classes: Broadleaved Evergreen Scrub (18%), Broadleaved Evergreen Dense (32%), Coniferous Evergreen Dense (21%) and above all, Shrubs (42%). The non-wildland fuels represent a 17% of the study area. To assess these results a two-step validation was performed:

Validation step 1 (over pilot area)**:** focused on the discrimination between deciduous and evergreen species. This was done using the National Forest Inventory (NFI3) field plots, distributed in a regular 1-km grid.

Crossing the ground- truth with the classification values at each of the 163 IFN3 plots falling within the "Deciduous"/ "Evergreen" classes of the pilot area yielded very satisfactory results (95,6% overall accuracy), particularely in what concerns Evergreen forests. Conversely the discrimination of Decidous trees in the classification was not always correct (33% commission error). The impact of this is not relevant since the percentage of the area covered by Deciduos vegetation was less than1,6%. A similar procedure was followed to assess the discrimination of Shrubs and Grasses, and comparable results were obtained: (86,7% overall accuracy).

Validation step 2 (over Málaga and Córdoba): focused on the discrimination of vegetation assemblages, a concept closer to the term "fuel type" (e.g.: dense pine plantation with high shrubs, or abandoned olive trees plantation with grasses and dispersed shrubs).

For this purpose two ancillary sources having information on vegetation assemblages were used as ground truth:

I. The LUCAS (Land Use / Cover Area Frame Statistical Survey) multipurpose (agriculture, environment) field survey, with more than 250.000 sample points throughout the EU. LUCAS 2009 campaign was downloaded from EUROSTAT Web site [23] (free access).

II. The Integrated product "SIOSE" [24] plus "Vegetation map of Andalucía" (scale 1:10.000), property of the Andalusian Government (free access).

By crossing the classification values with the validation sources (LUCAS and SIOSE) at the 171 valid LUCAS plots falling within the AOI, we deduced that 136 of them were correctly classified (80%) while 35 were not (20% error).
The analysis per fuel type class showed again particularly good results for the Shrubs (90%) and Coniferous Evergreen classes (96%). Whereas the plots falling in the Broadleaves Evergreen Dense, and specifically those in deciduous classes (incorrectly classified) were not enough in number to draw any conclusion.

It must be noted that several inconsistencies were observed between LUCAS and the Andalusian Land Use/Vegetation Map, on the one hand, and the EU layers defining the first levels of ArcFUEL classification on the other (CLC [25], the Forest Types Map). Nonetheless results yielded (80% of correctly classified plots) evidence a satisfactory performance.

Overall this work has been a rather intense exercise of assessment, as the classification was crossed with field data and local scale maps with information on vegetation assemblages in a significant number of points. Moreover, this exercise was difficult since the intervening ancillary datasets have different reference date (2005 and 2009), level of detail and legends. It is concluded that the difference in dates (Landsat scenes leading to the classification map dated 2009-2011) might be behind the poor results shown by the most dynamic classes: Grasses, on the one hand, and Deciduous species, on the other.

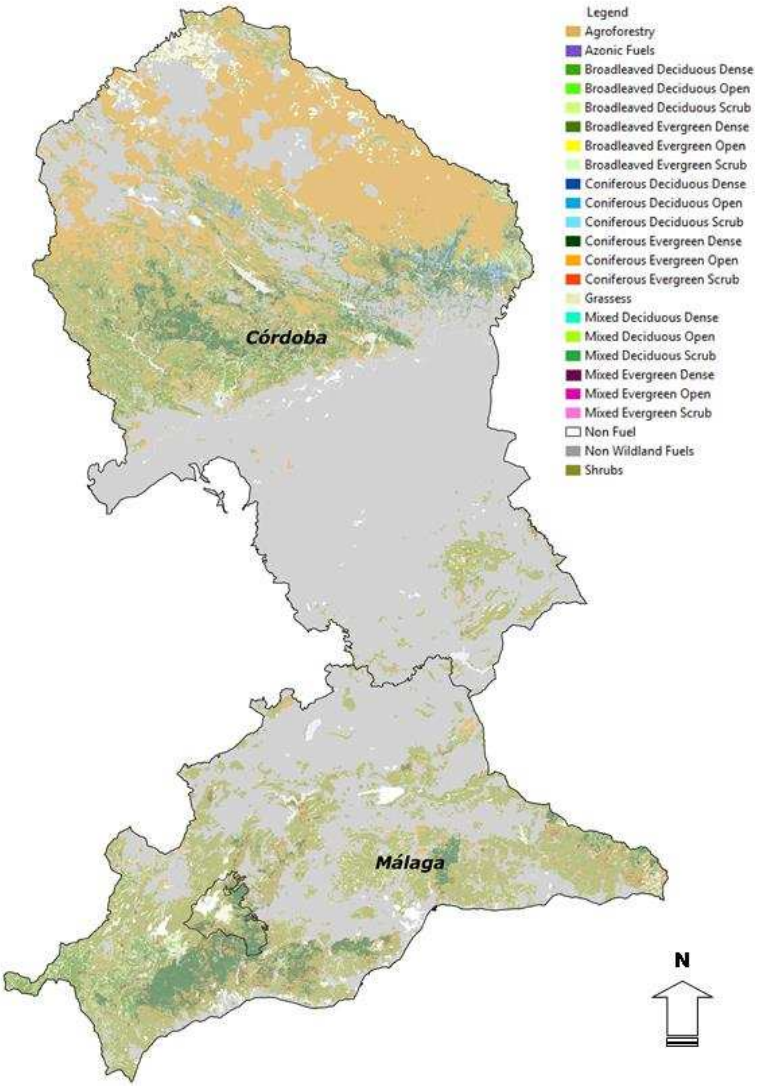

Figure 6. ArcFUEL fuel types over the study area in Spain (21.077 km2) and Pilot area (202 km2).

Field Validation

Purpose of the field validation is to create a dataset of point values for validating the ArcFUEL map. This comprises of the following steps:

1. We overlay LUCAS points to the ArcFUEL map and we separate LUCAS in two subsets of data, one with the LUCAS points which description coincide with ArcFUEL characterization and another with the LUCAS points which description differs from ArcFUEL. We keep the first subset as part of the ArcFUEL validation data set.
2. We use the second subset of point 1 and apply the following methodology per region:
    a. We select in each region randomly LUCAS points from the second subset and create the second part of ArcFUEL data set.
    b. We define a number of sampling points per region depending on its extent.
    c. We take care including all ArcFUEL types (AFT) in the data set derived.
    d. Sample points are located in a distance <300m from road and in slope <40%.
3. We randomly select 5% of the number of points defined in 2.b in elevation >1000m (LUCAS points are up to 1000m) taking into account the coverage of the ArcFUEL types.
4. During the field work:
    a. We fill the form with the data that we have defined (we have developed an android application for collecting these data).
    b. We allow taking as sample point a point close to the LUCAS point but representing better the forest fuel type in the specific location.
    c. We take additional sample points of representative fuel types along the way moving from one point to another.

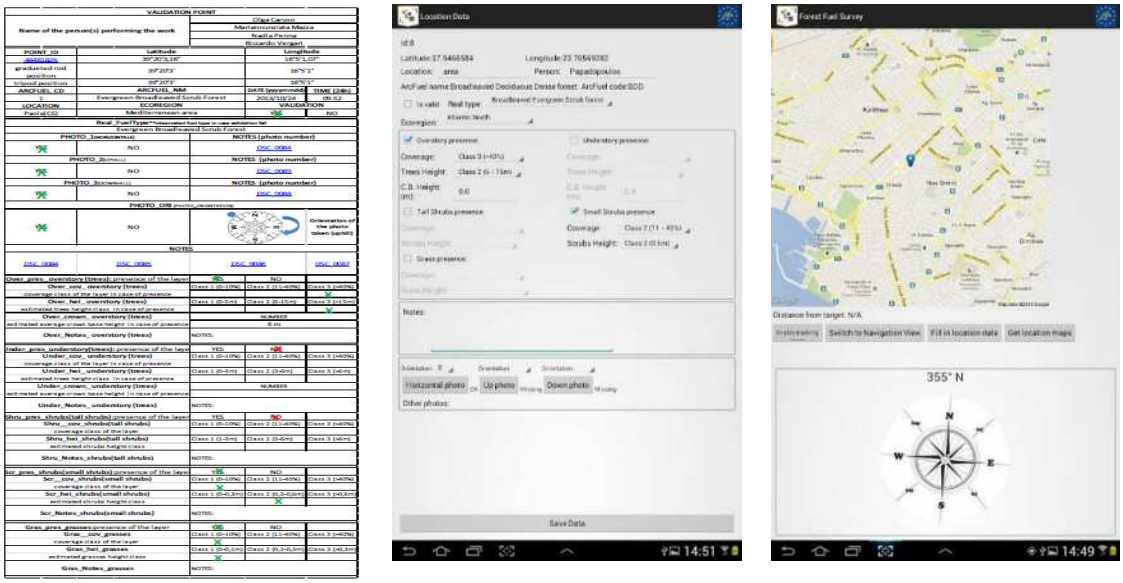

Figure 7. Field validation application, location data

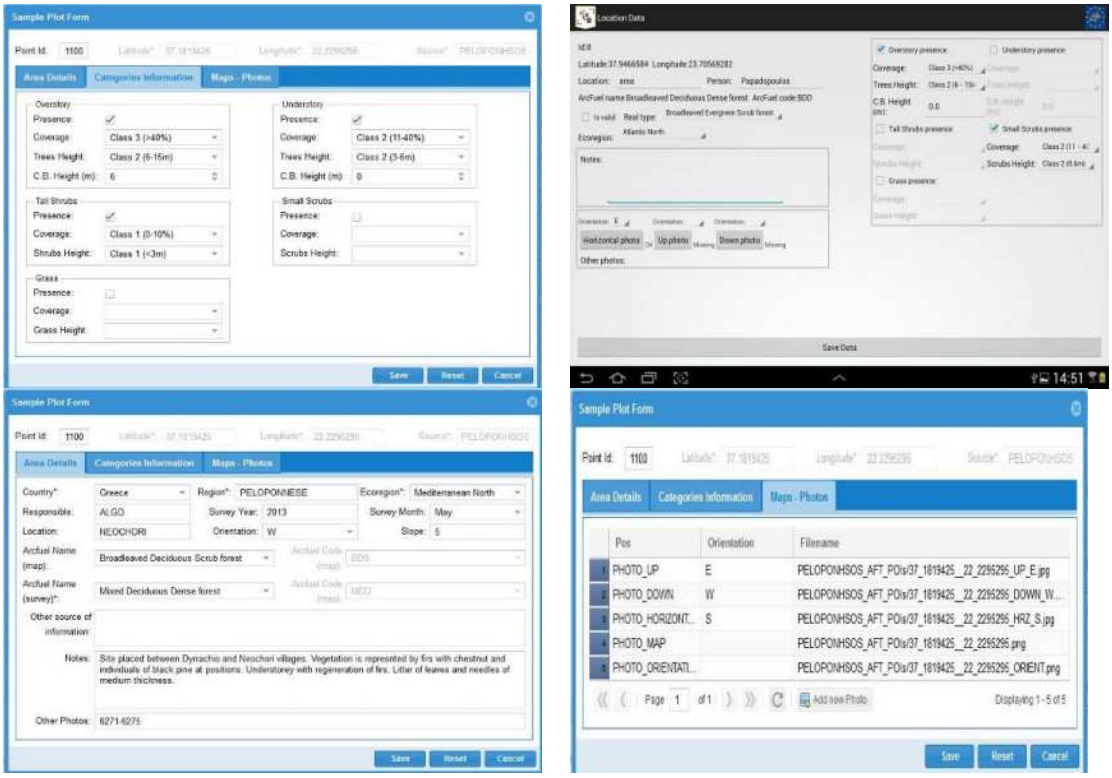

Figure 8. Field validation application, sample plots

5. We aggregate all data from the subsets mentioned above in point 2 (LUCAS=AFT), 3 (LUCAS≠AFT), 4 (>1000m) and 5 (additional AFT based points) for deriving the ArcFUEL validation data set.
6. In defining the above methodology we consider:
    a. We wanted to create a data set of point information for validating the accuracy and quality of the ArcFUEL map. Thus the main purpose was to create such a data set with distributed points, covering the area of interest and including all the fuel types present in each of the areas.
    b. We used LUCAS points in order to have information for a number of these points without new ArcFUEL survey but based on the new LUCAS survey data.
    c. We had to check deviation from LUCAS characterization in the field to see if and what the problem is.
    d. We had to enrich the ArcFUEL data set with additional points e.g. points at elevation greater than 1000m or points of representative fuel types.
    e. We considered 250 sample points to be distributed all over Greece and Portugal for the ArcFUEL map validation data set after the end of the field survey.

Fuel maps.

The LUCAS point dataset description was checked again to the ArcFUEL classification map to isolate points correctly classified. In addition to this overlay approach visual inspection using large scale orthophotographs of KTIMATOLOGIO SA [26] and Google Maps [27] was performed in order to identify any inconsistencies. A selective sample of these points is presented especially for randomly selected NATURA sites around project's areas.

Figure 9. Visual inspection to identify inconsistencies

8. Conclusions

The ArcFUEL methodology was tested and demonstrated producing forest fuel maps for Greece and Portugal at national scale and Italy and Spain at regional scale. The quality of the mapping was validated against field data.

During the field survey the ArcFUEL Consortium visited a total of 670 points in 4 countries, namely Greece, Portugal, Italy and Spain. The accuracy of the ArcFUEL methodology proved quite good, as it reached 73,2%. In detail, number of points visited during the field survey and accuracy of the ArcFUEL methodology in each country was:

- Greece: 298 points (81%)
- Portugal: 275 points (67%)
- Italy: 41 points (76%)
- Spain: 56 points (60%)

ArcFUEL delivered forest fuel maps with spatial resolution of 50x50m for Greece and Portugal at the country level and fuel maps of selected regions in Italy (Calabria and Sardinia) and Spain (Malaga, Cordoba).

ArcFUEL methodology proved to be a comprehensive method for rapid classification of forest vegetation into fuel types, delivering relevant input layers for fire modeling at an appropriate spatial resolution, using freely available data. Any future update of the input maps used in the ArcFUEL project will strongly improve the accuracy of the forest fuel maps. Synchronizing further the time reference of the input layers in the FCM production shall greatly improve the quality and accuracy of the ArcFUEL products.

The final fuel maps for Greece, Portugal, Italy and Spain are presented below:

Abstract
Wildfires are one of the most widespread factors of ecosystem degradation around the world. The present note reports the first experimental results of a wider-scale research project, whose aim is to develop methods for the analysis and the collection of field data, by means of a multidisciplinary approach, to evaluate land erosion hazard.
The experimental area is located in Mediterranean basin, on a steep slope in a hilly area of north-western Sardinia (Municipality of Ittiri, Italy), where a human caused fire occurred in August 2013. The area is mainly covered by the typical Mediterranean vegetation. The forest fire spread through the study area in August 2013 and the burn severity has been moderate, according to USDA burn severity classification system. After the fire, sediment fences were installed to trap sediments eroded by natural rainfall. Precipitations were recorded using tipping bucket rain gauge installed at the site.
Soil erosion rates from experimental plots were measured and estimated with silt fences technique taking into account different slopes and vegetation distribution. The study aims to compare the results obtained by ERMIT (Erosion Risk Management Tool) model application and post-fire sediment yields measured in the study area.
The application of the model shows that the area experienced most of erosion after the first rain events after fire occurring. Comparing experimental and model estimated data, there is evidence of ERMiT model overestimating in respect of sampled data for the first year. Future experimental data are needed to confirm this assumption and to contribute to calibrate ERMiT in a Mediterranean typical vegetation and climate environment.

Keywords*: erosion risk, ERMIT, burned area, forest fire effects*

Introduction

Several authors suggest that in the early months following the passage of a fire, the soil erosion increases dramatically (DeBano *et al*., 1998; Campo *et al*., 2006), even if gaps and further investigation in this field can be easily outlined and recommended (Shakesby, 2011). High soil temperatures can increase the erodibility of the soil surface, giving an indication of the susceptibility of the soil to the impact of raindrops, to runoff, and other erosive processes (Moody and Martin 2009, Scott *et al*., 2009). In extreme situations, burned areas of unstructured soils may be interested by processes of waterproofing and soils becoming hydrophobic (Imeson *et al*., 1992). Available sediment can be eroded from slopes and channels, transported and deposited downward in the valley driven by erosion energetic inputs: precipitation, runoff, wind, and gravity. The loss of vegetation and forestry sediments increase surface runoff in sloppy areas because longer flow paths are formed without interruption, without surface roughness, and because the wind speed increase. These changes increase the amount of energy available for erosion and sediment transport (Moody and Martin 2009a). The effects of fire on hydrology can be mitigated by the presence of ash: forest fires can leave a dry, porous layer of ash that covers the mineral soil (Cerdà and Robichaud, 2009).
The increase of landslide phenomena in slope areas crossed by forest fires, is well documented in the scientific literature (Curran *et al*. 2006; DeBano *et al*. 1998; Lane *et al*. 2006; Moody *et al*. 2009;

Neary *et al*. 2005). In general, the hydrological response at the catchment scale is inversely correlated to the effectiveness of the after fires treatment (Robichaud *et al*. 2008).
ERMiT is a web-based application developed by USDA (Robichaud, 2007a) that uses Water Erosion Prediction Project (WEPP) technology to estimate soil erosion, in probabilistic terms, on burned lands with and without the application of erosion mitigation treatments. Data inputs are: climate parameters, vegetation type, soil type, topography, and soil burn severity class. The above parameters were applied to the ERMIT model and it was possible to predict the probably erosion risk for the next 5 years.
The objective of this work is to show preliminary results of erosion sediments yield in a hilly burned area of north-western Sardinia (Italy) and the correspondent output data from the application of ERMiT model.

Methods

Study site and data collection

The experimental area is located in a hilly area of north-western Sardinia, (around urban area of Sassari, Italy, 40° 33'N; 8° 31'E), where a human caused fire occurred in August 2013 and burned an area of 28 hectares (Figure 1). The area is mainly covered by typical Mediterranean chaparral vegetation.
The climate is typically Mediterranean with water deficit conditions occurring from May through September and precipitations mainly concentrated in autumn and winter.
The mean annual rainfall is 730 mm and annual mean air temperature is 16.8 °C. Most fires occur during the summer season, from June to September.

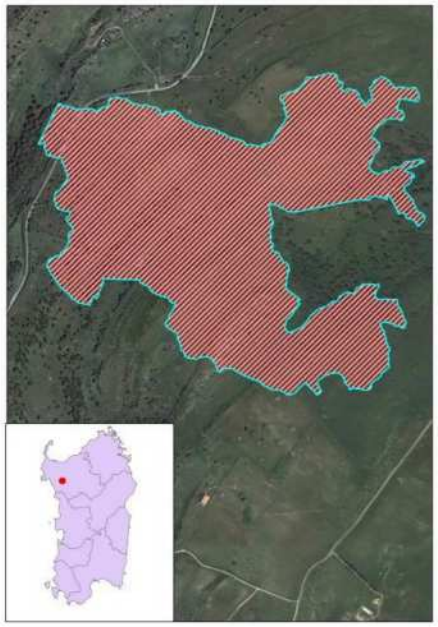

Figure 1. Study area and perimeter of burned area

In August 2014, sediment fences were installed in 10 plots in an area with a slope of 20% to capture sediment produced by natural rainfall (Robichaud and Brown, 2002).

ERMIT model

ERMiT (Erosion Risk Management Tool) is a web-based application that uses Water Erosion Prediction Project (WEPP) technology to estimate erosion in probabilistic terms, on burned and recovering forest, range, and chaparral lands with and without the application of erosion mitigation treatments. User inputs are processed by ERMiT to combine rain event variability with spatial and

temporal variabilities of soil burn severity and soil properties, which are then used as WEPP input parameters. ERMiT produces a distribution of rain event sediment delivery rates with a probability of occurrence for each of five post-fire years. In addition, event sediment delivery rate distributions are generated for post-fire hillslopes that have been treated with seeding, straw mulch, and erosion barriers such as contour-felled logs or straw wattles. In this work for every simulation has been considered only the results of the untreated hillslope.
User inputs for ERMiT are climate, soil texture, soil rock content, vegetation type (forest, range, chaparral), hillslope gradient and horizontal length, soil burn severity class for range and chaparral, and pre-fire plant community description (relative distribution of shrub, grass, and soil cover in percentages). User inputs are entered on a single interactive browser screen. ERMiT's "event sediment delivery exceedance probability" output can help managers to decide where, when, and how to apply treatments to mitigate the impacts of post-wildfire runoff and erosion on life, property, and natural resources. With ERMiT, managers can establish a maximum acceptable event sediment yield and use ERMiT to determine the probability of "higher than acceptable" sediment yields occurring (Robichaud, 2007b).
Simulations were carried out for the burned area taking into consideration the same input parameters for all the runs. The only change was made for the vegetation values immediately and 6 months after fire occurring. Successive validation of ERMiT was completed with field data.
Hill slope burned area was divided in 10 plots (10 m x 3 m) limited in the downhill edge by silt fences in order to contain eroded soil and debris of each specific plot. Silt fences used in this study are easy to be installed and costless (Robichaud and Brown, 2002), being made of wooden posts and geotextile fabric (figure 2). Eroded material is collected, weighted and analysed possibly soon after the major rain events.

Figure 2. Example of sample plot and sediment trapped in the silt fence

2.2.1. *Climate parameters*

Climatic data for ERMiT simulations referred to the closest weather station of Hydrological Department of Sardinia. Temperature and precipitation data series for the period 1988-2002 were considered. In ERMiT simulation runs, the monthly means of rainfall and the number of rainy days for each month of the year are considered. Mean, maximum and minimum temperature values were also input data for modeling.

2.2.2. *Vegetation*

Prevailing surrounding vegetation is Mediterranean chaparral in garrigue association, while as the areas where fire occurred is dominated by oak tree (*Quercus suber* spp.) forest. Ground cover ocular estimation (percentage of herbaceous, bare soil and stoniness surface) were made using a 1 m^2 point frame with wire intersections at 10 cm intervals (figure 3) with 3 repetitions per plot.

Vegetation cover measurements were made both soon after fire occurring in late August 2013 and in early days of May 2014, so after about 8 months. In this way different recovering attitudes and characteristics of the plots inside the area were considered.

Figure 3. Vegetation cover measurement

2.2.3. *Type of soil*

Several soil samples were collected at 0-10 cm depth, in burned plots. Analysis were performed in collaboration with the Geotechnical laboratory of Cagliari Province. Two trials of texture repetitions were conducted considering both sieving (for 0.075÷100 mm grains) and sedimentation (0.0055÷0.1117 mm grains). Results are shown in table 1. Soil is therefore constituted mostly by sand and clay.

Table 1. Basic statistics for each soil property

	pH	N g Kg^{-1}	% OC	P_2O_5 ppm	Silt %	Clay %	Sand %	2 mm %	1 mm %	0,5 mm %	0,2 mm %
mean	6,36	3,68	3,70	12,86	26,13	26,61	47,26	31,76	2,21	1,41	3,30
st. dev.	0,11	1,23	0,21	1,87	4,61	7,18	3,40	9,78	0,79	0,56	0,88

2.2.4. *Slope*

Slope was measured in the field using a digital level instrument (Stabila 86 Electronics). Several measures were made for each plot and the average slope was considered (20% in this case).

2.2.5. *Soil burn severity*

Burn severity was estimated applying USDA methodology as reported in the "Field guide for mapping soil burn severity" (Parsons *et al.*, 2010). Ocular estimation of fire severity and damages caused by burning and the comparison with clear pictures of similar situations allows to have a fast, reasonably precise classification of burn severity. The severity of the fire was considered "moderate" based on post fire analysis and vegetation recovering capacity, together with vegetation damages and limited infiltration rates of topsoil.

3. Results

Figure 4 shows the daily cumulative, maximum intensity 30 minute rainfall (I_{30} max) and the sample dates. The total precipitation recorded in the period September 2013 - April 2014 (653 mm) is about 90% of the mean annual rainfall. Four periods of sediment accumulation were carried out during the

experimentation, and sediments were removed from the silt fence on 10 September 2013, 29 January, 19 March, and 10 April 2014. These dates are reported in the figure 4 in black (sample).

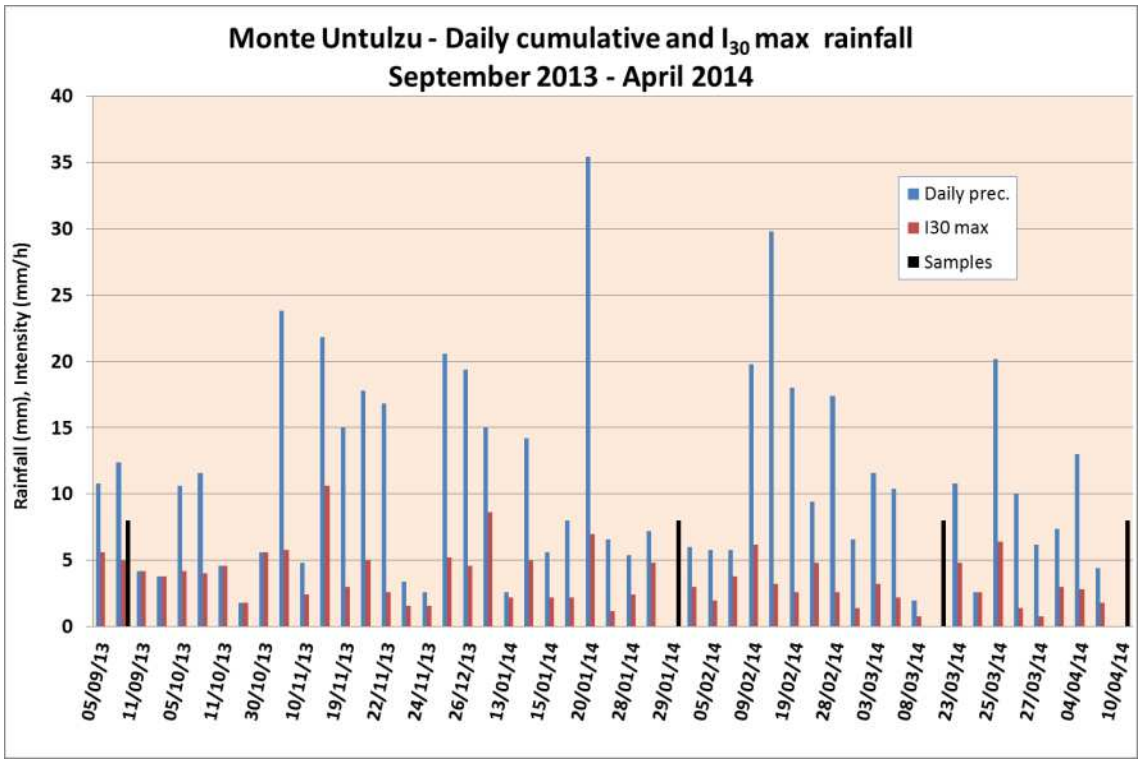

Figure 4. Daily cumulative rainfall and $I_{30\ max}$

Mean values of measured soil loss for each sample of plots with slope of 20% are reported in figure 5. The highest erosion was observed in the first sample (1.6 t ha^{-1}), whereas, in the last sample, event erosion rate was very low, only 0.02 t ha^{-1}.

Total soil erosion loss recorded during this study was 2.8 t ha^{-1}. Vacca *et al*. (2000) had much lower results in erosion plots under burned chaparral in southern Sardinia (0.51 – 0.26 t ha^{-1}); even lower sediment values (0.014 t ha^{-1}) were recorded in Bonassai, northwestern of Sardinia, on burned pasture (Rivoira *et al*., 1989) this low values are probably due to the low severity of fire.

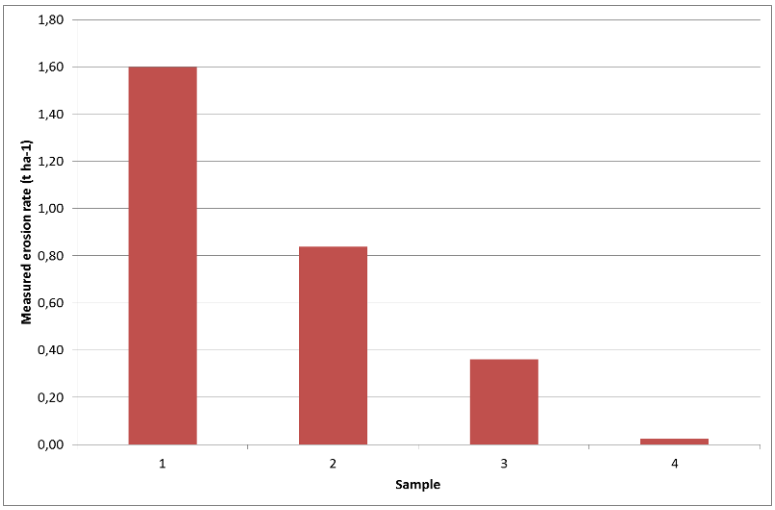

Figure 5. Mean values of measured soil loss (t ha^{-1})

The results of ERMiT simulations are shown in figures 6 and 7. Only untreated estimates were considered with different probability that sediment yield will exceed a certain threshold. Soil losses estimated by ERMiT for the first year are 3.23 and 3.13 t ha^{-1}, soon after fire and six months after fire, respectively.
Model results compared with the field measurements show how ERMIT model tends to overestimate erosion rates in typical Mediterranean vegetation and soil conditions. These preliminary results need to be confirmed by further investigation in coming years and also in different sites with similar vegetation, slope and soil conditions, given a defined fire severity and precipitation patterns.

Sediment Delivery					
Probability that sediment yield will be exceeded 20 % go	Event sediment delivery (t ha^{-1})				
	Year following fire				
	1st year	2nd year	3rd year	4th year	5th year
Untreated	3.23	1.66	0.7	0.6	0.5

Abstract
The aim of this study was to map the burned areas of the Selva El Ocote Biosphere Reserve for the period 1998–2012, using Landsat TM/ETM+ images. The method was based on a visual comparison of false color images and the pre/post-fire spectral indices Normalized Burn Ratio (NBR) and Normalized Difference Vegetation Index (NDVI); it used official records of wildfires from the National Commission for Natural Protected Areas and National Forestry Commission, and hotspots identified by the National Commission for Knowledge and Use of Biodiversity and the Fire Information for Resource Management System. Landsat images were downloaded during the fire season, January–June, for each year. According to the results, 54,756 ha were affected by 1095 fires during 1998–2012. We estimated that 352 of them involved tropical forest and 743 pasture, savannah and secondary tropical forest. The catastrophic years were associated with El Niño events 1998 (42,240 ha), 2003 (1,643 ha) and 2005 (1,248 ha), suggesting that the meteorological conditions contributed to the vulnerability of vegetation to fire. These results illustrate a method for analysing the pattern of spatial and temporal distribution of burned areas and for identifying zones that merit priority attention with regard to agricultural burning and wildfires.

Keywords*: burned area, Landsat, NBR, NDVI*

Introduction

Each year, Natural Protected Areas in Mexico are affected by wildfires of varying frequency, intensity and extent (Ressl *et al*., 2009). The factors influencing the occurrence of forest fires are physical (topography and climate), biological (community structure and functioning) and anthropogenic (often caused by the cultural use of fire, tourism and transport). In recent decades, the combination of climatic anomalies such as hurricanes, followed by long dry periods associated with the El Niño Southern Oscillation (ENSO) phenomenon (particularly during 1998, 2003 and 2005) has produced much organic combustible material and large forest fires. In southeastern Mexico all these factors converge to favour extensive burned areas in tropical rainforest (Román-Cuesta *et al*., 2003). To counter this, a global integrated fire management programme was developed for protected areas. The Selva El Ocote Biosphere Reserve in Chiapas State was the first to adopt and adapt this programme, including prevention, suppression, fire use and registration of all annual records of wildfires (CONANP & TNC, 2009). However, this programme does not have maps of burned areas.
For more than two decades, remote sensing techniques and satellite imagery have been used in various regions of the word to identify burned areas, using principles based on the spectral response of the deposits of ash and charcoal left after combustion of plant material. The spectral behaviour of burned areas is characterised by an increase in the reflectance of wavelengths in the visible region (0.4–0.7 µm), a decrease in the near-infrared region (0.78–0.90 µm), and an increase again in the mid-infrared region (1.3–8.0 µm) and thermal region (8.0–14.0 µm). These changes are related to the interruption of photosynthetic activity, changes in the internal structure of leaves and loss of water (Pereira *et al*.,

1999). Although scars may persist, burned areas may be remove by wind and rain a few weeks or months after the fire. Burn scars are more evident when trees or shrubs have been eliminated: whereas the effect remains for two to three weeks in pasture it can persist for several years in temperate forest (Robinson, 1991; Pereira *et al.*, 1999).

The discrimination of burned areas is based on the use of vegetation indices such as NDVI (Normalized Difference Vegetation Index), false color images, supervised classification and principal components (Roy *et al.*, 2005a; Chuvieco *et al.*, 2005); however, Normalized Burn Ratio (NBR) and Burned Area Index (BAI) are a better alternative because they use near infrared and short-wave infrared bands, which are more sensitive to the presence of charcoal and ash on the soil (Pereira *et al.*, 1999; Cocke *et al.*, 2005). This process includes a visual analysis of multitemporal images or automated detection using algorithms; both need to consider the wide diversity caused by severity of the fire and the time elapsed since the fire was extinguished, and vegetation type (Bastarrika *et al.*, 2011).

Several products based primarily on data with coarse spatial resolution can be used to survey burned areas at the global level. For example, the project Global Burnt Area (GBA) 2000, with 1 km spatial resolution, was developed during 2000 with SPOT-VEGETATION data, later named L3JRC, and generated results until 2007 (Tansey *et al.*, 2007). Also, the official product for burned areas MCD45, from Moderate Resolution Imaging Spectroradiometer (MODIS) images, with 500 m spatial resolution, has provided monthly reports from 2000 to the present (Roy *et al.*, 2005b). Similarly, some regional studies have been developed, such as in Latin America (Chuvieco *et al.*, 2006). All information has been limited to large fires (> 250 ha). Nevertheless, local-level studies require high spatial resolution images such as Landsat Thematic Mapper (TM), Enhanced Thematic Mapper (ETM+) or SPOT (Bastarrika *et al.*, 2011; Polychronaki & Gitas, 2012).

The Landsat near-infrared and middle-infrared bands provide stronger burned area discrimination than the visible bands and are less sensitive to smoke aerosol. The burned areas have low reflectance in all these bands, and so appear dark. The spatial and spectral appearances of the burned area vary within and between the two dates (Roy *et al.*, 2005a).

The aim of this study was to map burned areas in the Selva El Ocote Biosphere Reserve, Chiapas, for the period 1998–2012, using visual analysis of multitemporal Landsat TM/ETM+ images, in order to contribute to the spatial and temporal analyses of these events and identify priority areas regarding fire risk.

Methods

2.1. Study area

The study area is in southeastern Mexico, in western Chiapas State, south of the Nezahualcoyotl dam (16° 45’42” to 17° 09’00” N, and 93° 54’19” to 93° 21’20” W). At the end of 2000, the Selva El Ocote Biosphere Reserve, was established; it consists of 101,288 ha divided into two core zones with a total area of 40,432 ha and a buffer zone of 60,856 ha (Diario Oficial de la Federación, 2000) and its elevation ranges from 180 to 1500 m asl. It is a mountainous karstic region, with shafts, sinkholes and caverns. Warm and humid climates dominate, favouring the development of tropical rainforest, dry tropical forest and savannah, as well as pasture and agriculture lands.

Fire data and satellite images

The official fire records were provided by the National Commission for Natural Protected Areas (CONANP) and the National Forestry Commission in Chiapas State (CONAFOR). Also, hotspots (active fire) identified by the National Commission for Knowledge and Use of Biodiversity **(**CONABIO) and the Fire Information for Resource Management System (FIRMS) were downloaded (https://conabio.gob.mx; https://earthdata.nasa.gov/data/near-real-time-data/firms). The different data were visualised in layers and organised monthly with ArcMap software.

Fifty-nine Landsat TM/ETM+ images (Path/Row 22/48) for the period January – June from 1998 to 2012 were downloaded from the USGS Global Visualization Viewer (http://glovis.usgs.gov), Geotiff format, Level-1G, <43% cloud cover and georeferenced (Universal Transverse Mercator projection), with a ground spatial resolution of 30 m. Eight images were acquired out of the fire season to ensure cloud-free data for multitemporal comparisons.

The Land Cover maps produced by the National Institute of Statistics, Geography and Information Technology (INEGI) at scale 1:250000 were also available for the study area. This information was used to identify land cover classes affected by fire.

2.3. Discrimination of burned areas

Discrimination was based on a visual analysis of consecutive false color images Landsat images: bands 5(15.5–17.5 µm), 4(7.50–9.00 µm), 3(6.30–6.90 µm) and 7(20.90–23.50µm), 4(7.50–9.00 µm) 3(6.30–6.90 µm) displayed as red (R), green (G), and blue (B) respectively (Roy *et al.*, 2005a). Dark-red or purple areas (Figure 1) were considered to be potential burned areas that could be associated with charcoal and ash deposited after the combustion of plants (Pereira *et al.*, 1999). At the same time, the official fire records and hotspots were overlayed.

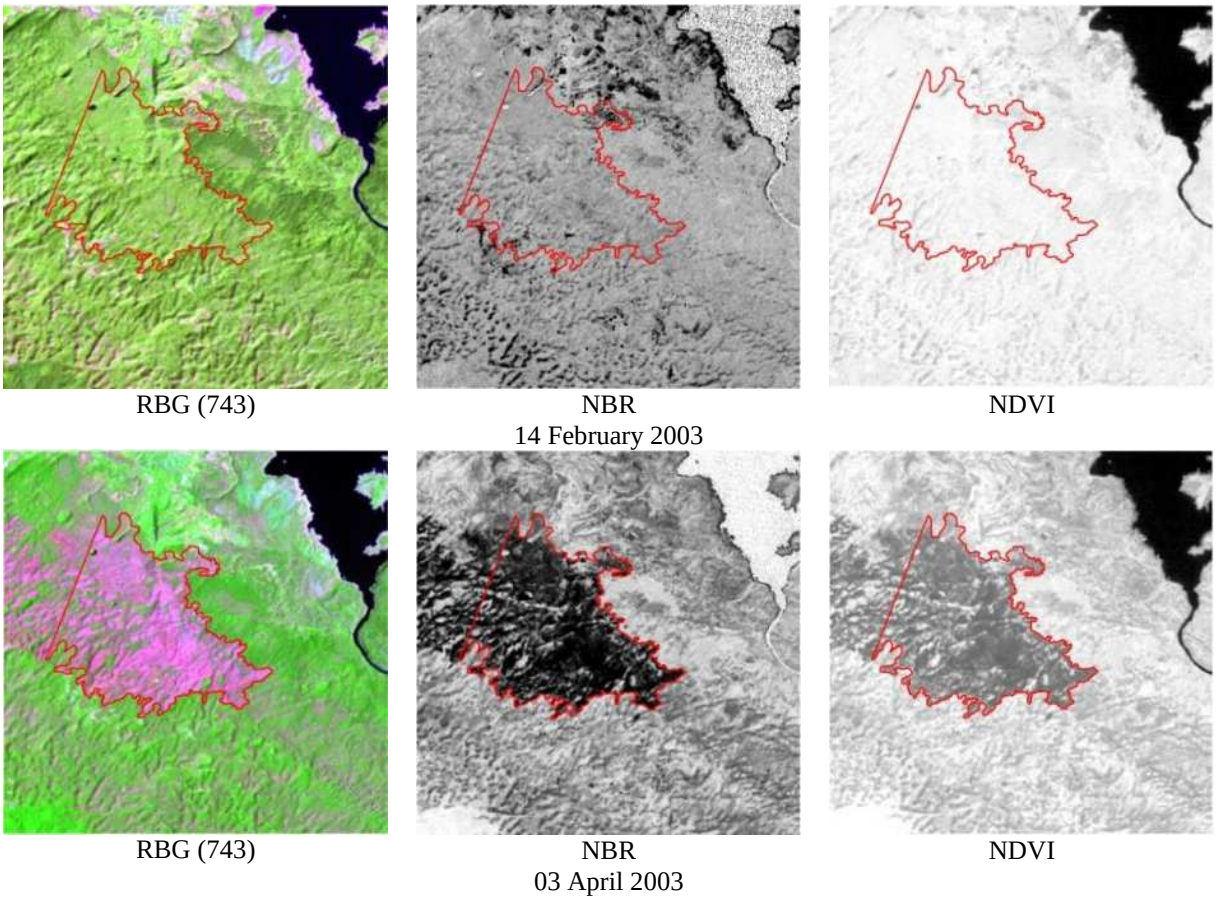

Figure 1. Visual comparison between pre/post-fire (top/bottom) Landsat ETM+ images. The fire perimeter in the Reserve is the red outline. At the top is part of the Nezahualcoyotl Dam.

To confirm the areas thus identified, a visual comparison between pre/post-fire spectral indices NBR (Normalized Burn Ratio: B4 - B7/B4 +B7) was used. A diminished NBR confirms the presence of a burned area (Cocke *et al.*, 2005). During this phase, the vegetation index NDVI (B4 - B3/B4 +B3) was also used to identify significant changes in the areas affected by fire (Figure 1). Fire perimeters were

digitised and labelled with the dates of images, the official record and the hotspot, as well as vegetation type. The different processes were supported by ArcMap and ENVI.

Results

According to the visual comparison in 1998, 229 fire perimeters were delimited, with surface variation from 0.3 to 2600 ha, and 42,240 ha affected; this was less than half of the total area. During 1999–2012, 866 fire perimeters were delimited, with surface variation from 0.3 to 600 ha, and 12,517 ha affected. We estimated that 352 involved tropical forest (wildfires) and 743 pasture, savannah and secondary tropical forest (agricultural burning). With the exception of 1998, burned areas smaller than 20 ha were more frequent (90%) at the buffer zone and near to villages and roads, confirming the relation with traditional fire use. Nowadays, in the core zone, many areas affected during 1998 have recovered their forest density; however, the portion west of the core zone sometimes experiences severe fires (Figure 2).

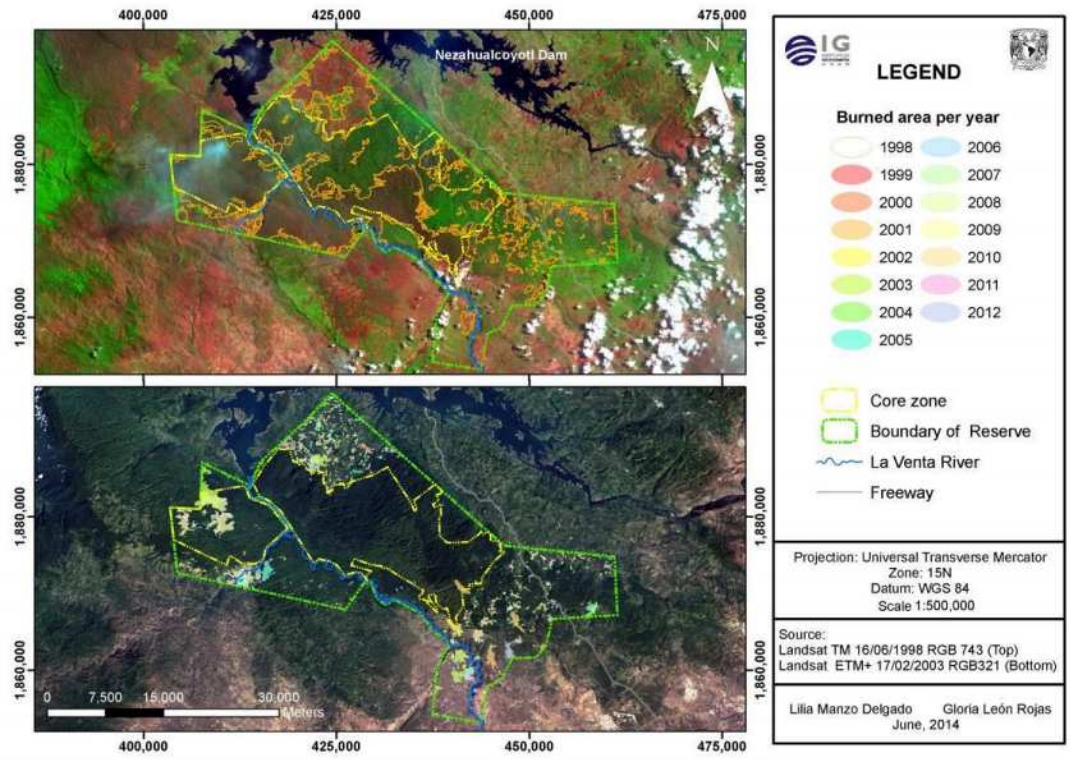

Figure 2. Burned areas of the Selva El Ocote Biosphere Reserve, Mexico, 1998 (top), 1999-2012 (bottom), from Landsat TM/ETM+

The catastrophic years were associated with El Niño events 1998 (42,240 ha), 2003 (1,643 ha) and 2005 (1,248 ha), suggesting that the meteorological conditions contributed to increased vulnerability of vegetation to fire. Comparative analysis between total fires and affected areas from Landsat images and official records of fires within the Reserve showed important differences each year (Table 1).

Table 1. Annual burned area derived from Landsat TM/ETM+ and official records of wildfires

Year	Landsat TM/ETM+				Official records	
	Agricultural burning (Number)	Surface (ha)	Wildfires (Number)	Surface (ha)	Wildfires (Number)	Surface (ha)
1998	111	10243	118	31997	7	22000
1999	3	13	2	12	2	1
2000	21	116	21	66	0	0
2001	9	195	31	893	6	211
2002	34	155	29	123	1	8
2003	12	342	17	1301	28	9275
2004	20	179	10	186	1	4
2005	35	571	29	677	10	553
2006	13	85	7	115	1	20
2007	13	130	13	76	8	82
2008	169	1063	14	78	3	5
2009	67	809	6	1537	6	2743
2010	57	732	25	547	3	24
2011	124	1676	29	104	0	0
2012	55	729	1	8	4	8

The month of May saw more agricultural burnings because it is a better time to prepare cropland, just before the start of the rainy season. At the same time, fires are common in the buffer zone; sometimes a few grow out of control and become forest fires in the core zone. The fire team of the Reserve are always alert; they have a range of measures for monitoring fire, such as CONABIO hotspots and fire reports, fire brigades and involvement of inhabitants of the communities in fire fighting. However, agricultural fires are a threat to the conservation of the Reserve.

High clouds from May to October are very common in the study area. This hindered identification of burnt areas for some years, particularly for 2003 during which there were many forest fires.

Hotspots were important for the discrimination of burned areas. A hotspot represented small agricultural burning (<1 ha) into contiguous land; multiple hotspots in the same area were associated with large wildfires (> 10 ha) that remained active for more than two days.

Official fire reports for the Reserve include underground fires; however, neither hotspot nor Landsat images could confirm these events. This issue is very important and it will be convenient necessary to use other methods to study these fires.

Conclusions

Visual analysis of multitemporal Landsat TM/ETM+ images was a good method for obtaining the first local burned areas map of the Selva El Ocote Biosphere Reserve, Chiapas, for 1998 and the period 1999–2012. These results illustrate an alternative means for analysing the pattern of spatial and temporal distribution of burned areas and for identifying zones that merit priority attention with regard to wildfires.

Extended Abstract

Introduction

An increasingly common post fire rehabilitation practice is the aerial application of mulch or hydromulch to the soil surface, with the goal of reducing post fire erosion. Mulch has the potential to alter soil organic matter cycling compared to areas that are allowed to naturally recover following high-severity wildfire. Following wildfire, soil surfaces are exposed to higher amounts of solar radiation and have low albedo; surface mulch can increase surface albedo and may decrease soil temperature in the summertime. In addition, mulch may alter soil moisture patterns by providing to a barrier to both surface water inputs and surface moisture evaporation. These alterations in temperature and moisture may have important impacts for soil microbial activity responsible for processing soil organic matter left behind following a wildfire. In addition, mulch provides a carbon substrate for soil microorganisms with little nitrogen to support its metabolism. As a result, mulch may induce net N immobilization with potential feedbacks to soil organic matter processing. These changes to the soil physical and chemical environment can alter soil organic matter turnover rates with important implications for soil productivity during post fire recovery.

Methods

We monitored changes in soil organic matter turnover resulting from aerial mulching practices on two large fires in the western United States: the 2002 Hayman Fire in the Rocky Mountains of Colorado and the 2005 School Fire in the Blue Mountains of eastern Washington and Oregon. Plots were established within hillsides treated with agricultural straw, hydromulch, wood strands, contour felling (Hayman Fire only), and unmulched areas in both burned and unburned areas. To supplement this monitoring, a controlled experiment was established on the 2012 High Park Fire in the Rocky Mountains of Colorado to determine effects of different mulch application rates on soil organic matter turnover. Plots contained two application rates each of agricultural straw and wood strands.

Soil organic matter turnover and soil environment

In two subplots per treatment, soil organic matter turnover was measured by monitoring changes in mass loss of buried wooden stakes over time. Control over organic matter quality was achieved by using the same organic material among sites and treatments, which assures comparison of decomposition as a function of treatment-induced abiotic and biotic soil conditions. Wood is a major component for surface and mineral forest soil, and has a slow decomposition rate that integrates changes in soil conditions over a long period of time. Wood is also an important factor after burning since wood is often left within the soil profile or on the surface. Aspen (*Populus tremuloides*) and pine

(*Pinus taeda*) stakes (dim: 2.5 x 2.5 x 30 cm) were buried vertically to a depth of 30 cm in the mineral soil, buried between the mulch and soil interface, and secured on top of the mulch surface. Each year, five replicate stakes from each fire, treatment and position were retrieved, dried, weighed for mass loss determination, and measured for loss in tensile strength. Soil temperature was monitored at all three sites. At the High Park Fire controlled experiment, soil moisture at two depths (5 cm and 20 cm) was also continuously monitored.

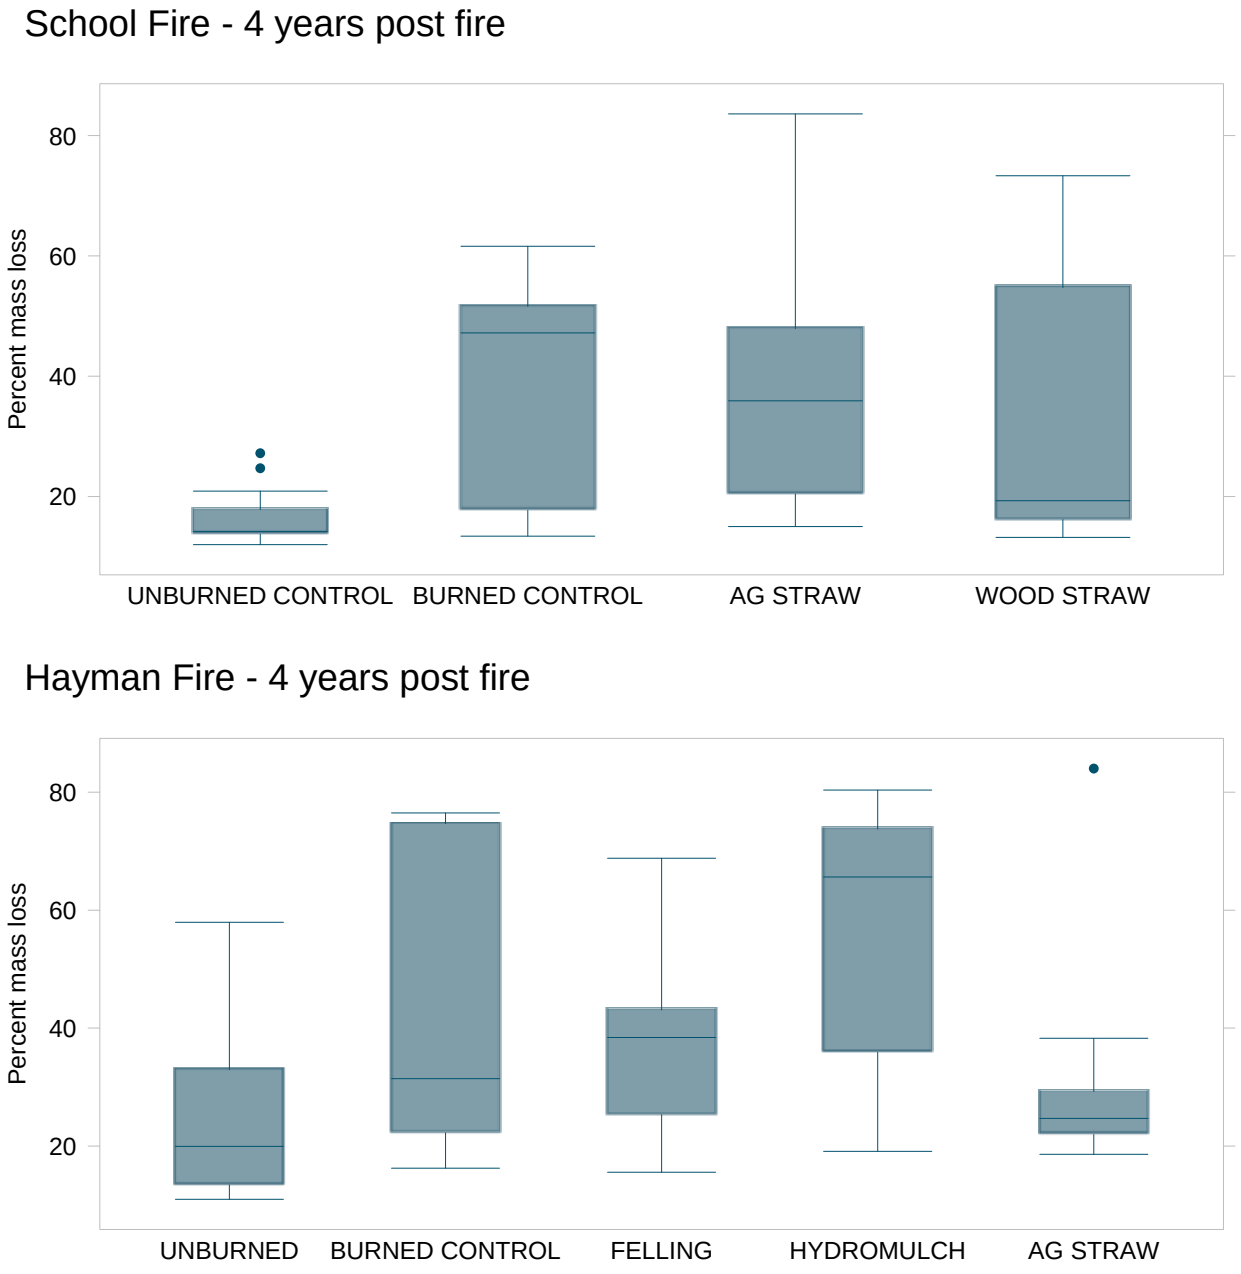

Figure 1. Mass loss from wood stakes four years following fire and mulch application at the School Fire (top) and Hayman Fire (bottom).

Results

Four years following fire, stake decomposition was increased in burned soil compared to unburned soil at both the Hayman and the School Fire (Figure 1). Following wildfire, char on the soil surface

decreases albedo and increases solar radiation absorption, which leads to temperature increases. Temperature is a key control over biological and chemical reactions involved in soil organic matter processing. In addition, wildfire often leads to an increase in soluble nitrogen to the soil; such nitrogen may allow for increased metabolism of carbon in the decomposition stakes by soil microorganisms.

Four years following application, mulch had little effect on stake decomposition at both the School Fire and the Hayman Fire (Figure 1). Initial differences in treatment, such as increased stake decomposition underneath hydromulch in the first year, disappeared later in the trajectory, leading to no differences among treatment seven years after mulch applications.

On the School Fire, wheat straw led to increased stake decomposition compared to the Hayman Fire. This may have been due to differences in climate, vegetation or soil texture between the two sites. The controlled experiment at the High Park Fire provided insight to mulch effects on soil organic matter turnover. Mulch increased summer time soil moisture, with the greatest effects seen at the 20 cm depth.

Conclusions

These findings support the idea that fire enhances soil organic matter turnover, at least in the first several years post burn. In addition, we have demonstrated that mulch applications may alter the initial stages of soil organic matter turnover, but with little long-term effects beyond the first few years. The Hayman Fire and the School Fire data have important limitations, however, due to the unreplicated nature of the hillside-scale mulch applications. The controlled experiments at the High Park Fire allowed a more robust test of mulch application on soil processes, suggesting that these initial effects on stake decomposition are derived from an altered soil environment. It remains unknown whether these intitial mulch effects on soil organic matter turnover establish a unique plant response trajectory compared to unmulched areas. More replicated mulching studies are needed, covering a range of soil textures and climates, that explicitly monitor soil processes important for organic matter turnover and soil productivity and tie these to plant responses.

Extended Abstract

Introduction

Even if the contribution of temporal series of remotely sensed data is well-admited, the use of temporal series of high spatial resolution images is limited because of the lack of data allowing developing these applications. The French project TOSCA is related to the analysis and the applications of multi-temporal remote sensing Landsat images. The aim of this project is showing the interest of multi-temporal series of data to obtain accurate information on large territories. For this project, multi-temporal Landsat images were tested for the spatio-temporal monitoring of burned area to evaluate post-fire damage.

The application of temporal Landsat images was realized on the Fontanès wildfire which occurred in Herault French department on the 30th August 2010 and which burned 2,590 hectares area.

Figure 1. Localisation of the study area according to Google Earth data (left side) and Fontanes wildfire on post fire Landsat 5 image (right side).

Two Landsat 5 images with 30 metres spatial resolution were considered: one acquired before the wildfire on the 12th September 2009, one acquired immediately after the wildfire on the 15th September 2010.

Methods to evaluate post-wildfire damages

Damages evaluation on the field

The monitoring of burned area consisted to relate post-fire damage levels evaluated on the field after the wildfire with vegetation there before the fire. 90 field surveys were spread uniformly on the study site to evaluate post-fire damage on homogenous vegetation types. For each field survey, damages were observed on four height strata of the vegetation (0-1 metres, 1-4 metres, 4-10 metres and more than 10 metres) and on each structural element of the vegetation (trunk, branch, leaf, fruit). Then, a level of damage was affected to each field survey:

- 0: no damage observed,
- 1: partially burned,
- 2: completely burned,
- 3: deep damages.

The weight given to the highest strata is more important than the other strata in order to take into account to the perception of the satellite sensor which considers the highest strata of the vegetation.

Damages evaluation according remote sensing techniques

Atmospheric corrections to detect clouds and aerosol and corrections to reduce environmental effects (fuzziness due to the atmosphere, lightning variation due to topography, etc.) were made by the CESBIO. Then, according to the field survey, supervised classifications were performed on the principal component analysis of the images: before the fire to identify fuel types, after the fire to characterize damage levels.

Results

3.1. Damages evaluation on the field in relation with the strata height

High and very high levels of damages concern lowest strata (0-1 m and 1-4 m strata) whereas moderate or low damages concern strata more than 4 metres. So damages decrease at the same time the height of the strata increases.

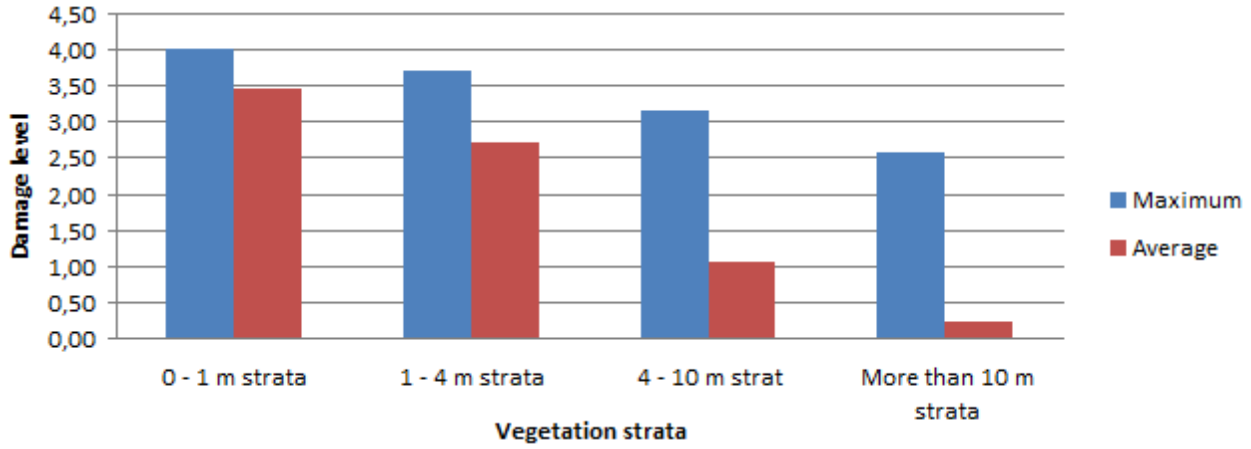

Figure 2. Damage observed on field data on the different vegetation strata

Damages evaluation by remote sensing techniques in relation with fuel type

The image before the wildfire allowed distinguishing 6 land cover classes, 5 of them characterizing fuel types: mature pine stand, young pine stand, hardwood, high and low shrublands, bare-ground. The image after the wildfire allowed distinguishing 6 levels of damage: no damage, moderate damage, high and very high damage on shrublands (high S, very high S), high and very high damage on tree stands. The comparison between observed damage and fuel types showed the most important damage on young pine stand and high shrublands. Damages are less important in mature pine stand characterized on your study site by vertical and horizontal continuity of the vegetation.

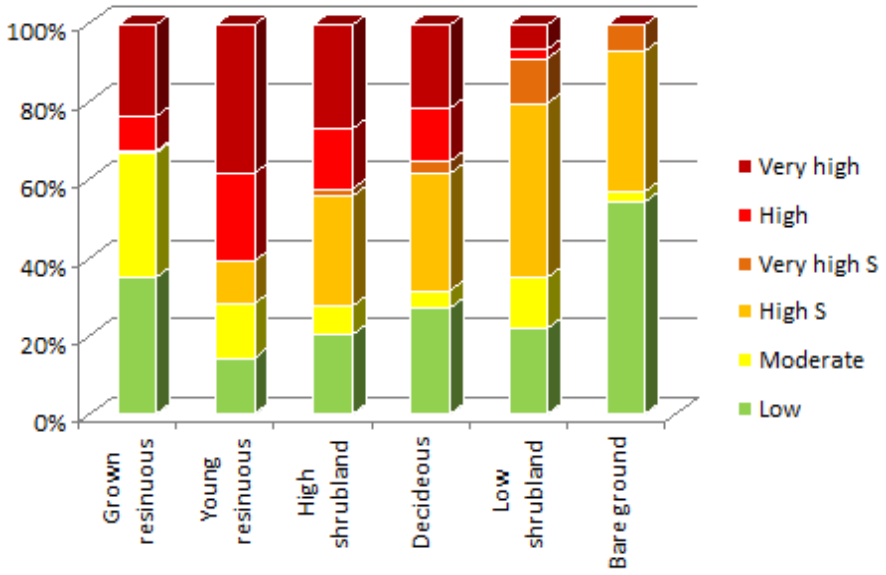

Figure 3. Damage observed according the post-wildfire image on the different fuel types

Conclusion

The spatio-temporal monitoring of burned area with remote sensing data allows the identification of the most sensitive fuel types against wildfire which is an important help to wildfire managers in the post-crises analysis but also in the wildfire prevention.

The Greek National Observatory of forest fires

Abstract
The Greek Forest Service has recently established the National Observatory of Forest Fires (NOFF) in collaboration with the Laboratory of Forest Management and Remote Sensing, Aristotle University of Thessaloniki (AUTH) and the Interbalkan Environment Center (i-BEC). The purpose of the i-BEC is to support the systematic monitoring of the quality of the environment in Greece, the assessment of potential risk related to natural hazards and the development of relevant technology and sound knowledge, applicable in the Balkan region. A series of indicators and decision support applications is used for the monitoring of selected environmental parameters in real time in order to support operational early warning and documented risk assessment.

Keywords*: National Observatory, wildfire, forest fire, risk assessment, Balkans, fire management*

The problem targeted

The adverse effects of forest fires can be prevented, or at least minimised, by implementing successful prevention, suppression and mitigation measures. The design and consequent success of such measures is highly dependent on the availability and reliability of up-to-date fire-related data, such as burned area or fire risk maps. Such data are often collected locally and inconsistently in order to be used in context of independent projects; hence, they can rarely be found in a consistent format and content over extensive areas. The lack of such data inhibits the capacity of designing successful measures at regional or national scales. This is also the case in Greece, despite the capacity brought by new technologies and the progress made during the last decades in the topics of fire risk assessment, fire modelling and spatial data management. The quality, completeness and reliability of the fire data in Greece is still questioned due to lack of operational and procedural standardization and data interoperability.
NOFF aims to collect various environmental data related to forest and fire management and to develop a series of modern products and services that will support the design of efficient forest fire prevention policies in Greece and the Balkan region, as well as the assessment of the fire impact. The observatory aims to become the focal point in Greece and a major Center in the Balkan region in handling forest fire related information.

Products and services

A number of different activities are planned for the following years including the development of a number of spatial products, information tools and fire management support services aiming to support all Balkan countries, the creation of the Greek forest fire web-portal, an early warning service, as well as dissemination and capacity building actions.
Currently, the development of the following products and services is in progress:

- A consistent methodology for mapping the forest fuel types occurring in the Balkan region.
- A fire risk index adapted to the soil, climate and vegetation peculiarities of the region.

- A methodology for the accurate mapping of burned areas using high resolution satellite imagery, which will be delivered within a service that can provide burned area maps on a yearly base or on demand.
- An interactive Fire Forest portal and associated mobile applications which will make the products and services of NOFF available to stakeholders, policy makers, and local and regional authorities.

The aforementioned products will be designed for operational use and they will be tested in cooperation with relevant public services. The developed tools are planned to have graphical and multilingual user interface that could be easily employed by experts in all Balkan countries. The rest of this section details the aforementioned products.

2.1. Forest fuel type mapping

Forest fuel maps are primarily used by fire behaviour simulation models, in order to accurately perceive and assess the risk, severity, propagation and environmental impact of forest fires. The developed methodology would have to be able to regularly map forest fuels over extensive areas at a low cost so that its operational use will be feasible. Towards this end, it will benefit from the experience already gained by previous forest fuel mapping projects (e.g. ArcFuel and FUELMAP) and minimise the need for costly field data collection, by primarily relying on the processing of readily available ancillary data—consistently available across the Balkan countries—and remotely sensed images.
The combined use of ancillary data, such as the CORINE land-cover map and the Joined Research Centre (JRC) forest type map, will allow the mapping of certain forest fuel types. The remaining forest fuel types will be mapped by processing remotely sensed images using object-based image analysis (OBIA) and advanced image classification algorithms (fuzzy rules, decision trees, support vector machines). These images will be collected during the summer and winter seasons by a Disaster Monitoring Constellation (DMC) sensor at a 22 m spatial resolution. Images from both seasons will be used to facilitate the distinction between forest fuels which display different seasonal behaviour, such as evergreen and deciduous tree species.
The methodology will initially be applied over the prefecture of Chalkidiki, which is located in northern Greece and extents over an area of about 2900 km2 covered by a representative range of forest fuel types found across Greece. The resulting forest fuel map will be validated with a series of field visits.

2.2. Fire risk index

An efficient index for mapping forest fire risk is currently being developed. The fire risk index will be computed based on soil, climate and vegetation peculiarities of the region. The production of the fire risk index takes advantage of the use of Landsat 8 images that are freely and regularly distributed over the internet, being thus capable to provide seasonal assessment of fire risk based on deviation from normal vegetation, topographic and meteorological conditions. The calculation of the fire danger index will be adjustable to local data, thus being easily applicable to the different countries of the region.
The operational fire risk index will be linked online via SMS and e-mail with the Greek Special Secretariat of Forests and the local forest services. For the creation of this index an algorithm will be developed that also takes into account historical weather data and the fire regime of each area. The final value will be weighted by a set of selected parameters and the development and the accuracy assessment of the fire danger index will be applied at the Region of Central Macedonia.

2.3. Burned area mapping

An in-house method for the accurate mapping of burned areas is currently being developed, using high resolution satellite imagery. The method can be used operationally at several scales (local, regional and national). The employed methodology will be implemented in two stages:

- Initially, the satellite image will be segmented through the application of an object-based image analysis (OBIA) technique. A number of higher order features will be extracted from the original image (on an object level basis) and a set of prototype reference objects will be selected by the user.
- Subsequently, a small subset of highly informative features will be determined through the application of an advanced feature selection methodoly, based on the principles of the so-called Fuzzy Complementary Criterion (FuzCoC). The burned area map will be produced by employing a Support Vector Machine (SVM) classifier on the selected feature subset, which presently constitutes one of the most accurate classification techniques based on supervised learning.

The first stage will be employed using a well-known commercial image processing software. For the second stage, a custom user interface is being developed, which will be used to apply the feature selection method and subsequent classification with minimum user interaction.
The employed method, which is sensor independent, is normally applied for mapping older fires, but it can also be used operationally to map new fires as well as for the reconstruction and mapping of historical events and the assessment of the fire regime. Initially, the methodology will be employed and validated in two areas of Greece recently affected by fires (Parnitha and Rhodes), using two IKONOS very high resolution satellite images. Ultimately, the whole methodology will be delivered within a service which will provide burned area maps on a yearly base or on demand.

2.4. Web portal and applications

A Forest Fire web portal will be created with the purpose of disseminating the NOFF's products and services to stakeholders, policy makers, and local and regional authorities. It will be accessible through a web browser and allow interested parties to visualise and interact with the maps and tools provided by NOFF through a friendly user interface. Thus, users will be able to benefit from what NOFF has to offer without the need to install and operate specialised and expensive software or a deep understanding of forest fire science. The portal will also host a depository for fire related data that will accommodate the data exchange within the scientific community and promote research.
In addition to the above, the Forest Fire web portal is planned to include a Public Participation GIS (PPGIS) that will bring the academic practices of GIS and mapping to the local level in order to support transfer of knowledge and promote the development of new knowledge. The idea behind PPGIS is to use and produce digital maps, satellite imagery, sketch maps, and many other spatial and visual products and tools in order to promote geographic involvement and awareness on a local level. Apart from the PPGIS, the Forest Fire portal will include the frequently updated map of fire risk and the most updated map of forest fuel types.
A number of mobile applications (SMS alerts, smart phone application) are anticipated for the ubiquitous access to the data resources as well as for distributing information and relevant early warning messages related to the level of fire risk to pertinent fire management groups including the Forest Service and Fire Service personnel.

Main results

Apart from the networking and capacity building objectives, the results expected from the establishment of NOFF are related to the integration of scientific knowledge and technological tools in the operational practice of fire prevention and forest protection. A series of mapping products and a suite of EO data processing services will be available through the NOFF to all Balkan countries, thus providing several opportunities for scientific cooperation among the neighbouring countries. The forest fuel map, the Fire Danger Index and the Burned area mapping service are the key results that

NOFF delivers. Furthermore a web repository of fire management data and information related to this region of Europe will be also developed.

Conclusions

The objective of the NOFF is to develop and promote the aforementioned fire management information products and services to interested parties and forest fire stakeholders both at national and a regional (Balkan region) level. This will be accomplished through the organisation of workshops, seminars and short courses that will ensure the optimization of use and performance of the products and services described above. The aim of NOFF is to become a regional center of fire management technology and information, providing the background for organizing relevant inter-Balkan activities with the participation of fire experts and potential end-users from different Balkan countries.

Trends and changes of fire danger in Italy and its relationships with fire activity (1985-2008)

Abstract
The comprehensive understanding of trends in fire activity and associated drivers is crucial to anticipate future trends and regulate fire potential impacts, by means of efficient fire and fuel management strategies. A valuable tool to examine past changes on fire potential and danger across fire regions is represented by fire weather indexes. In this study, spanning from 1985 to 2008, recent trends and patterns of fire danger and the relationships between the Canadian Fire Weather Index (FWI) System components and fire activity were investigated across Italy. Although time series trend analysis revealed a statistically significant increase in temperature, no clear pattern of fire danger increase was unveiled, while the number of days with high fire danger level increased significantly, especially in central and southern Italy. Monthly fire activity was modeled using as explanatory variables FWI components and significant coefficient of determination were obtained. The applied statistical approach (multiple linear regression) explained a consistent part of the fire occurrence variance all year long ($p<0.001$), although relevant differences across Italy were found.

Keywords*: fire danger indexes, percentile analysis, trend analysis*

Introduction

According to the last Intergovernmental Panel on Climate Change (IPCC, 2014), observed climate trends showed a variation in temperature and rainfall over Europe. There are different degrees of confidence that future climate will show an increase in high temperature extremes (*high confidence*) and meteorological drought (*medium confidence*), but small or no changes in wind speed extremes (*low confidence*), with diverse patterns varying considerably within and between regions.
It is well known that extreme weather events, such as extended drought and heat waves, facilitate and promote forest fire activity in Southern Europe. For example, during the dry spells in 2005, 2007 and 2009 a high number of large wildfires were recorded in South European countries (Pereira *et al*., 2005; EEA, 2010c; Koutsias *et al*., 2013; Salis *et al*., 2013). Future fire risk is projected to increase in Southern Europe (Carvalho *et al*., 2011; Dury *et al*., 2011; Vilén and Fernandes, 2011; Lung *et al*., 2013), along with the occurrence of high fire danger days (Arca *et al*., 2012) and fire season length (Pellizzaro *et al*., 2010). In this framework, the analysis of past conditions and the factors that shaped fire pattern plays a crucial role for the comprehensive understanding of trends in fire activity, so as to anticipate future fire potential and changes (e.g., Carvalho *et al*., 2010; Zumbrunnen *et al*., 2011; Amatulli *et al*., 2013), and to assess the ecological effects of forest fires, thus reaping the benefits (Moreno and Chuvieco, 2012).
During the last decades, fire weather indexes were often used to examine past changes on fire potential and danger across fire regions (e.g. Camia *et al*., 2008; Carvalho *et al*., 2008; Mäkelä *et al*., 2012; Wastl *et al*., 2012). These systems, combining relevant weather variables into suitable indexes, are usually valuable tools to estimate potentially dangerous conditions, as fire intensity or large size fires, and to help forest fires services in effective prevention and response to forecasted danger. A clear comprehension of the relationships between these indexes and fire occurrence features, as well as their

efficiency, is of paramount importance in the implementation of fire policies and management (Carvalho *et al*., 2008; Bedia *et al*., 2012). Furthermore, the identification of areas with high fire danger and risk under severe and extreme environmental conditions is of utmost importance to cope and regulate their potential impacts through fire and fuel management (e.g. Fernandes, 2009; Arca *et al*., 2009; Salis *et al*., 2012b). Moreover, fire danger measurements are very valuable for all fire-fighting services, as they enable minimizing the level of uncertainty by combining scientific knowledge and operational experience (Valese 2008; Taylor and Alexander 2006).

One of the most commonly used fire danger rating systems across the world is the Canadian Fire Weather Index System (FWI), developed by Van Wagner and Pickett (1987). FWI has been very effective not only in Canada, where it was developed, but also in the Mediterranean area, as demonstrated in literature (e.g., Viegas *et al*., 1999; 2001). An important comparative study assessing the performance of different danger indexes in Southern Europe has revealed that FWI is the fire danger index best correlated with fire occurrence in Spain, France, Italy and Southern Portugal (Viegas *et al*., 1999). Therefore, FWI is a reliable fire danger system also in dry Mediterranean vegetation and climate conditions, which are very different from Canadian conditions where FWI was designed. However, despite its successful application in recent studies in Mediterranean regions (Moriondo *et al*. 2006; Valese 2008; Carvalho *et al*. 2008), it is noticeable that the performance of FWI and its relationship with fire occurrence show different response patterns according to the area considered (Carvalho 2008).

In relation to this, few works are available in Italy. With the intention to fill this knowledge gap and thus contribute to the understanding of past fire danger conditions, the main goals of this study are to (i) investigate and characterize recent trends and patterns of weather and fire danger in Italy, and then to (ii) unravel the relationships among the Canadian Fire Weather Index (FWI) System components and both fire number and burned area.

Methods

Study area and data collection

The area under investigation is Italy, which covers an area of about 301,000 km^2 comprising the boot-shaped Italian Peninsula and a number of islands including the two largest of the Mediterranean sea, Sicily and Sardinia. The climate of Italy, according to Köppen-Geiger (1954) climate classification, can be distinguished into 7 broad climatic regions, from the Mediterranean climate (characteristic of all coastal areas excluding the North-East) with mild and wet winter and hot and dry summers, to the Tundra climate with mean temperature below 10°C all year long. According to the Corine Land Cover classification (CLC 2006; EEA, 2007), agriculture is the main land use in Italy, covering 51.8% of the territory, closely followed by forested areas (40.2%). Artificial surfaces occupy about 5% of the territory.

National fire data were obtained for the period 1985-2008 from two sources of data, the European Fire Database (EFD) from the Joint Research Center (JRC) and the Sardinian Forestry Corp (CFVA, Corpo Forestale e di Vigilanza Ambientale della Regione Sardegna) database. The EFD is the largest repository of information on individual fire events in Europe (Camia *et al*., 2010). The database summarizes, on a monthly basis, the number of fire events and the total burned area of a given NUTS (Nomenclature of Territorial Units for Statistics) 3 unit (administrative level of province). A preliminary analysis of the EFD database revealed a data gap for Sardinia Region from 1985 up to 1997, so the CFVA fire daily database was used instead for the whole study period.

The weather data were obtained from the interpolated (25x25 km) daily meteorological database developed in the framework of "Monitoring of Agriculture with Remote Sensing" (MARS) project. The database was created using different weather data sources such as direct observations from meteorological stations, and from remote sensing platforms. The dataset, comprising the time period 1985-2008, consists of daily value of air temperature, precipitation, wind speed, and vapour pressure.

Since relative humidity data were not available in the MARS database, we estimated it from the air temperature, vapour pressure, and the dew point temperature (Snyder and Show, 1984).
Finally, fire and weather datasets were aggregated in a database at 25 km resolution grid and on a monthly basis using ArcGIS 9.3 ©-ESRI.

Fire danger indexes and statistical analyses

Fire danger was calculated through the Canadian forest Fire Weather Index System (FWI), which provides a rating of fire danger through fuel moisture and fire behaviour potential (Van Wagner, 1987). The FWI is composed by 6 sub-codes, the first 3 rating fuel moisture content of the forest floor layers and the other 3 the potential fire behaviour. The Fine Fuel Moisture Code (FFMC) rates the moisture of litter and other dead fine fuels at the top of the surface fuel layer; Duff Moisture Code (DMC) embodies the moisture content of loosely compacted, decomposing organic matter weighing about 5 kg m^{-2}, when dried (this is an indicator of fuel consumption in moderate duff layers and medium-sized woody material (Carvalho 2010)); and the Drought Code (DC) represents the moisture content of the deep layer of compact organic matter.
As outlined above, the other 3 sub-codes estimate the potential fire behaviour, combining the previous fuel moisture codes and weather. The Initial Spread Index (ISI), obtained by the combination of wind and the FFMC component, assesses the rate of fire spread without the influence of variable quantities of fuel; the Build Up Index (BUI) combines DMC and DC components to represent the total fuel available for combustion; and the final Fire Weather Index (FWI) is the combination of ISI and BUI components and represents the intensity of fire spreading as a rate of energy output per unit of fire front length. As highlighted by Alexander (2008), each individual component of the FWI system is actually a fire danger index, revealing different aspects of fire danger that are difficult to synthesize into one single number.
Usually, the FWI system is computed by daily meteorological variables recorded at noon. In this study, FWI was computed using daily meteorological values from MARS database as proxy of instantaneous values at 12:00. After the FWI system calculation, the dataset comprised daily values for all the 565 cells derived from the MARS dataset and for the whole 24-year period.
To handle this amount of data, a preliminary hierarchical cluster analysis, based on the fire/weather dataset, was performed to identify homogeneous areas in terms of fire occurrence and climate (pyro-climatic areas) (Bacciu *et al*., 2014) (**Erro! A origem da referência não foi encontrada.**). The Mann-Kendall non-parametric statistical test was thus applied to evaluate the existence of trends on fire danger components and weather data series. As commented by Wastl *et al*. (2012), a shift in fire danger might be induced by an increase of either absolute index values or number of days with elevated index values. We thus calculated the number of days, for each year and pyro-climatic area, exceeding the threshold of the FWI 95th percentile of the whole time period. Then we proceeded with the Mann-Kendall non-parametric statistical test over the past 24 years to investigate on the eventual increase of fire extreme days. Mann-Kendall test was performed using an Excel macro named MAKESENS created by Salmi *et al*. (2002).
Finally, historical fire activity was analysed in relation to monthly averages of FWI system components to understand the relationships among variables and to develop statistical models to be used to project fire activity in the near future. Separate analyses were carried out at cluster level and a classical stepwise Multiple Linear Regression analysis was applied for the period 1985-1999 (training dataset). The Multiple Linear Regression is one of the most common methods applied to analyse relationships between fire activity and fire danger/weather parameters (e.g. Carvalho *et al*., 2008; Camia and Amatulli, 2009; Bacciu *et al*., 2014). The stepwise approach combines entry and removal of regression terms, which were accepted or discharged as long as they meet significance criteria. The natural logarithm was used to normalise burned area and fire number for the normality requirement, as it is a common procedure followed in other modelling works (Carvalho *et al*., 2008; Amatulli *et al*., 2013). The 9-year period 2000-2008 was then used as external validation dataset. The performances

of the model equations were evaluated using the R^2 coefficient of determination between estimated and measured values.

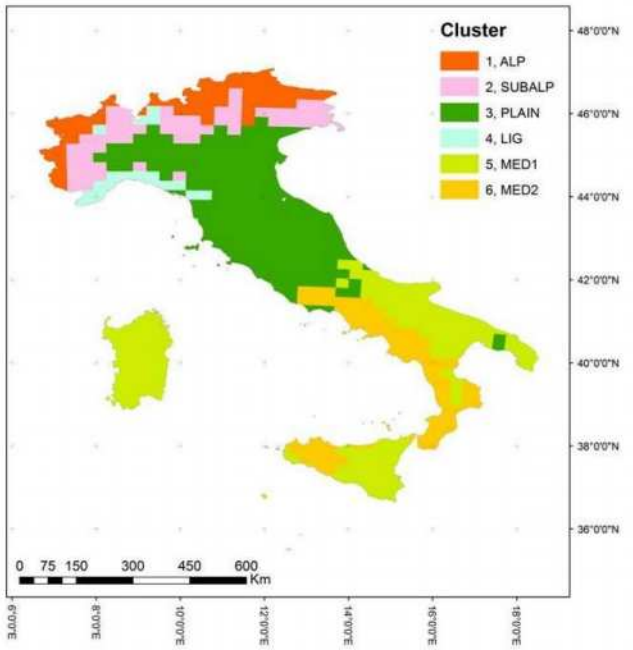

Figure 1. Map of pyro-climatic regions in Italy (from Bacciu et al., 2014)

Results

The descriptive statistic of the fire-regime metrics at cluster level is shown in Table 1. The most fire-prone zones are located in the Southern clusters (MED1 and MED2) although a marked fire activity also occurred in LIG (19% burned area over total, 2 fires km^{-2}). From 1985 to 2008, about 2.5 million of hectares were burned (~10% over the Italian total area), about 230,000 fire ignitions occurred, and the annual average burned area was ~100,000 ha. The maximum recorded area burned was in 1993 and 2007 (9.2% and 9.1% over the total, respectively). High level of inter-annual variability of burned area (computed through the coefficient of variation, cv) was found in Northern clusters (ALP and SUBALP) with low fire activity (0.2-0.4 fires km^{-2}), suggesting a stronger influence by weather and climate. As expected, clusters with marked Mediterranean climate and significant fire activity (i.e. Sardinia, Calabria, and Sicily, which had the highest area burned values and number of occurrences in Italy) showed a low inter-annual variability in both fire number and burned area, probably due to persistent human activities.

Five-year averages of maximum and minimum temperatures as well as precipitation and relative humidity are displayed in **Erro! A origem da referência não foi encontrada.** for each pyro-climatic area. The Mann-Kendall trend test highlighted a generalized significant positive pattern for air temperature variables in all clusters (overall almost 0.5°C and 0.7°C per decade for maximum and minimum temperature, respectively). On the other hand, annual precipitation trends were not significant and the signs of the slopes were different across areas, while on the contrary relative humidity showed overall a significant negative pattern.

Table 1. Number of fire (FN) and burned area (BA) statistics at cluster scales, for the period 1985-2008. CV is the coefficient of variation

CLUSTER	CODE	FN (*1000)	BA (ha*1000)	% BURNED OVER TOTAL	FIRE DENSITY (FN km^{-2})	AVG FIRE SIZE (ha)	CV FN	CV BA	FIRE SEASON (Month)
Cluster 1	ALP	6,2	62,0	1,99	0,20	9,97	0,49	1,22	12,1,2,3
Cluster 2	SUBALP	13,8	147,5	4,27	0,40	10,66	0,46	1,20	12,1,2,3
Cluster 3	PLAIN	37,2	279,1	2,62	0,35	7,50	0,47	0,77	7,8,9
Cluster 4	LIG	21,4	193,9	19,00	2,10	9,06	0,52	0,76	12,1,2,3,8
Cluster 5	MED1	89,8	1109,9	13,90	1,12	12,36	0,38	0,60	6,7,8,9
Cluster 6	MED2	64,4	669,4	16,90	1,63	10,40	0,41	0,66	6,7,8,9

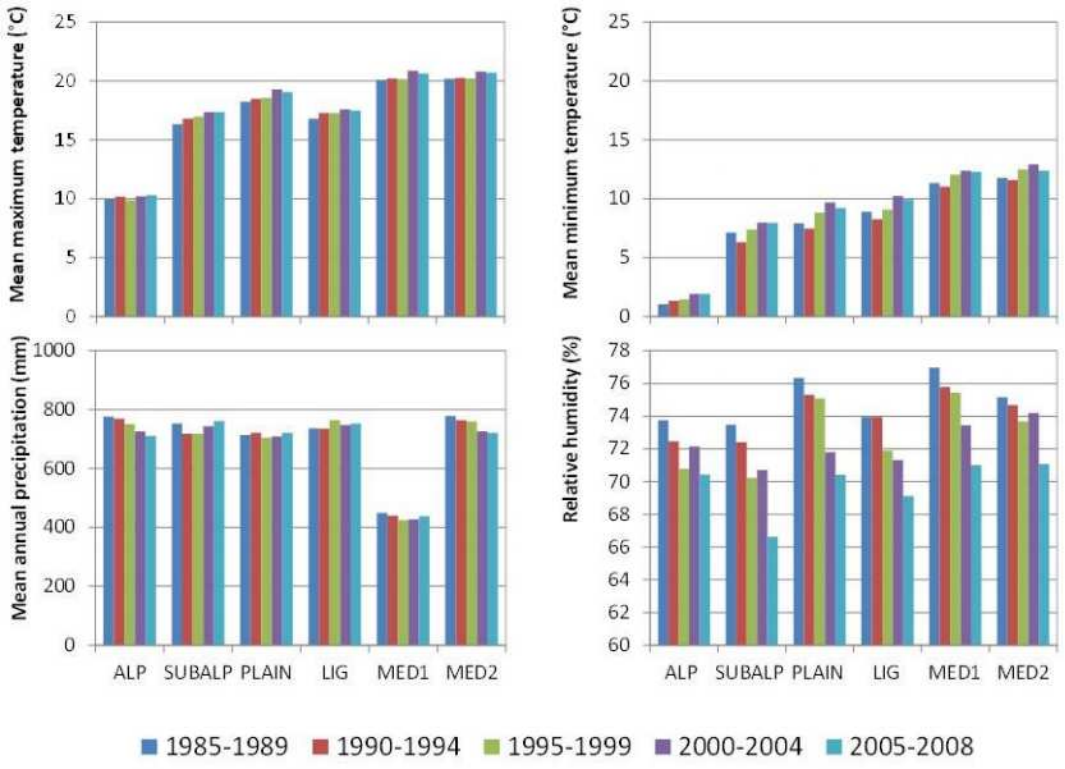

Figure 1. Evolution of mean maximum and minimum temperature, annual precipitation and relative humidity on a five-year basis (1985-1989, 1990-1994, 1995-1999, 2000-2004-2005-2008) in pyro-climatic areas

Overall, the statistical analysis of the mean forest fire danger index values (**Erro! A origem da referência não foi encontrada.**) revealed few significant changes during the 24 year of analysis. According to the Mann-Kendall trend test, there was a significant downward trend ($p<0.01$) in DC for ALP cluster, and a significant upward trend in four out to six cluster in ISI index. The number of days with exceptionally high meteorological fire danger was assessed calculating the annual number of days above the 95th percentile threshold. The analysis showed overall a statistically significant increase during the analyzed period, ranging from 1 to 8 days per decade. Overall, the mean number of extreme fire danger days ranged from 4 in cluster ALP to 30 in cluster MED1. The most important increase in number of extreme fire danger days were recorded in PLAIN and MED1 clusters. Ranging from an average of 22 days in 1985-1996 to 39 days in the period 1997-2008, MED1 exhibited a significant

increase of 43%. A stronger increase (65%) was recorded in SUBALP area, which went through an average of 7 days during the first period to 19 days in the period 1997-2008.

Table 2. Mann-Kendall trend test (Z score) results for mean FWI System components for each pyro-climatic area and mean annual number of days exceeding the FWI 95th percentile of the whole 24-year period.

** p= 0.05; ** p= 0.01; ***p= 0.001*

	Mann-Kendall trend Test Z						Estreme fire danger days

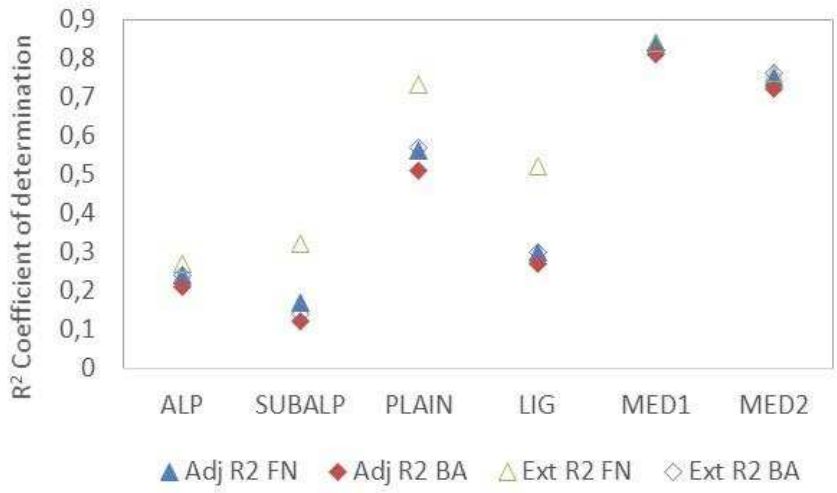

Figure 3. Monthly fire number and burned area explained variance (Adj R^2) and external validation values (Ext R^2)

Coefficients of determination (R^2) resulting from the Multiple Linear Regression analysis of monthly area burned and monthly number of fires considering the whole year for the six clusters across Italy are given in Figure 3. All coefficient were highly significant with $p<0.001$. We also checked for collinearity through the variance inflation factor (VIF). In those cases where predictors entered the final stepwise model and their VIF was higher than the value of 10, thus creating multicollinearity problems (Myers, 1990), we decided to exclude those variables from the regression in order to avoid any further inconsistencies. Finally, an informal analysis of the data using histograms and scatterplots was performed to reveal threats to the assumption of linearity of residuals of the dependent variable (data not shown).

The explained variance ranged from 17 to 84% for fire number and from 12 to 71% for burned area. Clusters in northern and central regions showed the lowest variances, accounting from 17% up to 56% for fire number and from 12% to 51% for burned area in cluster SUBALP and in cluster PLAIN, respectively. On the other hand, pyro-climatic areas in southern regions exhibited variances above 70%, for both fire number and burned area. The external validation R^2 values (period 2000-2008) are slightly bigger than the internal validation.

Discussion and conclusion

In this study, we investigated recent trends in both climate and fire danger parameters and we highlighted the relationships between the FWI System components and fire activity in the 6 pyro-climatic areas identified by Bacciu *et al*. (2014).
As a first analysis, we applied the non parametric Mann-Kendall test to assess the statistical significance of weather and fire danger trends. The results of our study indicated the overall increase of temperatures, highlighting that the warming did not have homogeneous impacts all over the country, corroborating other findings over the past decades in Italy and in other areas of the Mediterranean Basin (e.g., Brunet *et al*., 2007; del Rio *et al*., 2012; Koutsias *et al*., 2012). Furthermore, annual precipitation records presented an unclear trend, except in the Alpine area. This data is consistent with the findings of Wastl *et al*. (2012), which reported for this area a slight increase of about 8% in annual precipitation. Moreover, our results highlighted a dichotomy in signs that seems to be in agreement with the results of other researchers.
Generally, the slope of the mean annual fire danger was positive at nearly every cluster, statistically significant in MED1. The situation in ALP cluster, as revealed by the weather variables, was the opposite with a statistically significant downward trend in mean values, probably influenced by the increase in total precipitation. The first results are in agreement with Moriondo *et al*. (2006), who found an increase in mean fire danger in the Mediterranean Basin. On the other hand, the clear decrease of the danger in ALP pyro-climatic area is in contrast with findings reported by Wastl *et al*. (2012) that showed a general increase of fire danger despite this trend was highly variable in consideration of the spatial and the time scale. The wide-ranging positive trend in fire danger corresponded also to a general increase in the frequency of extreme fire danger events. The analysis of the annual number of days above the 95^{th} percentile threshold showed that although southern clusters were characterized by a high number of extreme fire danger days, considerable increment occurred also in northern and central clusters.
Finally, by modelling both fire number and burned area on the basis of monthly FWI components in the different clusters, this study contributes to the understanding of the relationships between fire activity and fire danger indices. Although the study area presented a generalized decrease in both fire number and burned area for the period 1985-2005 (Spano *et al*., 2014; Bacciu *et al*., 2014), the multiple regression analysis showed that FWI system components (especially FFMC and ISI) are good predictors, especially for the clusters with summer fires. Similarly, Amatulli *et al*. (2013) highlighted the drought code (DC) and the initial spread index (ISI) as predictors consistently selected in the equations using the Multiple Linear Regression approach. Results achieved by Carvalho *et al*. (2008) in Portugal revealed that FWI mean and maximum values contributed to explain a great part of the variance in burned area.
Although fire activity in Italy is influenced by a number of factors not related, as fire danger, to weather conditions, the simple statistical models developed in this work can reproduce an important part of the inter-annual fire variability. Thus, the identified relationships could be incorporated in predictive models of fire risk and short- and long-term fire planning strategies that, in turn, could be boosted by the enhancement and a wider use of long-range climate outlooks (such as the seasonal and decadal predictions, e.g. Borrelli *et al*. (2012); Bellucci *et al*. (2014)). Furthermore, the developed models could be used as inputs for the construction of future fire scenarios (e.g., Amatulli *et al*., 2013) to understand the future magnitude of the issue and thus to develop new fire risk mitigation strategies.

Acknowledgements

The Authors would like to thank the JRC and Forest Service of Sardinia (CFVA) for providing fire occurrence data for this study. The researchers leading this work received funding from the Italian Ministry of Education, University and Research and the Italian Ministry of Environment, Land and

Sea under the GEMINA project, from the OFIDIA Project "Operational FIre Danger preventIon plAtform" (European Territorial Cooperation Programme Greece-Italy 2007-2013), and from the PRIN CARBOTREES Project- "Climate change mitigation strategies in tree crops and forestry in Italy" (Prot. 201049EXTW).

Abstract
The PREFER FP7 project aims delivering a series of map products based on Earth Observation data, which can support and improve fire and forest management in EU. Among these products are maps of Burn Scars from forest fires which are created using complex remote sensing techniques and image processing algorithms. In this paper is presented the validation methodology and the results relative to the evaluation of the burn scar product of PREFER in Greece.

Keywords*: PREFER, burn scar, burned area mapping, validation, Greece, fire management, forest management*

Introduction

Every year Southern Europe is affected by numerous uncontrolled forest fires having large impact on the natural environment and the regional economies. PREFER project of the FP7 Space Theme aims to support forest fire preparedness and prevention as well as post-fire management for vegetation recovery. The project has the objective to develop an on line service for delivering a series of map products, that are based on the use of Earth Observation data from space-borne sensors, which may support the improvement of fire management in EU. Among the products are maps of scars caused by forest fires that are produced using complex remote sensing techniques and image processing algorithms.
PREFER is designed to improve systematically the current capacity of mapping burnt areas both in terms of area threshold (EFFIS' current thresholds are 40 ha in Rapid Fire and ca.10 ha in Fire Damage assessment modes) as well as in terms of spatial resolution (currently 250m in Rapid Fire and 30-50m in Fire Damage assessment modes, respectively). The need of systematic mapping at much higher resolution combined with the task of managing large number of fires in real time require improved process automation and robust solutions for operational burn scar mapping at national or regional level. The high accuracy of mapping burn scars allows assessment of fire affected areas to become operational.

The problem targeted

In recent decades, a higher frequency of wildfire in mid- and high latitudes has been observed, partly as a result of climate warming. Burn scar refers to areas that are destroyed by forest fire, grass fire and controlled burning and have not yet recovered (Liu *et al*, 2014). To assess and estimate the impact of the fire on forest ecosystems, the area of the burn scars, as the most significant parameter for running post-fire models, has to be acquired (Vafeidis and Drake 2005). At this stage, the task of burn scar identification and mapping is undertaken mainly through analysis of remotely sensed data. Multi-temporal satellite data provide several interpretative advantages over single date data for mapping

burned areas (Pereira *et al*. 1997, 1999, Eva and Lambin 1998). These include a reduction in the likelihood of spectral confusion with spectrally similar static land cover types, the option to use relative rather than absolute changes in spectral values to account for spectral differences between pixels and dates, and the opportunity to define the date of burning more precisely.
The underlying problem for most of the burn scar mapping methods is that each of them can only capture limited aspects of burned vegetation, but very few of the methods can comprehensively examine as many aspects as possible, through which a more reliable result should be achieved. Another problem with existing burn scar mapping methods is the difficulty in choosing an optimal threshold. However, it has been noted that fixed threshold methods performed poorly for varying atmospheric effects and different land covers (Barbosa *et al*., 1999).
The Burn Scar mapping capacity is particularly challenging in areas with limited visibility because of persistent cloud cover, haze and/or smoke (G.Laneve and G.Cadau, 2006). Such cases require the development of robust mapping techniques based on X-band (Cosmo-SkyMED, TerraSAR-X) very high spatial resolution data and C-band (Radarsat-2 and the forthcoming ESA Sentinel-1) Synthetic Aperture Radar data. Three different products namely Burn Scar Map HR Optical at scale 1:25,000-1:50,000, Burn Scar Map HR SAR at scale 1:10,000-1:50,000 and Burn Scar Map VHR at scale 1:2,000-1:5,000 are produced using the multi-patented (B.Hirn and F.Ferrucci 2003 and 2006) procedure called MYME2 (B.Hirn and F.Ferrucci, 2005), based on Pseudo Invariant Targets (PCT/IT04/000376,WO2005/005926A1,EP/1642087).
The accuracy and quality of the burn scar layers, which are produced following the above mentioned automatic procedures, have to be tested and validated in order to verify the performance of the algorithms and the accuracy of the approach adopted for the development of the relative products.

Methodology

The objective of the validation is to identify any systematic deviation between burn scar mapping and real data based on observations as well as to identify eventual false detected fire spots in order to investigate the source of the errors and potentially improve or document the performance of the PREFER algorithms and the data processing techniques.

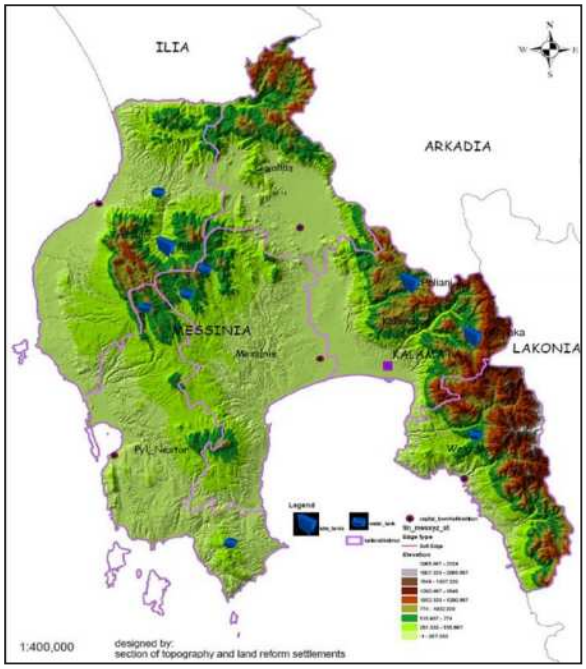

Figure 1. Pilot area of PREFER project in Greece (Messinia Region)

The validation of the burn scar product includes comparison of the data layers produced by the automated PREFER techniques and the MYME2 procedures against field observed or ancillary and archived fire data in the pilot areas of PREFER established in all the Mediterranean EU countries. The Greek pilot area (Figure 1) for the PREFER project, where the PREFER burn scar mapping products are validated, is the region of Messinia in Peloponnesus (Greece). Furthermore PREFER results are compared with data delivered by other automated burned area mapping services.
Mountainous areas cover the northern and eastern part of the Greek pilot area although low forest vegetation is spread in the entire region. Forest fire problem is quite significant in the region, which suffered severe damages during the mega-fires of 2007 in Peloponnesus.
For the map validation, fire data and burned scar maps provided by IESC were considered. The assessment was done during ground survey conducted the autumn of 2013. The survey referred to the burned areas of the year 2013 while for the previous years (2009-2012), fire data from the files of the Forest Service, the Hellenic Fire Corps and the Messinia Regional Administration services were used.

Figure 2. Missed fire (left), false fire (center) and properly detected fire (right) in the Greek pilot area of PREFER

The validation methodology of the burn scar mapping includes both qualitative and quantitative aspects. Missed fires (not detected) and false fires (detected without being verified in the field or the fire records) define the qualitative aspects of the validation methodology (Fig.2). Assessment of the accuracy of the burned area and calculation of the fire perimeter are considered as quantitative aspects of the metthodology (Fig.3). Burn scar mapping data can be compared with GPS measurements on the

ground and field collected data in case of recent fire (before the rain period start) as well as with fire records in case of past fires, in which case fire trace are lost.

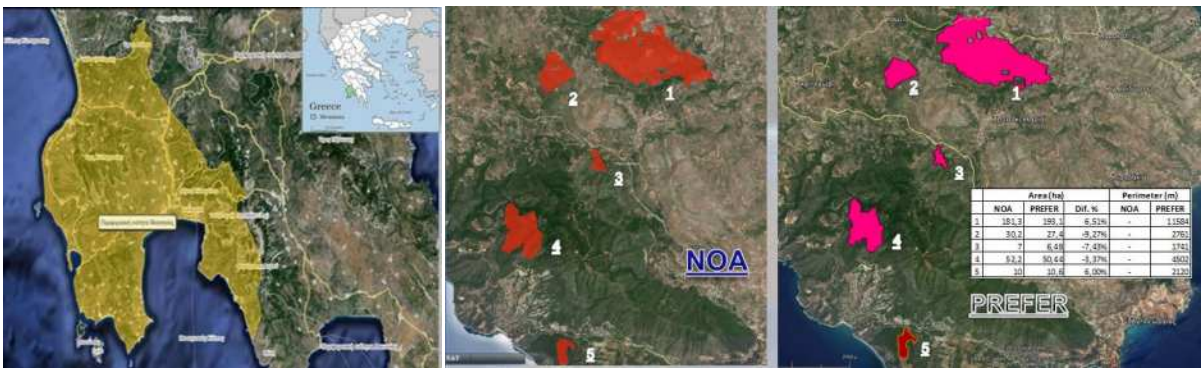

Figure 3. Greek pilot area of PREFER (left) and comparison of PREFER Burn Scar Map (right) and Diachronic BSM of NOA (center)

Vector data of the burned areas within the reference period (2009-2013) were collected from the Forest Service and compared with the produced burn scar maps of PREFER.

Interviews with potential stakeholders of the specific PREFER product are organized in order to ensure the user acceptance concerning the accuracy of the product as well as for collecting feedback concerning the final design of the burn scar maps that will be delivered by the on-line service of PREFER.

Main results

Although the validation task shall continue for the next years, preliminary results show that the PREFER algorithms perform quite well and the results of qualitative validation against the 2013 fires are very accurate. Some minor issues that identified concerning past fires need to be checked further since they may be influenced by the reliability of the fire records kept by the public services.

The length of time that the spectral signature of the burned area is detectable after the fire depends on the physical evolution of the post burn surface (vegetation regrowth, dissipation of ash and charcoal by wind and rain). Thus the dates of the satellite images can be important in particular towards the beginning and the end of the fire season. Similarly distinction among scars due to vegetation loss caused by forest fires and vegetation loss caused by other factors (eg forest area clearing) shall be further investigated.

A first quantitative comparison of the results against records of the forest service show that the accuracy of areal extent ranges between 73% and 92%. In any case the estimation of the relevant PREFER service is more accurate than other automated products tested in the same region in the past. Furthermore the burn scar mapping product of PREFER need to be designed properly in order to fulfill the operational requirements of the potential end users (Forest Service, Fire Service, Environmental organizations, Local and Regional Authorities) distinguishing among wildfires and prescribed fires in agricultural areas. Finally product availability, continuity and cost issues shall be considered in context of the PREFER service exploitation plan.

Conclusions

The results of the validation of the burn scar mapping products of the PREFER portfolio of EO-based maps are quite encouraging. The product specifications and its accuracy are suitable for addressing the operational fire management needs. Further validation and redesign of the product format in context of the PREFER service will be required. Relevant inputs from the respective stakeholders' groups are

currently collected in order to document thoroughly the required performance of the relative technique and procedures as well as for shaping properly the product in order to be acceptable by competent end users.

Abstract
This work presents an automated regional algorithm that allows detecting burned areas in Brazil based on information from TERRA/AQUA MODIS data. The procedure relies on the so-called W burning index, that requires daily reflectance from the 1km MODIS Level 1B calibrated radiance from bands 2 (near infrared) and 20 (middle infrared). Burned pixels are first identified as those located in the neighbourhood of active fires and associated to values of W and temporal changes in W larger than a fixed threshold. Pixels in the neighbourhood of the previously identified ones are then tested as burned ones based on contextual tests performed on associated values of W and temporal changes in W. Validation of results was performed over Cerrado region using high resolution burned area maps derived from Landsat imagery, paying special attention to the omission and commission errors. For comparison, validation of NASA/MODIS burned area products MCD45A1 and MCD64A1 is also carried out over the same area. Results from the new algorithm present considerably lower omission error when compared to NASA/MODIS products. The two NASA products present very low commission errors (ranging from 2 to 10%) but they are affected by very high occurrence of omission errors (greater than 60% in almost all cases analysed). The new product has larger commission errors (ranging from 20 to 40%) but a large fraction of those (more than 40%) occur at the borders of the scars and may therefore not be strictly viewed as false alarms; there is also a clear reduction of the omission cases (below 40% in all cases).

Keywords*: Burned areas, MODIS, remote sensing.*

Introduction

In Brazil, the conversion of vegetation into pasture and agricultural land using fire practices is a key source of greenhouse gases and trace gases to the atmosphere. Besides, lower moisture conditions enable the use of fire as a tool for land management during the dry season. Furthermore, fire used for burning crops and pastures frequently goes beyond control affecting neighbouring vegetation and becoming a major concern due to the potentially vast area of vegetation affected.
Despite the explicit vulnerability for fire of Brazilian ecosystems, together with the unequivocal need for reliable fire information, to the best of our knowledge hardly any products were developed to operationally monitor burned area in the Brazilian ecosystems. This issue is of particular interest since the accuracy of burned area (BA) maps is closely related to the specific characteristics of a given region (e.g., pre-fire land-cover type and conditions, background soil, fire severity, post fire processes and atmospheric conditions).
The aim of the present work is to develop an automated regional algorithm that allows detecting burned areas in Brazil based on information from TERRA/AQUA MODIS data. The procedure relies on the so-called W burning index (Libonati *et al*., 2011), that uses daily reflectance as obtained from the 1km MODIS Level 1B calibrated radiance from band 2 (near infrared - NIR) and band 20 (middle infrared - MIR). Burned area pixels in the images are first searched in the neighbourhood of active fires, selecting the pixels where specific thresholds of W and of temporal W changes are exceeded. Pixels in the neighbourhood of the previously identified ones are then considered as burned pixels based on contextual tests performed on associated values of W and respective temporal changes. Validation of

results is performed over Cerrado region using high resolution BA maps as derived from Landsat imagery, paying special attention to the omission and commission errors. For purposes of comparison, a similar validation of NASA/MODIS BA products MCD45A1 and MCD64A1 is also carried out over the same area.

Data

Calibration data consist of top of the atmosphere (TOA) values of MIR radiance, NIR reflectance and thermal-infrared (TIR) brightness temperature, as acquired by the MODIS instrument on-board TERRA and AQUA satellites. Data were extracted from the TERRA/AQUA MODIS Level 1B 1 km V5 product, MOD021/MYD021 (MCST, 2006) and correspond to channels 2 (NIR, centered at 0.858 μm), 20 (MIR, centered at 3.785 μm) and 31 (TIR, centered at 11.017 μm). Geolocation data as well as land/sea mask and solar and view angle information for each MODIS 1-km sample were obtained from the MODIS Geolocation product (MOD03 and MYOD03). Both MODIS Level 1B 1 km V5 and MODIS Geolocation products were obtained from the Image Generation Division (DGI) of the Brazilian National Institute for Space Research (INPE). DGI/INPE is responsible for, among other satellites and sensors, the reception, processing and distribution of MODIS images acquired by TERRA and AQUA satellites and the products are made available in Hierarchical Data Format (HDF) format. It may be noted that all MODIS products mentioned above are also free available via the MODIS website.

Information about active fires was based on data provided by GOES, NOAA, MSG-2, TRMM, ATSR, AQUA and TERRA satellites. Data were acquired from INPE active fire database.

Results obtained in the present work were compared with reference BA data as derived from Landsat TM imagery over Jalapão, a region located in the state of Tocantins (Figure 2). The BA scars dataset was derived using a semi-automatic algorithm developed at INPE and the results were verified by independent analysts. The methodology is based on multi-temporal compositing of Landsat imagery and priority is given to select cloud free images less than 32 days apart. The periods covered by the BA dataset July-August 2005, June-September 2006 and June-September 2010. The study region covers about 187 x 187 km^2 and lies within Landsat TM paw/row 221/67. The region belongs to the Cerrado biome and has been increasingly affected by fire in the last years. For instance, during the 2010 dry season, Jalapão has accounted for 60% of all fire events detected in the Cerrado biome.

Results were further compared with those from the two MODIS BA official products namely the MCD45A1 Burned Area Product (Roy *et al*., 2005) and MCD64A1 Direct Broadcast Monthly Burned Area Product (Giglio *et al*., 2006). MCD45A1 and MCD64A1 BA products were freely downloaded from the University of Maryland ftp sites. Tiles for the two BA products over Brazil between 2005 and 2010 were then mosaicked and remapped using the Modis Reprojection Tool.

MCD45A1 is a monthly Level 3 gridded 500 m product containing per-pixel burning and quality information, and tile-level metadata. Quality information is given using five confidence levels of detection from 1 (most confident) down to 4 (least confident). Confidence level 5 denotes detections over agricultural areas, as identified by the MCD12 land cover mask. As stated in MODIS Collection 5.1 - Burned Area Product - MCD45 User's Guide, level 5 detections should not be used in any quantitative analysis because of the low accuracy of BA detection when fire is due to agricultural practices. The MCD45A1 Science Data Sets used in our analysis include all quality assurance flags from 1 to 4.

MCD64A1 is globally available on a monthly basis back to August 2000 at 500m resolution. The MCD64A1 Direct Broadcast Monthly Burned Area Product is currently used in the framework of the Global Fire Emissions Database (GFED) initiative and will replace MCD45A1 in the upcoming MODIS Collection 6. Among the five data layers from MCD64A1, only the Burn Date was used in our study, as this product does not have flags containing confidence levels.

Methods

3.1. Pre-processing

Values of MIR reflectance were retrieved from MODIS channel 20 (MIR) radiances by applying to daytime imagery the methodology developed by Kaufman and Remer (1994) and using TIR (MODIS channel 31) brightness temperature as a surrogate for land surface temperature. Following Libonati *et al*. (2011), special attention was paid to the presence of high solar zenith angles (SZA), all images acquired at solar zenith angles greater than 55° having been rejected. When TERRA and AQUA images were both available for the same day, the image selected was the one with the lowest SZA. Images with view zenith angles (VZA) greater than 45° were also rejected in order to prevent large distortions in pixel size. Pixels associated to water bodies were also masked using the land/sea mask from the MODIS Geolocation product (MOD03, MYD03).

As discussed in Libonati *et al*. (2011), burned surfaces tend to have values of W very close to zero, especially shortly after the fire event, whereas green vegetation tends to be characterized by higher values of W (about 0.3). Intermediate values of W generally correspond to vegetation of small density and/or to the emergence of the soil background. Clouds and cloud shadows are often associated to high values of W (greater than 0.4). We have accordingly rejected pixels associated to W values greater than 0.4, which were flagged as contaminated by clouds/shadows.

3.2. Temporal composites

Multi-temporal image compositing is an operational means of mitigating the gap of information about the land surface due to the presence of cloudy pixels which is especially high in the tropics (Sousa *et al*. 2003). Compositing also contributes to reducing the daily reflectance variability and residual atmospheric effects (Holben *et al*., 1986). Compositing techniques have been therefore widely used for BA detection (Barbosa *et al*., 1998; Stroppiana *et al*., 2002; Sousa *et al*., 2003; Stroppiana *et al*., 2003; Chuvieco *et al*., 2008).

Following these approaches, monthly minimum composites of W were computed, the chosen span of one month representing a compromise between the need to retain the burned signal and the requirement of having a reasonable number of pixels to generate a meaningful minimum value of W.

3.3. Selection of burned pixels (stage I)

Identification of burned pixels is performed in two stages. First (stage I), the analysis is restricted to pixels belonging to 3x3 pixel buffer zones centred in pixels where active fires were identified during the compositing period. Information on active fires is extracted from the INPE database (see http://www.dpi.inpe.br/proarco/bdqueimadas/) as obtained from data provided by GOES, NOAA, MSG-2, TRMM, ATSR, AQUA and TERRA satellites. The defined buffer may be viewed as an area of influence/coverage of the identified active fires, taking into account that we are using data with different spatial resolutions (e.g. 3 km for MSG/SEVIRI, 1 km for TERRA/MODIS).

As pointed out by Giglio *et al*. (2006), algorithms aiming at BA detection based on active fire detection (Roy *et al*. (1999), Fraser *et al*. (2000), Pu *et al*. (2004), George *et al*. (2006), Loboda *et al*. (2007)) may fail to uncover burned areas due to active fire omissions either because of the time of satellite overpass or due to obscuration by clouds, smoke and vegetation. Schroeder *et al*. (2008) have quantified the impact of cloud obscuration on GOES active fires in the Brazilian Amazonia. They showed that in some regions 15% of GOES active fires were omitted due to cloud cover. When assessing fire continuity over time and space, Schroeder *et al*. (2005) suggest the integration of multiple datasets in order to reduce the uncertainties in fire counts when derived using a single system. Giglio *et al*. (2009) also pointed out that BA detection may benefit from the fusion of multi-sensor active fire observations. We therefore believe that the problems associated to active fire omissions are considerably mitigated by relying on information on hot spots from a collection of sensors on board different satellites.

Pixels in the 3x3 buffer zone are then classified as burned ones when there is a change in W between monthly composites that is likely to have been induced by a fire event. It is worth mentioning that in stage I, such changes in W have to be large enough so that possible contaminations by active fire commission errors (false alarms) is substantially reduced.

Let W1 and W2 be the values of W for a given pixel in two successive monthly composites. This pixel is considered as burned if the following conditions are all fulfilled:

I. the pixel belongs to a 3x3 pixel buffer;

II. $W2 \leq 0.16$;

III. $\Delta W = W2 - W1 \leq 0.0$.

Estimates of thresholds of W2 and ΔW were obtained by applying classification trees using observed values of W2 and ΔW for burned and unburned pixels in a sample of around 25,000 MODIS pixels covering Amazonia and Cerrado. Figure 2 shows maps of W for September 2005 composite (left) and of ΔW for differences of W composites between September and August over the study region. It may be noted that areas affected by fire present values of W well above the prescribed threshold of 0.16 together with negatives values of ΔW.

3.4. Selection of burned pixels (stage II)

Stage II of the selection procedure aims at identifying pixels that although presenting less intense signals in either W or ΔW are likely to be burned ones because of their vicinity to pixels already classified as burned. The weaker radiometric signal may be due to partial burning or to low fire severity. The procedure consists in the following steps:

I. L*et al*l pixels classified as burnt pixels in stage I be considered as seed points;

II. For each seed point, let N be the total number of seed points inside a grid of 5x5 pixels centred at the considered seed point; in case N>=3, let $\hat{W}$ and δW be the mean and the mean absolute deviation of seed points within the grid. Let W* be the value of W for a pixel inside the grid that is not a seed point; this pixel is then classified as a burned pixel and considered as a new seed point if the two following conditions are fulfilled:

   a. $\Delta W^* = W^*2 - W^*1 \leq 0.0$

   b. $W^* \leq \hat{W} + (\delta W)$

III. Step II is recursively performed until no new seed points are generated.

IV. The burned area is obtained by summing up all identified burned pixels.

Figure 3 presents an example of the procedure. It may be noted that most burned pixels are identified in stage I, using the most restrictive criteria; then, during stage II, the number of added burned pixels steeply decreases with the number of iterations.

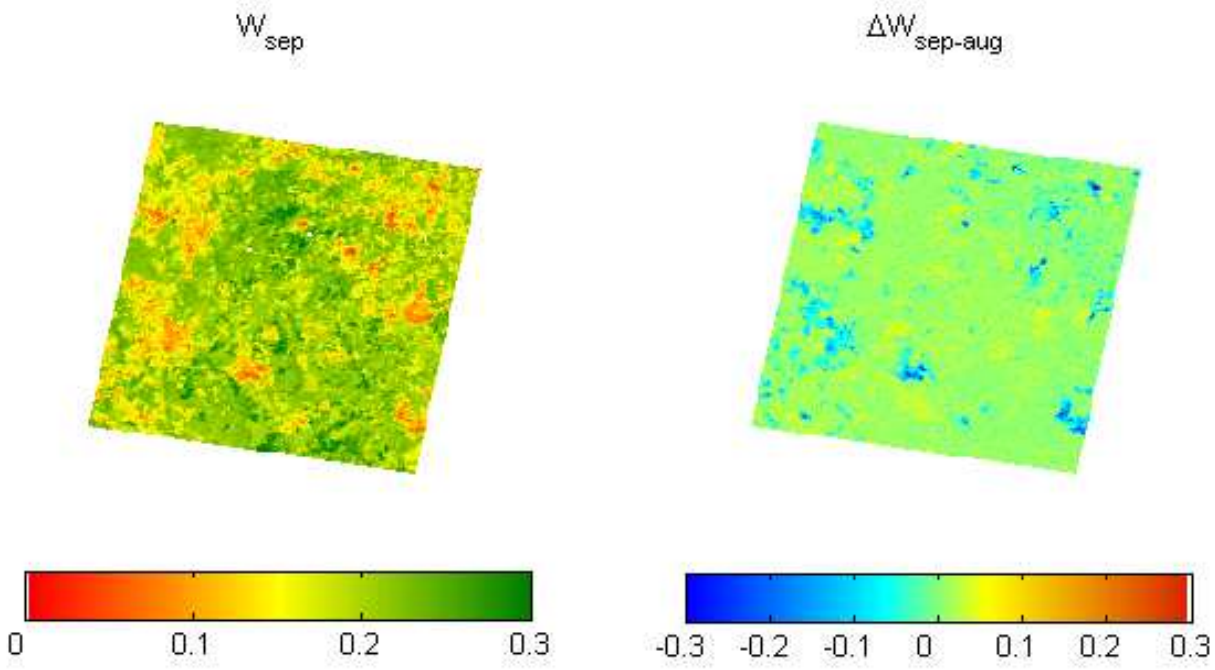

Figure 2. Maps of W for September 2010 composite (left) and of ΔW between September and August composites over the study region shown in Figure 1.

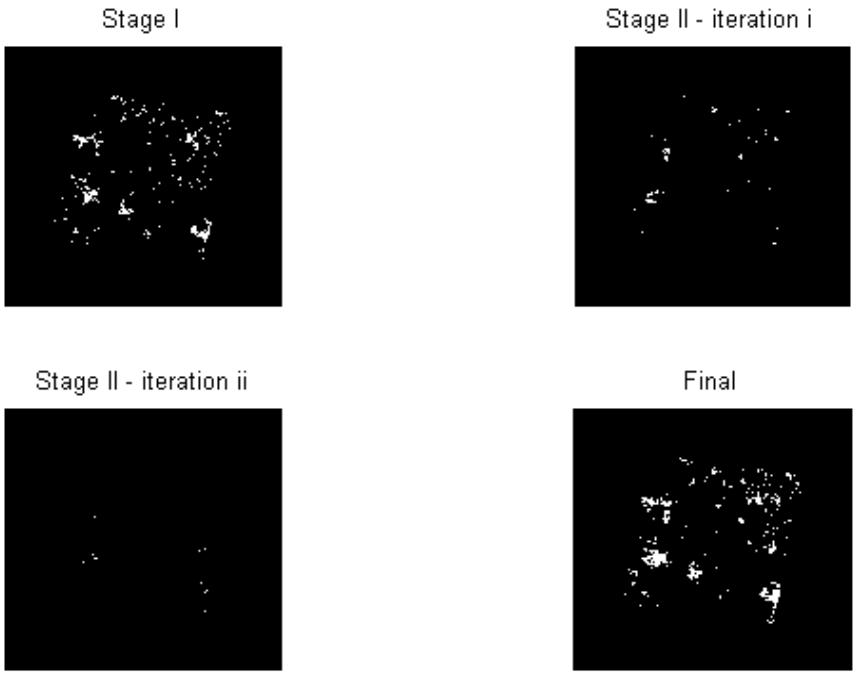

Figure 3. An example of results obtained during stages I and II of the algorithm.

Validation

The quality of a given thematic map derived from remote sensing is usually assessed based on a systematic comparison with other maps (reference maps) also derived from remote sensing. The evaluation is often made based on contingency tables, also known as confusion or error matrices (Story and Congalton, 1986; Smits *et al*., 1999; Foody, 2002). Contingency tables (Table 1) provide a very effective means to analyse the number of correctly and incorrectly classified pixels over a study region. The quality assessment will rely on the following four verification measures that may be derived from contingency tables:

1. The overall accuracy (OA), defined as the fraction of correctly classified pixels, either as burned or unburned:
   $OA=(a+d)/(a+b+c+d)$ (1)

2. The omission error (OE), defined as the fraction of burned pixels in the reference map that were not classified as such in the BA product:
   $OE=c/(a+c)$ (2)

3. The commission error (COE), defined as the fraction of pixels classified as burned in the BA product that are unburned pixels in the reference map:
   $COE=b/(a+b)$ (3)

4. The bias (B), defined as the ratio of the number of pixels classified as burned in the BA product to the number of burned pixels in the reference map:
   $B=(a+b)/(a+c)$ (4)

Whereas OA reflects the agreement between the BA product and the reference map, OE and CE provide information about the reliability and discrimination power of the developed classifier. An unbiased classification exhibits in turn a value of bias equal to one, whereas a bias greater (less) than one indicates the events were over (under) classified.

Table 1. Contingency table for the dichotomous case of pixels classified as burned vs. unburned over a given study region. The total number n of pixels number of pixels is split into four categories with number of occurrences given by a, b, c and d.

		REFERENCE MAP		
		Burned	Unburned	
BA PRODUCT	Burned	a	b	a+b
	Unburned	c	d	c+d
		a+c	b+d	n=a+b+c+d

The traditional contingency table assumes that each pixel belongs to a single class; however, several studies (Foody, 1996, 2002; Gong and Howarth, 1990; Karaska *et al*., 1995) have shown that use of pure pixel approaches is a common source of error in the accuracy assessment of remote sensing products, since reference maps generally have higher resolution than the map being tested. As shown by Binaghi *et al*. (1999), the problems posed by mixed pixels may be circumvented by using fuzzy theory, which allows each pixel to belong to multiple classes with different degrees of membership.
In the present work, the agreement/disagreement between the Landsat TM reference data (30 m resolution) and either our product (1 km resolution) and MODIS MCD64A1 and MCD45A1 products (500 m resolution) are computed taking into account the proportion of BA from reference data within the product pixel. This approach is based on the work by Boschetti *et al*. (2004) who pointed out the need of taking into account the percentage of BA in each pixel of the coarse product when comparing coarse and high resolution BA maps. For instance, if a pixel is classified as burned by the BA product and has 60% of BA from reference data, so this pixel will have a proportion of 0.6 as true burned and 0.4 as commission error (as opposed to a weight of 1 as true burned and 0 as commission error that would be assigned following the traditional approach). In the same way, if a pixel is classified as unburned by the BA product and has 20% of BA from reference data, so this pixel will have a proportion of 0.8 as true unburned and 0.2 as omission error of the non-occurrence. This kind of approach seems to be fairer to the computation of the measures accuracy than the traditional one, since it takes into account the real proportion of reference burned pixel within the product pixel. Recently, Padilla *et al*. (2014) and Tsela *et al*. (2014) have conducted similar approaches when validating algorithms for global BA.

Results

The very own characteristics of the BA product based on the above-described algorithm, hereafter referred to as AQM (from "área queimada", meaning burned area in Portuguese) may be brought into evidence by comparing its performance with the ones of MODIS MCD64A1 and MCD45A1 products. As described in section 3.3, performance of the three products was validated against a reference map of burned scars derived from Landsat TM using verification measures derived from confusion matrices where a mixed-pixel approach is followed that takes into account the proportion of the BA from reference data within the pixel. The same procedure was applied to AQM and the two MODIS global

products. As described in section 3.1, the study was conducted over Jalapão, for a period of 3 years (2005, 2006 and 2010).

In general, the overall accuracy (OA) for MCD64A1 and MCD45A1 BA products is slightly higher than for AQM (Figure 4); it may be however noted that OA satisfies the principle of equivalence of the events (Wilks, 2006), giving equal credits for burned and unburned classes. This property is not always desirable, particularly in the case of BA detection studies where the burned event is more relevant than the non-occurrence event (unburned event). Both MCD64A1 and MCD45A1 products present very low values of CE but they are affected by quite high values of OE; the two NASA BA products appear therefore as conservative in the sense that a low level of false alarms is attained at the cost of quite high occurrence of omission cases. The AQM product presents in turn a rather low value of CE together with a clear reduction of OE that reflects a higher probability of detection of burned pixels. Finally, the AQM product presents an unbiased behaviour (B~1), whereas the NASA BA products tend to underestimate the number of pixels classified as burned in the reference map (B<1).

A better insight into the different characteristics presented by AQM and the two NASA BA products is obtained by looking at the characteristics of pixels correctly classified as burned areas (hits) or contributing to omission and commission errors (Table 2), as obtained when comparing AQM and MODIS MCD64A1 and MCD45A1 versus reference map of burned scars derived from Landsat TM over Jalapão in 2005, 2006 and 2010. Corresponding fractions of pixels located inside (I), on the external border (B) and outside (O) the reference scars were also computed and, for hits and omissions, evaluations were also made of the fractions of low burned pixels (L), i.e. those covered less than 50% by burned areas in Landsat reference map and of high burned pixels (H), i.e. those covered more than 50% by burned areas.

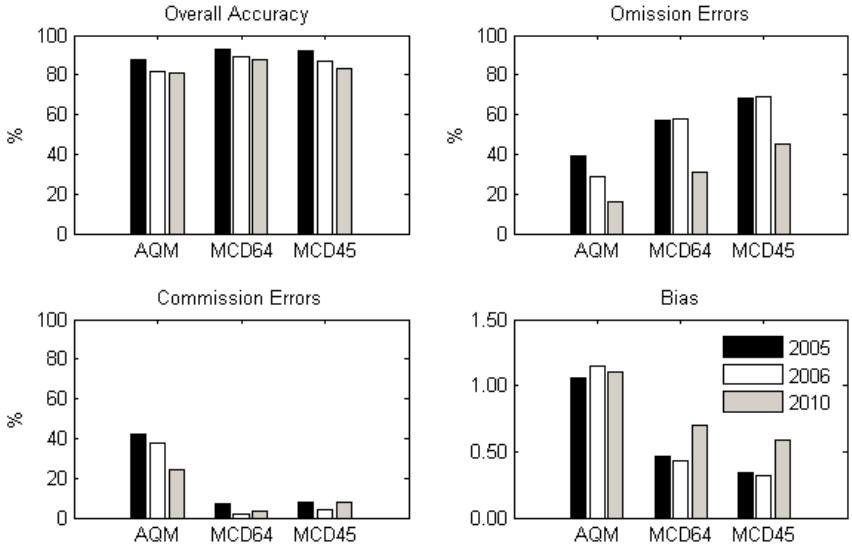

Figure 4. Verification measures as obtained from confusion matrices of AQM and MODIS MCD64A1 and MCD45A1 versus reference map of burned scars derived from Landsat TM over Jalapão in 2005, 2006 and 2010.

As shown in Table 2, for all three products the large majority of hits is associated to pixels located inside burned scars, but the AQM is able to correctly identify a substantially larger number of burned pixels, 30% of them located in the external borders of the scars (an amount quite larger than those by the NASA products that are below 20%).On the other hand, the AQM product is able to correctly identify as burned 43% of pixels with low fraction of burned area (less than 50%), an amount that is more than the double of that by MCD64A1 (21%) and almost the double than that by MCD45A1 (23%). The AQM product presents a substantially lower number of omission errors than the NASA

products, but for all three products the larger fractions are associated to pixels located in the borders of scars and to pixels with low fraction of burned area (less than 50%). The very large number of commission errors by AQM also presents a large contrast with the very low number by the two NASA products; however, more than two fifths of commission errors in AQM are associated to occurrences in pixels located in the borders of the scars suggesting that they are not to be viewed as 'false alarms' in the strict sense, but as an overestimation of the size of the real scars. This problem is likely to be associated to errors in geo-referencing of a small number of MODIS images that propagate into the multi-image composites. Obtained results may be visually confirmed in Figure 5 that shows pixels where true burned areas were detected (green), together with omission (blue) and commission (red) errors from AQM (left) and MCD64A1 (right) in Jalapão during 2010. The AQM product shows higher probability of detection of burned pixels, i.e. lower OE than MCD64A1 that presents a higher value of OE and a very low value of CE. A large fraction of pixels with commission errors in AQM are located in the external borders of the scars (delimited by the black lines).

Table 2. Number of hits, omission errors and commission errors when comparing AQM and MODIS MCD64A1 and MCD45A1 versus reference map of burned scars derived from Landsat TM over Jalapão in 2005, 2006 and 2010 together with corresponding fractions of pixels located inside (I), in the external border (B) and outside (O) the scars in reference maps and, for hits and omissions, the fractions of low burned pixels (L), i.e. covered less than 50% by burned areas in Landsat reference map and of high burned pixels (H), i.e. covered more than 50% by burned areas.

	Hits	Omissions	Commissions
AQM	15961 I=70%; B=30% L=43%; H=57%	12649 I=42%; B=58% L=64%; H=36%	7466 O=59%; B=41%
MCD64A1	9492 I=82%; B=18% L=21%; H=79%	19118 I=46%; B=54% L=67%; H=33%	325 O=51%; B=49%
MCD45A1	7132 I=81%; B=19% L=23%; H=77%	21478 I=50%; B=50% L=62%; H=38%	545 O=43%; B=57%

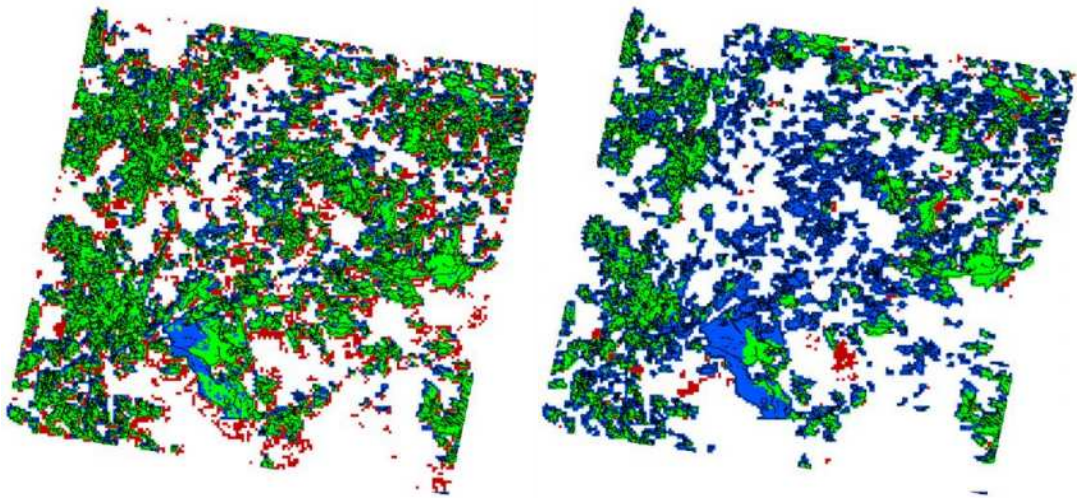

Figure 5. Maps showing pixels where true burned areas were detected (green), together with omission (blue) and commission (red) errors. TM reference scars (black lines) are superimposed. Results shown are those obtained from AQM (left panel) and MCD64A1 (right panel) over Jalapão in 2010.

As shown in Table 3, during the three years analysed the area of study was characterized by high frequency (87-90%) of small scars (<100ha) that accounts for a small percentage (8-19%) of the total BA. Large scars (> 1000ha) are rare (1-2%) but they account for a large amount (42-64%) of the total BA. As opposed to regions where large scars are predominant, low resolution instruments will tend to underestimate BA in regions where burned scars are small and fragmented. A large number of omission errors in therefore to be expected It is therefore to be expected in all three analysed products (Table 2) but, as already pointed out, the AQM is able to identify a larger fraction of low burned pixels than the NASA products. The AQM product appears therefore as more sensitive to sub-pixel burned areas, even when working at a lower spatial resolution (1km) than the NASA products (500m); this is probably due to the use of MIR reflectance by the algorithm.

Table 3. Fractions of total number of scars and of total burned area for three classes of scars as derived from Landsat TM data over Jalapão in 2005, 2006 and 2007.

	Classes	Fraction of total number of scars	Fraction of total burned area
2005	<100ha	90%	16%
	100-1000ha	9%	38%
	>1000ha	1%	46%
2006	<100ha	89%	19%
	100-1000ha	10%	39%
	>1000ha	1%	42%
2010	<100ha	87%	8%
	100-1000ha	11%	27%
	>1000ha	2%	64%

Conclusions

An automated regional algorithm able to detect burned areas in Brazilian biomes was developed using information from MODIS imagery at 1km resolution. The algorithm relies on the so-called W burning index that is defined in a transformed NIR-MIR space. Pixels are classified as burned ones when there is a change in W between 30-day composites that are likely to have been induced by a fire event. Identification of burned pixels is performed in two stages. First, the algorithm is restricted to pixels belonging to buffer zones centred in pixels where active fires were identified from a variety of sensors on-board geostationary satellites and polar orbiters. Then the algorithm is successively applied to pixels in the vicinity of pixels that were classified as burned.

The resulting AQM product was validated against reference maps of scars derived from Landsat TM images over a study region located in the Cerrado biome. For purposes of performance assessment, two operational NASA products, MCD64A1 and MCD45A1, were also validated against the same reference maps. Because the products to be validated have different spatial resolutions than that of reference maps (e.g. AQM with 1km and Landsat scars with 30 m), the error matrix was estimated following a new approach based on the assumption of mixed pixels, where the agreement/disagreement between product and reference data are computed taking into account the proportion of BA from reference data within the product pixel.

The two NASA products present very low commission errors (ranging from 2 to 10%) but also very high occurrence of omission errors (greater than 60% in almost all cases analysed). The AQM product has larger commission errors (ranging from 20 to 40%) but a large fraction of those (more than 40%)

occur at the borders of the scars and may therefore not be strictly viewed as false alarms; there is also a clear reduction of the omission cases (below 40% in all cases).
Performance of the AQM product may be attributed to two main factors. On the first hand, the usage by the algorithm of the W index, that was specifically designed to identify burned areas and takes advantage of the ability of MIR reflectances to discriminate burned areas. On the second hand, the usage of multiple sensor active fire observations that considerably contribute to mitigating the problem of failing to uncover BA due to active fire omissions either because of the time of satellite overpass or due to obscuration by clouds, smoke and vegetation. It is worth mentioning that active fire information from NPP/VIIRS (which is being disseminated by INPE since 25/09/2013) is also planned to be introduced operationally in the algorithm, contributing to increase the spatial and temporal coverage of fire observations.
The AQM approach is currently in pre-operational phase at INPE and additional tuning experiments are currently being carried on. More validation sites are also being developed at INPE using Landsat TM imagery that will allow performing accuracy assessments of the algorithm for different biomes.

Abstract
Delays in the initial attack of new fire starts can happen locally when two or more fires burn simultaneously. The occurrence of multiple-fire-day situations may pose a real problem if suppression resources are limited, which almost always are. We analyzed multiple-fire-days in Galicia (Spain) from 2002 to 2005 with the goal of predicting these multiple fire situations by using Artificial Neural Networks. We carried out two types of analysis with our seasonally-structured data: to identify the relevant variables in the multiple versus single daily outcome (classification problem) and to predict the number of fires within the multiple-fire-days observations (prediction problem). The accuracy for the best Spring model was around 59-60% which located multiple occurrences in higher altitudes and public forest properties, near roads and recreation areas, with lower temperatures, lower quantity of pastureland and higher FFMC. Best classifications for the Summer period were around 60-61% and associated multiple fires to lower elevation areas, higher proportion of public and communal forests, near roads and higher drought indices. Predictions of actual number of fire occurrences in the Spring period reached 62% accuracy with a similar variables selection as the Spring classification model. Predictions for the Summer period lacked accuracy (44-50%) suggesting more complex patterns, probably due to mixed causes.

Keywords*: Artificial Neural Network, Daily Fire Prediction, Human-caused fires, Simultaneous fires*

Introduction

Short-term forest fire suppression performance depends on number and behavior of active fires (Haight and Fried 2007). Fire behavior is set by conditions in the fire environment that are difficult or impossible to control (fuels, weather, and topography), but numbers of ignitions in many countries, and particularly in the Mediterranean, are linked to human risk. Delays in the start of initial attack of new fires can happen locally when two or more forest fires are burning simultaneously, and the time required to extinguish a forest fire grows exponentially with detection and response time. For fire suppression resources sufficient to manage one fire, the simultaneous occurrence of two, three or more fires do create a challenge (Rachaniotis and Pappis 2006, IAFC and NFPA 2010). Forest fire managers must make crucial decisions every day on the amount and the type of fire suppression resources required and their allocation. Budgetary constraints under rising fire extinction costs (Liang *et al.* 2008, Calkin *et al.* 2014) often prevent maintaining enough suppression resources to potentially manage all possible active fires in all subdivisions of a region (i.e. Galicia, Alonso-Betanzos *et al.* 2003). When worse-case scenarios occur, and unlikely high-risk peaks couple with favorable conditions for burning in the fire environment, available fire suppression resources stretch beyond planned levels and are overloaded.
The prediction of these rare days with multiple fire starts, or multiple-fire-days (MFD), would be useful to fire managers (De Haan 2006). There are many studies which have focused on deployment of suppression resources (from Simard and Young 1978 to Calkin *et al.* 2014), but only Kirsch and Rideout (2005) and Haight and Fried (2007) tried to incorporate the effects of a number of possible simultaneous fires, but without estimating a probability or modeling this process. Previous studies

which attempted to predict MFD occurrence relied only on daily weather data or danger indices by using a Poisson distribution (Martell *et al.* 1987), binary logistic models (Andrews and Bradshaw 1997) or non-linear models (Garcia Diez *et al.* 1994, 1996, 1999). Garcia Diez *et al.* (1994, 1996, 1999) analyzed data between 1986 and 1993 in Galicia, concluding that fires (all causes) were primarily related to unfavorable weather conditions (past- and present-day weather). Their best MFD prediction had an accuracy varying between 52 and 72% over their study period.

Although MFD may be associated in some countries (Canada, USA) with dry lightning storms (Rorig *et al.* 2007), in most countries they are associated mainly to human activity (Omi 2005, Tanskanen and Venäläinen 2008, IAFC and NFPA 2010). Arsonists often set several ignition points to increase damage before firefighters arrive (Omi 2005, De Haan 2006), as do farmers in agrarian traditional rural activities (i.e. pastoral use of fire to regenerate rangelands in the Mediterranean, Ruiz-Mirazo *et al.* 2012). Martell *et al.* (1987), Garcia Diez *et al.* (1994, 1996, 1999) and Andrews and Bradshaw (1997) only considered weather variables related to the biophysical fire environment in their MFD occurrence analysis and did not include human risk factors.

There are already an important number of research papers on the general topic of fire occurrence prediction and the analysis of human risk in the fire literature (from Crosby 1954 to Rodrigues *et al.* 2014) and in Spain (i.e. Lozano *et al.* 2007, Chuvieco *et al.* 2009, Vasilakos *et al.* 2009, Vilar *et al.* 2010, Padilla and Vega-Garcia 2011, Vilar del Hoyo *et al.* 2011, Rodrigues *et al.* 2014). Fire occurrence studies have dealt with socioeconomic (i.e. Martínez *et al.* 2009) or geographic factors and biophysical variables (Lozano *et al.* 2007), but the occurrence of multiple-fire-day situations has been rarely approached.

Our aim was to explore these relationships between human risk factors, biophysical variables and multiple fires caused by people on a daily basis, with a view to aid fire management to anticipate and locate potential fire suppression overload events.

Methods

Study area

The study area is the Autonomous Community of Galicia, the Northwestern region of Spain (Figure 1). Galicia encompasses around 3 million ha (6 % of the Spanish territory) near the Atlantic Ocean (North and East boundaries). The humid Atlantic climate provides an average annual rainfall over 1,200 mm that favors the rapid growth of vegetation, which would be grasses and broadleaved tree species in natural conditions. The Galician vegetation has been highly modified through time. Population is distributed over 3,000 towns with a higher concentration on the coast and forests, mainly located in rural areas in the interior, that have long been highly fragmented by this human impact. Forest ownership is private (33 % of forests) either individually (64 % private forest area) or communally (36%). About 40% of forests have artificial origin, as many properties were reforested after the 1950's with *Pinus pinaster* and *Eucalyptus globulus* for their high economic interests for the pulp and plywood markets. Historical evidence attests the use of pastures by livestock for at least 6000 years (Kaal *et al.* 2011) and livestock production is currently the most important economic activity in the region.

Galicia is the Spanish administrative region with the highest number of human-caused forest fires (HCFF) (MAGRAMA 2013). Between 2001 and 2010, 86,036 HCFF have occurred in Galicia, a 44.1 % of all human-caused forest fires accounted for in the country in the same period, and the trend appears to be growing in this Atlantic region of the Iberian Peninsula (Carvalho *et al.* 2010). Fires take place basically into two well-defined time periods, end of winter and summer (Marey-Pérez *et al.* 2010), and are linked to socio-economic activities and the traditional pastoral use of fire (Marey-Pérez *et al.* 2010, Torre-Antón 2010). The high mean annual number of fires, and the spatiotemporal clustering of part of these fires in MFD in Galicia, led to its selection as study area.

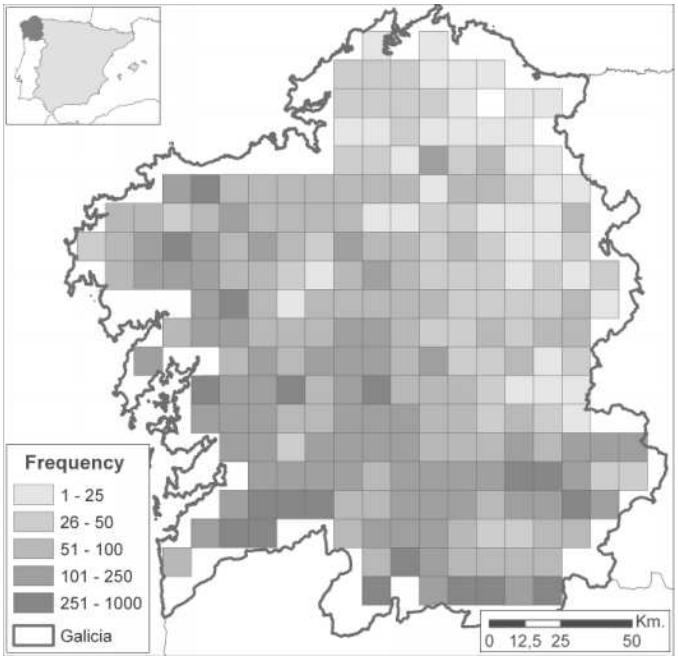

Figure 1. Galicia's location. This figure shows the human-caused forest fire frequency occurred during the period 2002 to 2005 in each of the 239 10x10 sq km UTM quadrates.

2.2. Study period

The data consisted on historical records of daily HCFF occurrences, daily weather data and geographic characteristics for Galicia in a 10x10 sq km UTM grid, for the period from 2002 to 2005. This period was restricted to four years due to data acquisition limitations (the spatially interpolated daily weather data available (Padilla and Vega-Garcia 2011)), but 4-5 years is the usual planning period for fire prevention in Spain.

2.3. Fire data

The Spanish fire history database (EGIF, 1983 – 2011) was provided by the Spanish Forest Service of the Ministry of Agriculture, Food and Environment (MAGRAMA). We extracted 28,442 HCFF records between 2002 and 2005 (both included) and summarized daily number of fires in a 10x10 sq km UTM grid for Galicia (19,612 observations). The grid consisted of 239 quadrates, after some irregular units in the coastal line were excluded in order to obtain a regular grid of equal-area (100 ± 1 km^2) quadrates. There was only one quadrate in which there was no fire in the study period. Though one fire occurrence per quadrate and day is quite common in Galicia (14,340 cases), MFD occurrences are rarer events (5,272 cases). In our study period, number of fires per day and quadrate ranged from 2 (3,354 observations) to 15 fires (just 1 observation).

The database was divided according to the seasonality of fires in Galicia (Marey-Pérez *et al*. 2010, Xunta de Galicia 2014). "Seasons" were defined by considering the daily frequency of the HCFF data, summarized by quadrate, and separating periods by minimum peaks of occurrence. Accordingly, the first period comprised from January 19th to May 11th (5,472 cases, 8,699 Spring fires), the second from May 12th to October 21st (13,735 cases, 19,248 Summer fires) and the third from October 22nd to January 18th (407 cases, 475 Winter fires). The third period had a very low number of records, so it was discarded for modeling.

We carried out two types of analysis with our data. Our first goal was the identification of variables that were relevant in the multiple (MFD) versus single (SFD) daily outcome. This classification analysis required coded data: SFD observations were coded as Y = (1, 0) (just one fire occurred in the day and quadrate) and MFD observations were coded Y = (0, 1) (more than one fire occurred in the

quadrate and day). In order to have a balanced database for analysis (Vega-Garcia *et al.* 1996) we randomly selected the same number of cases for SFD and MFD records. This database contained 3,532 records in Spring and 6,900 in the Summer seasonal period (10,544 observations in total, annual data). The second goal was to predict quantitatively the number of HCFF within the MFD observations. We randomly selected the same number of observations for each class in order to have a balanced database for analysis. We limited the minimum number of observations per class to 100 because an increase of the daily fire frequency diminishes the number of cases and the modeling errors could increase. The maximum number of classes to predict was 6 (X = 1, 2, 3, 4, 5 and more than 5 HCFF per quadrate and day) when working with all the data (annual data) and five (X = 1, 2, 3, 4 and more than 4 HCFF per quadrate and day) when working with the data for each seasonal period. The seasonal MFD databases contained 820 and 1,055 observations for the Spring and Summer periods, respectively.

2.4. Explanatory variables

Our explanatory variables (Table 1) were the same as in the study of daily HCFF occurrence in Spain by Padilla and Vega-Garcia (2011). The cartographic information on these factors came from the Biodiversity database of the Spanish Ministry of Environment. Weather was provided by the Department of Geography of the University of Alcalá with permission of Meteológica SA (Madrid, Spain). The geographic factors included forest land ownership and infrastructures; physiography was described by elevation, slope and aspect variability; vegetation was represented by the percentage occupied by each Rothermel's fuel model (1972) in the quadrate. The weather data included daily records of rainfall, temperature, relative humidity, maximum dew point temperature, wind speed at 12 hours UTC, solar radiation, presence of snow and cloudiness. The Meteorological Fire Danger Index Processor (MFDIP) described in Camia *et al.* (1998) was used to compute several fire danger rating indices widely used.

2.5. Methodological approach. Cascade correlation ANN

Artificial Neural Networks (ANN) models are a reliable alternative to traditional statistical methods, especially when dealing with large databases, non-linear systems (Scrinzi *et al.* 2007), not normally distributed variables (Hilbert and Ostendorf 2001) or highly correlated variables (Vega-Garcia and Chuvieco 2006). For a given database representing a set of historical events these algorithms are capable of identifying and fitting very complex non-linear patterns by iterative adjustment (Kuplich 2006). These models have been applied before to the study of forest fires (e.g. Vega-Garcia *et al.* 1996, Vasconcelos *et al.* 2001, Alonso-Betanzos *et al.* 2003, Vega-Garcia and Chuvieco 2006, Vasilakos *et al*. 2009) reaching good accuracies and good generalization capability, so ANN models were selected for this work in an attempt to gauge their potential in modeling MFD events.

As losing generalization capacity by overtraining a net is a common problem, it is customary to apply an *early stopping* procedure, based on the separation of the database in two subsets: one for training or "learning", and part (test set) used to control the evolution of error committed in this independent set, and stop training if the error starts to increase (Hasenauer *et al*. 2001, Jutras *et al*. 2009). Accordingly, before construction of the models the database was randomly split in two subsets: 70 % of the cases were used for the training process, and the remaining 30 % were used to test the progression of the iterative learning processes and to prevent overtraining of the models that might limit their generalization capacity. No independent validation dataset was segregated (100% cases were used for validation), as the models were designed to be explicative and not to predict future occurrences.

Table 1. Acronyms and abbreviations of each independent variable

Acronyms and Abbreviations	Variable	Acronyms and Abbreviations	Variable
Geographical variables		Geographical variables	
Human Risk Factors		Physiography	
Forest Land Tenure		DEM_MN	Elevation mean
FOREST_PV	Private	DEM_SD	Standard deviation of the elevation
FOREST_PB	Public	SLOPE_MN	Slope mean
FOREST_VC	Communal	SLOPE_SD	Standard deviation of the slope
FOREST_PR	Protected	ASPECT_VAR	Number of aspect classes
Infrastructure		Meteorological variables	
TOWN_DI	Distance to towns		
RECRE_DI	Distance to recreational areas	Raw weather variables	
RESER_DI	Distance to reservoirs	P24	Daily rainfall
ROAD_DI	Distance to roads	T_MAX	Maximum temperature
DENS_PO	Density of population	RH_MIN	Minimum relative humidity
		DewTmpMax	Maximum dew point temperature
Vegetation		WIND	Wind speed at 1200 hours UTC
Area occupied by each	Rothermel's fuel type (%)	SOLAR_R	Solar radiation
FUEL_01	Fuel type 1	CLOUD	Cloudiness
FUEL_02	Fuel type 2		
FUEL_03	Fuel type 3	Fire danger rating indices	
FUEL_04	Fuel type 4	FWI	Canadian Fire Weather Index

FUEL_08	Fuel type 8	PROB	Portuguese Drought Index
FUEL_09	Fuel type 9	ISI	Initial Spread Index
FUEL_00	No vegetation		
FUEL_TY	Number of different fuel types		

The backpropagation algorithm (Rumelhart *et al*. 1986) associated to the multilayer perceptron (Hecht-Nielsen 2005), with one hidden layer and a sigmoid activation function, has been the algorithm most often used for predicting fire occurrence (Vega-Garcia *et al*. 1996, Vasilakos *et al*. 2009), but other techniques such as genetic algorithms (Vasconcelos *et al*. 2001), Levenberg-Marquardt models (Alonso-Betanzos *et al*. 2003), perceptron neural networks (Bisquert *et al*. 2012) or cascade-correlation networks (Vega-Garcia and Chuvieco 2006) have also been used for modeling forest fire occurrence.

The cascade-correlation model created by Fahlman and Lebiere (1990) was used in this work, following the procedure described in Alcázar *et al*. (2008) and Vega-Garcia and Chuvieco (2006). Initial architecture was set to two layers (input/output), and no hidden units. The number of hidden nodes was optimized during the training phase, as candidate hidden units were tested and added (or not), creating an optimal multi-layer structure (Fahlman and Lebiere 1990) at the end of the learning phase. We controlled final size to make sure number of weights was within the order of magnitude that our data would allow, and favored simple architectures. Training was based on an adaptative gradient learning rule (Bridle 1990, Fahlman and Lebiere 1990), a fast variant of the general algorithm of back-propagation (Werbos 1994) that featured a weight decay factor to reduce complexity of the

models (NeuralWare 2009). Several models were built and tested starting training with different random weights, and with different random distributions of individual observations among the three datasets (training, test and validation).
Classification performance for the two cases (SFD and MFD) in the three datasets (training, test and validation) was evaluated by using the total percentage correctly classified, or Accuracy, and the confusion matrix provided by Predict® 3.24 software (NeuralWare 2009). The predictive capacity of the number of daily forest fires (X = 1, 2, 3, 4, 5, 6) was evaluated by using the linear correlation (r) between the observed and the estimated fire occurrences in three data subsets (training, testing and validation). In the selection of the best models, other diagnostics were analyzed, such as relative entropy of the network (the lower, the better the model was), internal correlation (the higher, the better) (NeuralWare 2009), and architecture complexity (we favored models with low number of input variables, processing elements and layers as stated before).
We sought balanced accuracies for the three datasets. For the best model, a sensitivity analysis was applied to identify relevant variables by computing a matrix of partial derivatives of the output variables with respect to each of the input variables (NeuralWare 2009). High values of this sensitivity measure indicated that slight variations of an input variable produced considerable changes in the classification of SFD or MFD, and vice versa. A positive sign in the sensitivity analysis would generally indicate a direct relationship between dependent and independent variable; a negative sign would indicate an inverse relationship. This is a standard diagnostic procedure commonly used to gain insight into a multilayer neural network solution (Alonso-Betanzos *et al.* 2003, Alcázar *et al.* 2008).

Results

Cascade-correlation binary classification accuracies were around 60% with a 7-8-2 ANN structure, for the annual data. This model suggested that MFDs occurred in areas with lower elevation (DEM_MN, average MDF value: -0.200) and lower temperatures (T_MAX, -0.107), higher FFMC (1.321) and higher DC (0.125).

Accuracy for the best Spring model (CL_SP) was also around 59-60% (Table 2), but DEM_MN had a positive response (contrariwise to the annual binary classification model). T_MAX was included in some models evaluated, with negative sign. MFD occurred more frequently in higher altitudes, with higher percentages of public forests (FOREST_PB), where temperatures are lower and near roads

(ROAD_DI) and recreation areas (RECRE_DI), with lower quantity of pasture FUEL_02 and higher FFMC.

Best classifications for the second seasonal period (Summer, CL_SU) were located again around 60-61%, similar to the first period. T_MAX was included only in few models, but in those cases, the sign of T_MAX was positive. MFD (Table 3) were associated to lower elevation areas with higher proportion of public and communal forests (FOREST_PB and FOREST_VC), near roads, and higher drought indices (DMC and DC).

Numerical models

No model could be accepted to adequately discriminate the exact number of human-caused forest fires per day and quadrate for the annual data, so we focused our efforts on the seasonal models.

Predictions of fire occurrences (1 to 5 values) in the Spring seasonal period (PR_SP) reached 61% accuracy (Table 4). The structure of the net was relatively complex (high number of variables in the hidden layer, structure 11-14-1). The average error was approximately 1 fire, with an absolute error of 3. In this case, higher HCFF occurred in quadrates with higher percentage of private forest (FOREST_PV), but lower public forest (FOREST_PB), lower population density, higher shrub fuel (FUEL_06) percentage located in high slopes, and higher PROB and DMC (drought indices).

Results in the Summer period (PR_SU) were somewhat worse (44-50% in the best model, Table 5). Drought indices (DC, DMC, etc.) were the most often selected variables. In the best model, the quantity of input variables was high, but the net had only 3 nodes in the hidden layer (24-3-1). A large quantity of anthropogenic-related variables was included in this net model, locating fires mainly near roads and recreational areas, but far from towns and reservoirs. This model indicated that HCFF were more numerous in locations near roads and recreational areas, higher proportion of public and protected forests, lesser percentage of private and communal forests, lesser altitude and slope variation, and higher danger and drought indices.

Discussion

Multiple fire days in quadrates in Galicia could be correctly separated from the more usual occurrence of single fire days in seasonal time spans using Cascade-Correlation models. Variables and trends were similar in most of the models evaluated, which suggested robustness in the model building processes and relevance of these variables in the final solution. Binary classification seasonal models (X = 1 or more than 1 human-caused forest fire per day and quadrate) have higher accuracy than predictive models (X = 1, 2, 3, 4 or more than 4 HCFF per day and quadrate) especially for the Spring "season". This better accuracy suggests that Spring fires caused by humans are probably more homogeneous and related to a smaller number of causes mainly linked to vegetation management, like agricultural residues burning or shrubs removal (Chas-Amil *et al.* 2010a). On the contrary, the lower accuracy and the higher number of variables of the Summer models seem to reveal that human-caused forest fires in summer are more heterogeneous in cause (i.e. agricultural burning, shrubs removal, arsonists, negligence, machinery), making especially difficult trying to predict the number of fires per quadrate and day (Morillo 2013, personal communication).

Our models show that the probability of MFD was influenced by structural or geographic variables -population, forest ownership, vegetation and topography- and by temporally changing daily variables -weather variables and fire danger assessment indices- during the study period. While accuracy was similar in all the models (around 60%), some variables were different or exhibited opposite trends in them. These findings are in agreement with known causes of fires and their temporal distribution, as described previously (Chas-Amil *et al.* 2010a). Our results indicate that fire activity can vary considerably between different locations in a given day in Galicia in agree to Marey-Perez *et al.* (2010), as in other work elsewhere by i.e. Boychuck and Martell (1988) in Canada or Vasilakos *et al.* (2009) in Lesbos Island (Greece).

Regarding weather variables, the maximum temperature factor influence varied with season, but fire danger indices were positively related to higher fire incidence in all seasons. Spring and Summer MFD were more likely on windy days with lower relative humidity, which may be translated as days with higher danger indices (FFMC, DMC, DC or PROB) in agreement with Garcia Diez *et al.* (1994, 1996, 1999) and Vasilakos *et al.* (2009). The Galician weather is humid and rainy most of the year except in Summer, but there are inland areas where a geographic gradation towards the Mediterranean climate creates drier weather conditions (and higher danger indices) than in the Atlantic region. In Galicia, danger indices may be high when dry weather conditions prevail, such as in summertime with the

higher maximum temperatures and fuel moisture deficit, but also with low daily relative humidity and atmospheric stability in winter (colder days) (Garcia Diez *et al.* 1999) which explains the opposite seasonal temperature pattern found in different models. Spells of low relative humidity (RH) in late winter – early spring produce vegetation water stress during these periods and facilitates fuel ignition, which is why shrublands burning takes place mainly in late winter - early spring, but it is also carried out during the summer, when is masked by other agricultural burning activities and other arson or negligence fires (Chas-Amil *et al.* 2010b, Morillo 2013, personal communication).

The selection of the structural/geographic variables is consistent with the descriptions of the fire problem in Galicia by Chas-Amil *et al.* (2010a, 2010b) and also helps to understand this pronounced seasonality. Altitude is the main distinctive geographic factor. Spring MDFs are more usual in higher altitudes (generally inland); meanwhile Summer MDFs mainly occur in lower altitudes (generally coastal).

According to the Spanish forest fire database, about 75 % of human-caused forest fires in Galicia are related to the rural use of fire for vegetation management (Torre-Antón 2010). Fire use is common in Southern rural areas inland, with higher altitudes and slopes, where most wildfires take place (Chas-Amil *et al.* 2010a, 2010b). Rural population concentrates in valley areas with high livestock productivity, mainly cattle, which feed on grasses. Livestock management requires grasses and the cheapest and traditional way to eliminate shrubs, mainly gorse and heather (Díaz-Vizcaino 2005), is the use of fire (Kaal *et al.* 2011). The second most common fire cause in Galicia is agricultural residues burning. Agriculture is also an important economic activity in Galician rural areas and stubble burning is quite common (MAGRAMA 2013).

Lower altitudes are located in Western and Northern Galicia (Fig 1., at the boundary with the Atlantic Ocean). According to Chas-Amil *et al.* (2010b), in Western Galicia, human-caused forest fires have more diverse motivations. The Southwest is dominated by arsonists; meanwhile the Northwest is dominated by unspecified motivations as revenge, timber prices, land use changes or resentments. Other near township's fires are related to agricultural and livestock activities. As in Vasilakos *et al.* (2009), our models related summer MDFs to lower altitudes in which human settlements (towns, recreational areas, etc.) are more usually placed and recreation and agriculture are the most important economic activities (Chas-Amil 2007). These activities are related to forest fires especially in the boundary of human activities-forest interfaces (Martinez *et al.* 2010). In these Galician regions forest are not valued by the population (Marey-Pérez *et al.* 2010, Torre-Antón 2010), which increases the risk of fires. Public forests and Communal forests were selected in our best Summer binary and predictive models, also in agreement to the conclusions of Marey-Perez *et al.* (2010).

Useful as these explanatory models may be, we are driven to consider that complex spatiotemporal patterns exist. In order to better to explore these relationships between human risk factors, biophysical variables and multiple fires caused by people on a daily basis, with a view to aid fire management to anticipate and locate potential fire suppression overload events, causality will have to be specifically incorporated in future models. However, cause records are currently incomplete, as full investigations are precluded by the high daily fire loads.

Acknowledgements

he authors gratefully acknowledge the fire occurrence historical data from the National Forest Fire Statistics database (EGIF), Ministry of Environment and Rural and Marine Affairs (MAGRAMA) and weather data from the Department of Geography of the University of Alcalá and Meteológica SA (Madrid, Spain). Common analysis of the costs and effectiveness of extinguishing materials and aerial firefighting

Agoston Restas

National University of Public Service, Budapest, Hungary, Restas.Agoston@uni-nke.hu

Abstract
Introduction: Aerial firefighting is known to be a very costly firefighting technique, which encourages professionals to investigate its effectiveness and to be aware of the influential factors as well as to strive to find a way to reduce costs and increase efficiency prior to making a decision. Method: examination is basically based on mathematical calculations, comparative analyses and proportioning. Simple charts, matrixes and graphs help to evaluate the findings and to explain and illustrate the relationship between them. Among the research methods, logical deductions and the application of practical experience can be found. Results: the research introduces a new method of examining the effectiveness of aerial firefighting, which helps to conduct analyses and comparisons based on real data. This method contributes to a better understanding of key factors affecting effectiveness, gives guidance on the possible ways to increase effectiveness, their potentials and limitations.

Keywords*: aerial firefighting, professional effectiveness, economic efficiency, absolute index, standard index, comparative index, vertical and horizontal divisions, matrix analysis*

Introduction

Although aerial firefighting is known to be a very costly firefighting technique, we must admit that in several cases it is the only possibility to extinguish large-scale forest fires. The high expenses of firefighting must urge professionals to investigate effectiveness of aerial firefighting and to be aware of the influential factors as well as to strive to find a way to reduce costs and increase efficiency prior to making a decision.
The success and effectiveness of aerial firefighting is influenced by many factors. It would be a complex and complicated task, if not impossible, to evaluate all of them. Despite this, the author picked a few basic factors which have considerable impact on the economic efficiency of aerial firefighting. One of them is the extinguisher itself together with its extinguisher ability. It certainly varies from extinguisher to extinguisher. The promotion materials of different companies selling extinguishers clearly demonstrate these differences, by highlighting the unique, beneficial feature of the given extinguisher.
The other basic factor is the cost of the transportation of the extinguishers to the scene or with other words, its efficiency. If we accept that there are differences in the extinguisher ability, we must conclude that the more effective extinguishers are worth being used despite the higher transportation costs. The extent of the efficiency of the latter factor is influenced by not only the transportation costs but the costs of the extinguisher itself. The author studies the correlation between the above factors.

2. The effectiveness of the extinguishers and related expenses

We know several methods of examining the effectiveness of extinguishers. Some of them are generally accepted and standardised in certain countries, e.g. LIFT[1], TM2[2] methods, while others are merely

[1] LIFT – Lateral Ignition and Flame Spread
[2] TM2 – Test Method 2 Combustion Retarding Effectiveness Test

used for the purposes of researches (Batista, 2011; Fiorucci, 2011a; Fiorucci, 2011b; Morris, 2011). The effectiveness of the extinguisher is shown by the way it puts out a fire, that is, how it is able to reduce the speed of fire spread (v_0) or even stop it (v_x; $v_x<v_0$, or $v_x=0$). Obviously, the latter is the final solution, but with most methods, their ability to reduce the speed of spread is considered a sign of their effectiveness (e.g. LIFT). The author accepts the previous method to analyse this topic, that is, an extinguisher is considered effective not only if it extinguishes the fire completely but also if it reduces the speed of fire spread. In the end, the steady reductions of the speed results in stopping the fire spread or, in other words, complete extinguishment. As a result, the effectiveness of extinguishers reducing the speed of fire spread to varying extents is different, too. Obviously, the more it reduces the speed of fire spread, the more effective it is.

The varying abilities to extinguish a fire must be accompanied by further differences, so the expenses are most likely to be dissimilar. Provided that we accept the previous statement, that is, not only the total extinguishment of the fire is effective, but also the reduction of the speed of fire spread, then professional effectiveness depends on the extent of speed reduction. Professional effectiveness considers significant only the goal, which is in this case the higher extent the extinguisher reduces the speed of fire spread. The resources used and the expenses are, however, ignored (Restas, 2011). Extinguishers reducing the speed of fire spread by the same extent are assessed as having the same professional effectiveness, irrespective of the expenses they incur.

Nevertheless, efficiency in terms of economics is about much more than the above; in addition to the speed of spread, the costs entailed also need to be taken into account. If we bear the costs in mind as well, the extinguisher of the same effectiveness but with lower prices is clearly more efficient economically.

The most general extinguisher is water. Its cost is so insignificant compared to other extinguishers that it is often overlooked. Water is not only used by itself but to produce other extinguishers like retardants or foams. If we disregard the cost of water, the cost per unit of extinguishers depends on two factors: mixing rate of the agent (R_{foam}) and the price of one unit of the agent (p_{foam}).

$$c_{foam} = R_{foam} p_{foam} \qquad (1)$$

In the case of advanced foams, the prescribed mixing rate is 0.5-3%, which means that 5-30 litres of concentrate is needed to make 1 m^3 solution. This solution produces 6-12 m^3 foam, which stops or reduces fire spread by covering the vegetation. The extinguisher ability of foams is naturally a combination of several factors, e.g. separation, isolation, cooling effects.

Identical extinguisher abilities may be characterised by expanditure rate as well, in the case of foams; in the example above this value is 6-12 ($R_{exp\ foam} = 6 \div 12$). Certainly, other features are also important, but expanditure rate is generally regarded as a feature indicating the initial extinguishing ability of the foams. Foam of low expanditure (high foam density) will stream down to the ground – like Newtonian fluid – instead of staying on the vegetation, thus it will not take part in effective extinguishment. Conversely, foam of high expenditure (low foam density) can be blown away by airflows.

If both the cost per unit and the extent to which it is able to reduce the speed of fire spread are dissimilar, then – assuming linear change – the ratio between them and its scale determine which extinguisher is more efficient economically. In this study, the author presumes that the effect resulting from the changing prices of the extinguishers and the related effect on the speed of fire spread (affecting effectiveness) is a linear variable.

The analysis of the extinguishers' effectiveness

Evidently, we need to take into account the different types of extinguishers and we had better start with the simplest one. The most general extinguisher is water, it is often used by itself, but it can also

be mixed with retardants or foam-forming substances. The additives, obviously, are aimed at increasing the effectiveness of extinguishing with water, so they are more effective. As a result, it is logical to start with water and use it as a reference point. This is the simplest solution, which often succeeds in reducing the speed of fire spread ($v_w<v_0$) by itself. In terms of professional effectiveness, it represents one of the extreme values (the starting value) in the above range.

If we use retardants or foam-forming substances, we have to compare their ability to reduce the speed of fire spread to that of the water and to each other's (e.g. v_A, v_B). When comparing them to water – whether we look at the retardant or the foam –, professional effectiveness must be higher, since in the opposite case it would not make sense to waste resources on them.

The goal of extinguishers is to put out the fire or to reduce the speed of its spread. The extent of the reduction ($v_0 \rightarrow v_x$) is obviously correlated to the initial speed of fire spread (v_0). When comparing the different values of professional effectiveness, it reasonable to use the most simple extinguisher's, the water's effect as a starting point, that is, to what extent it is able to reduce the speed of fire spread; then compared to this value, the effects of the other extinguishers can be ranked. The author examined two different extinguishers (foam) in the experiment without naming them so that it does not harm the producers' interests (foam "A" and foam "B").

Different extinguishers are very likely to reduce the speed of fire spread by different extents. The difference between the speeds of fire spread measured at places treated (v_x) and not treated (v_0) with extinguishers can be determined simply by deducting one from the other, so the results can be ranked.

$$v_W = v_0 - v_1 \quad (2)$$

$$v_A = v_0 - v_2 \quad (3)$$

$$v_B = v_0 - v_3 \quad (4)$$

$$v_0 > v_1 > v_2 > v_3 \quad (5)$$

Based on the above the following are regarded as base values (with sample values):

- The speed of fire spread: v_0 (=10 mmin^{-1})
- The speed of fire spread when using water: v_1 (= 6 mmin^{-1})
- The speed of fire spread when using foam "A": v_2 (= 5 mmin^{-1})
- The speed of fire spread when using foam "B": v_3 (= 4 mmin^{-1})

Based on the values in the previous example we can calculate the effects of reducing speed:

- The effect of water to reduce speed: v_W =4 mmin^{-1}
- The effect of foam "A" to reduce speed: v_A =5 mmin^{-1}
- The effect of foam "B" to reduce speed : v_B =6 mmin^{-1}

Ranking the above figures:

$$v_W < v_A < v_B \quad (6)$$

In addition to the speed of fire spread, we can certainly examine other parameters, too. Presumably, we can put out the fire completely using the extinguishers, but the length (e.g. l_x) of the segment extinguished varies from one extinguisher to the next. Basically, this method can be applied in this case as well, the results do not change.

$$l_W < l_A < l_B \quad (7)$$

We can conclude from the above that they do help to determine the ranking of professional effectiveness, but actually they cannot provide guidance in comparing neither their relative effectiveness nor their economic efficiency.

Indexes describing the extinguishers' effectiveness

In order to determine effectiveness more precisely, we can make calculations using different factors, whose results can be used as indexes.

4.1. Absolute index

We get absolute index (Y_x) if we correlate the extinguishers' effect to reduce the speed of fire spread to the initial speed of the fire.

$$Y_W = \frac{v_0 - v_W}{v_0} = 1 - \frac{v_W}{v_0} \quad (8)$$

Based on the above the absolute indexes of the three extinguishers (water, foam "A", foam "B") are the following:

$$Y_W = 1 - \frac{v_W}{v_0} \quad (9) \qquad Y_A = 1 - \frac{v_A}{v_0} \quad (10) \qquad Y_B = 1 - \frac{v_B}{v_0} \quad (11)$$

The absolute indexes provide guidance on the extent by which the different extinguishers are able to reduce the speed of fire spread. Its value may be 1 or lower than 1; in the first case, the extinguisher not only slowed down fire spread but extinguished it completely. The closer the result is to 1, the slower the fire spread became, and in other words, the more effective the given extinguisher is. As a matter of logic, the other extreme value is possible as well. Thus, when $Y_x=0$, the extinguisher failed to reduce the speed of fire spread.

Table 1—Absolute indexes of extinguishers (with example values)

	Y_W	Y_A	Y_B
Water	$1 - \frac{v_W}{v_0}$ (0.4)		
Foam A		$1 - \frac{v_A}{v_0}$ (0.5)	
Foam B			$1 - \frac{v_B}{v_0}$ (0.6)

4.2. Standard index

The professional effectiveness of extinguishers can be expressed in other ways, too. The reduction of the speed of fire spread can be correlated not only to the initial speed of fire spread but also to the effect of the reference extinguisher. The author calls it standard index (Z_x). By correlating them to water, the simplest extinguisher, it becomes apparent how the professional effectiveness of the other extinguishers vary – affected by the additional costs, the expenditure. In terms of professional effectiveness, it is a more accurate guidance, as it does not compare the extinguisher directly to the fire but to the reference point, to water (having the lowest cost).

$$Z_A = \frac{Y_A}{Y_W} \text{ (12), and} \qquad Z_B = \frac{Y_B}{Y_W} \text{ (13)}$$

Table 2—Standard indexes of extinguishers (with example values)

	Z_A	Z_B
Foam A	$\frac{Y_A}{Y_W}$ (1.25)	
Foam B		$\frac{Y_B}{Y_W}$ (1.5)

Obviously, values higher than 1 are acceptable in the above case. If the value is 1, it shows that using additives in water does not result in increased effectiveness, so the resources spent on them were wasted. The higher the value is or the farther it is from 1, the more effective the extinguisher is.

4.3. Comparative index

Following the idea above, we can get the relative difference between the effectiveness of the two different extinguishers by using relation. This is the comparative index (G), the ratio of the standard indexes of the two different extinguishers to be compared.

$$G = \frac{Z_B}{Z_A} \text{ (14)}$$

The result shows the relation between the professional effectiveness of the two extinguishers. The farther its value is from 1, the bigger the difference is between the effectiveness of the two extinguishers. If the value is 1, there is no difference the professional effectiveness of the two extinguishers.

It does not affect our calculations which data (feature) we use as divisor or dividend. Naturally, we get a higher quotient by dividing the higher value, so that extinguisher is more effective professionally. On the basis of the values of the example, foam "B" performed better in the test (G=1.5/1.25=1,2), its effectiveness is 1.2 times higher or 20% higher than that of foam "A".

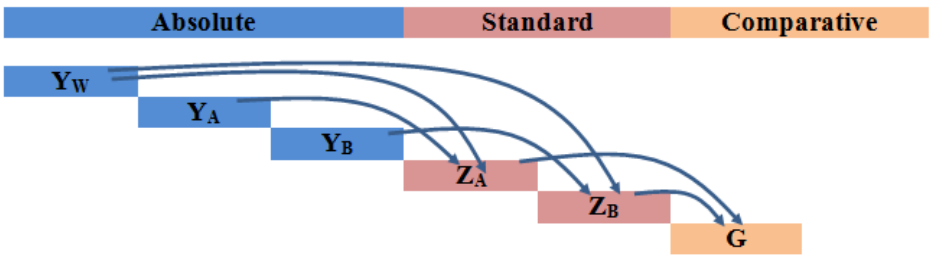

Figure 1. Logic of the indexes of the professional effectiveness of the extinguishers

Based on the above, we determined the professional effectiveness of particular extinguishers, but we do not know how much a unit of them costs. We need to answer it later on. The relationship between the indexes of the professional effectiveness of the extinguishers is depicted in Figure 1.

Effectiveness of the logistic – costs of aerial firefighting

After the examination of the professional effectiveness of the extinguishers, the following questions arise: How is the given extinguisher transported to the frontline? How much does it cost? Its logistics is conducted by air transportation (aerial firefighting), which is known to be very costly. The cost analysis of this logistics task raises the issue of economic efficiency, which, by itself, still shows only professional effectiveness, as we will see.
The cost of aerial firefighting consists of several parts: the operation of the aircraft as well as the price of the extinguisher used. According to the author, it is a common mistake that the two are often dealt with separately, which might lead to false conclusions. It will be demonstrated later on. When assessing the economic efficiency of the extinguishment, it is imperative to treat both of them together. Provided the costs of the aircraft are constant and we calculate with a definite amount, then the efficiency of aerial firefighting depends on the price of the extinguisher and its extinguishing effectiveness.
The operation cost per unit (c_{aff}) is decisive in the cost per unit of the aircraft (c_{AFF}), that is, the efficiency. Besides this, we also have to take into account the transport capacity of the aircraft (Q_{aff}) and in a given unit of time how many turns or deliveries it can carry out (n_{aff}), that is, what is the cost of transporting a unit of extinguisher to the fire front.
Following the above idea, we need the following information to calculate effectiveness (with sample:

- The cost of the aircraft in an hour: (=1000 €h^{-1})
- The transport capacity of the aircraft: (=1000 kg)
- The number of turns (deliveries): (= 10 h^{-1})

The transport cost of one unit of extinguisher can be calculated in the following way using the data above:

$$c_{AFF} = \frac{c_{aff}}{Q_{aff} n_{aff}} = (0.1 €kg^{-1}) \quad (15)$$

Similarly to the principles applied in the assessment of the professional effectiveness of the extinguishers, the transportation costs (aerial firefighting) need to be ranked as well. Water is applied in many cases, but its cost is rarely taken into account or not at all (e.g. from lakes, the sea), so in fact, only the costs of the aircraft are looked at, they dominate. The above suggests that this case ought to be viewed as the starting point or reference point. Regarding the costs, it represents one of the extreme values of the above range.
If we use retardants or various foam-forming substances, beside their effect of reducing the speed of fire spread, we also have to consider their related costs. In this case, the operation cost of the aircraft (15) and the cost of the extinguisher (1) together make up the total cost.
In the simplest case, we need to consider only the costs related to water. Based on the above, its reason is that the cost of water as an extinguisher is not regarded at all or only as a minimal amount ($C_w \approx 0$). Thus, we only have to calculate with the operation cost of the aircraft. In order to make the comparison simpler, it is reasonable to discuss the cost of one unit of the extinguisher (c_{AFF}).
It follows from the above that in the case of two aircrafts with identical operation costs – and other conditions also being identical, – that one is more efficient which is able to deliver more extinguisher to the scene within a given time. If the amounts are the same, the aircraft with lower cost can be viewed

as more efficient. To determine the latter, the costs of the given extinguisher have to be specified; the data required to do so:

- The required mixing rate of foam "A": 3 %
- The price of foam-forming substance "A": 6 €kg^{-1}
- The required mixing rate of foam "B": 3 %
- The price of foam-forming substance "B": 12 €kg^{-1}

Calculating the costs of the two extinguishers with the help of the form (1):

$c_A = R_A p_A = 0.018\,€\text{kg}^{-1}$ (16), and $c_B = R_B p_B = 0.036\,€\text{kg}^{-1}$ (17)

Indexes describing the aerial firefighting's effectiveness

Similarly to the indexes of the professional effectiveness of the extinguisher, those of the aerial firefighting can be specified, too. In the following section, these calculations will be presented, illustrated with examples.

6.1. Absolute index

Based on the above water can be regarded as the reference point. Now mostly, the operation costs of the aircrafts are taken into account, while with the other extinguishers we need to add the costs of the extinguishers as well. This is the absolute index (C_x):

$$C_W = \frac{c_{AFF}}{c_{AFF} + c_W} \cong 1 \quad (18)$$

Based on the above, the formulas to determine the costs of the extinguishers can be constructed:

$$C_W = \frac{c_{AFF}}{c_{AFF} + c_W} \quad (19) \qquad C_A = \frac{c_{AFF}}{c_{AFF} + c_A} \quad (20) \qquad C_B = \frac{c_{AFF}}{c_{AFF} + c_B} \quad (21)$$

The cost of the water is not ignored. The author determined its value arbitrarily to be 5% of the operation cost of the aircraft.

Table 3—Absolute indexes of aerial firefighting (with example values)

	C_W	**C_A**	**C_B**
Water	$\frac{c_{AFF}}{c_{AFF} + c_W}$ (0.95)		
Foam A		$\frac{c_{AFF}}{c_{AFF} + c_A}$ (0.33)	
Foam B			$\frac{c_{AFF}}{c_{AFF} + c_B}$ (0.43)

The absolute index correlates the total cost of the extinguisher used to the cost per unit of the aircraft. Then, according to the values we get, the logistics methods can be simply ranked, which is about professional effectiveness strictly in terms of the expenses. Without the effectiveness of the extinguisher, this is not a relevant economic analysis either.

Its value can be 1 or less than 1; in the former case we do not look at the cost of the extinguisher (water), while in the latter one we do. The closer the value is to 1, the lower the cost of the extinguisher itself relative to the cost per unit of the aircraft.

6.2. **Standard index**

Similarly to the professional effectiveness of the extinguishers, the standard indexes of the logistic (U_x) can be created, too. In this case we correlate the cost per unit of the different extinguishers to that of the water. Then we get the quotient of the cost of the extinguisher and that of the water, as a reference cost.

$$U_A = \frac{R_A p_A Q_{aff} n_{aff}}{c_{aff}} = \frac{C_A}{C_W} \quad (22)$$

The formula for the two extinguishers:

$$U_A = \frac{C_A}{C_W} \quad (23), \text{ and} \quad U_B = \frac{C_B}{C_W} \quad (24)$$

The above offer us a more accurate guidance in the effectiveness of logistic, because they do not correlate directly to the cost per unit of the aircraft, but to the cost related to a reference point, that is, the water. It is also correct if the cost of the water is minimal, then the index value of its effectiveness will obviously be higher. If we ignore the cost of water and its index value is 1, the absolute and standard index values of the other extinguishers will be identical.

Table 4—Standard indexes of aerial firefighting (with example values)

	U_A	**U_B**
Foam A	$\frac{C_A}{C_W}$ (0.35)	
Foam B		$\frac{C_B}{C_W}$ (0.45)

6.3. **Comparative index**

Following the above idea, the relative difference between the effectiveness of the delivery of the two extinguishers can be calculated with relation. This is the comparative index (W), which is the quotient of the standard index values of the two different extinguishers.

$$W = \frac{U_B}{U_A} \quad (25)$$

The result shows the difference between the effectiveness of the delivery of the two extinguishers. The farther its value is from 1, the bigger the difference is between the effectiveness. If the result is 1, there is no difference between the effectiveness of the delivery of the two extinguishers. It does not affect our calculations which data we use as the divisor or the dividend. Naturally, we get a higher quotient by dividing the higher value, so that extinguisher is more effective professionally.

On the basis of the values of the example, foam “B” performed better in the test (W=0.45/035=1.29), its effectiveness is 1.29 times higher or the effectiveness of aerial firefighting (delivery) is 29% higher than that of foam “A”. The relationship between the indexes of the delivery is depicted in Figure 2.

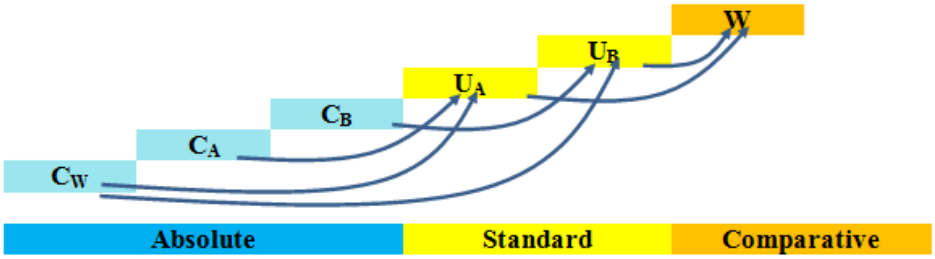

Figure 2. Logic of the indexes of the professional effectiveness of the delivery

Qualifier indexes describing the aerial firefighting's efficiency

In the previous sections the professional effectiveness of both the extinguishers and the application of aircrafts were outlined. The comprehensive evaluation of the effectiveness of the firefighting can be conducted by consulting the so-called qualifier indexes created by the author.

7.1. Absolute index

The absolute index of qualifier (M_x) is the product of multiplying the absolute indexes of the extinguishers and the delivery, which show their professional effectiveness. They can be determined in the following way:

$$M_W = C_W Y_W \quad (26) \qquad M_A = C_A Y_A \quad (27) \qquad M_B = C_B Y_B \quad (28)$$

The above details are summarized in Table 5. The table contains the values of the calculations with the data of the example as well.

Table 5—Absolute indexes of qualifying the aerial firefighting efficiency

	M_W	M_A	M_B
Water	$C_W Y_W$ (0.38)		
Foam A		$C_A Y_A$ (0.175)	
Foam B			$C_B Y_B$ (0.27)

The relationship between the indexes is shown in Figure 3, which clearly shows that we can get the qualifier indexes by combining the professional indexes of the extinguishers and their logistics needs, that is, aerial firefighting. These indexes move towards economic efficiency.

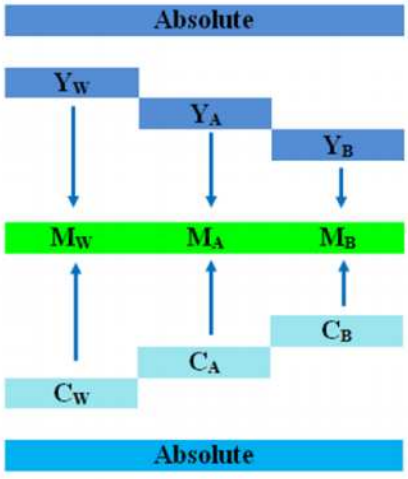

Figure 3. Logic of the absolute indexes of qualifying the efficiency of the aerial firefighting

Numerous calculations can be made with the data above, whose results are inequations that show the threshold values of efficiency. They are summarised in Tables 6-8 to aid understanding. Theoretically, the following deductions can be made from the data of Table 6 regarding water and foam "A":

- Water has an economic advantage as long as $C_W > 0.184$ or $Y_W > 0.438$ remains constant under other conditions.
- Application of foam "A" may gain an economic advantage if $C_A > 1.15$ or $Y_A > 0.76$.

The above has a theoretical approach, for example the value of C_A cannot exceed 1, since it would mean putting out the fire. It shows that the goal of the above is not specifying the extreme values, but rather finding a reasonable and beneficial way to increase the effectiveness of the extinguisher – by increasing its extinguishing ability or improving its delivery method. In practice, it is probable that the joint, though minor improvement of both factors is more feasible than a major improvement of a single factor, even if the mathematical results are the same.

Table 6— Conditions of the efficiency of the "A" foam

$C_W > \frac{C_A Y_A}{Y_W}$	$C_W > 0.184$	$C_A > 1.15$	$C_A > \frac{C_W Y_W}{Y_A}$
	$C_W = 0.4$	$C_A = 0.5$	
$C_W Y_W > C_A Y_A$	$M_W = 0.38$	$>$ $M_A = 0.175$	$C_W Y_W > C_A Y_A$
	$Y_W = 0.95$	$Y_A = 0.33$	
$Y_W > \frac{C_A Y_A}{C_W}$	$Y_W > 0.438$	$Y_A > 0.76$	$Y_A > \frac{C_W Y_W}{C_A}$

The above can be applied with the other extinguisher, too. Thus, theoretically, the following deductions can be made from the data of Table 7 regarding water and foam "B".

- Water has an economic advantage as long as $C_W > 0.284$ or $Y_W > 0.675$ remains constant under other conditions.
- Application of foam "A" may gain an economic advantage if $C_B > 0.884$, or $Y_B > 0.63$.

The statements made earlier also apply to this case. Increasing the effectiveness of the foam from two directions could be simpler or more beneficial than improving a single factor significantly.

Table 7— Conditions of the efficiency of the "B" foam

$C_W > \frac{C_B Y_B}{Y_W}$	$C_W > 0.284$	$C_B > 0.884$	$C_B > \frac{C_W Y_W}{Y_B}$
	$C_W = 0.4$	$C_B = 0.6$	
$C_W Y_W > C_B Y_B$	$M_W = 0.38$	$>$ $M_B = 0.27$	$C_W Y_W > C_B Y_B$
	$Y_W = 0.95$	$Y_B = 0.43$	

$Y_W > \frac{C_B Y_B}{C_W}$	Y_W >0.675	Y_B >0.63	$Y_B > \frac{C_W Y_W}{C_B}$

The above implies the foams could also be compared to each other instead of the water. It produces the values in Table 8. Theoretically, the following deductions can be made from the data above regarding foam "A" and foam "B".

- Foam "B" has an economic advantage as long as $C_B > 0.41$ or $Y_B > 0.29$ remains constant under other conditions.
- Application of foam "A" may gain an economic advantage if $C_A > 0.82$ or $Y_B > 0.54$.

Table 8— Conditions of the efficiency of the foam "A" and "B" to each other

$C_B > \frac{C_A Y_A}{Y_B}$	C_B >0.41	C_A >0.82	$C_A > \frac{C_B Y_B}{Y_A}$
	C_B =0.6	C_A =0.5	
$C_B Y_B > C_A Y_A$	M_B =0.27 >	M_A =0.175	$C_B Y_B > C_A Y_A$
	Y_B =0.43	Y_A =0.33	
$Y_B > \frac{C_A Y_A}{C_B}$	Y_B >0.29	Y_A >0.54	$Y_A > \frac{C_B Y_B}{C_A}$

It is logical that the statements made earlier are also valid in this case, that is, enhancing the unfavourable features from two directions could be simpler or more beneficial than improving a single factor significantly.

7.2. **Standard index**

Similarly to the previous ones, the standard qualifier indexes (H_x) are the products of multiplying the professional effectiveness of the extinguisher by that of aerial firefighting. The data above are summarised in Table 9. The table contains the values of the calculations with the data of the example as well.

$$H_A = Z_A U_A \quad (28) \text{ and } H_B = Z_B U_B \quad (29)$$

Table 9—Standard indexes of qualifying the aerial firefighting efficiency

	H_A	H_B
Foam A	$Z_A U_A$ (0.438)	
Foam B		$Z_B U_B$ (0.675)

Numerous calculations can be made with the data above, whose results are the threshold values of effectiveness. They are summarised in Tables 10-11.

$$Z_A U_A = Z_B U_B \quad (30) \quad H_A = Z_A U_A \quad (31)$$

$$H_B = Z_B U_B \quad (32) \qquad Z_A U_A < Z_B U_B \quad ..(33)$$

The relationship between the qualifier standard indexes is shown in Figure 4, which clearly shows that we can get the qualifier indexes by combining the professional indexes of the extinguishers and their logistics needs, that is, aerial firefighting.

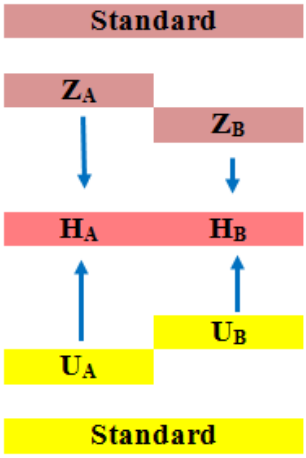

Figure 4. Logic of the standard indexes of qualifying the efficiency of the aerial firefighting

Theoretically, the following deductions can be made from the data regarding the relationship between foam "A" and foam "B".

- Foam "B" has an economic advantage as long as $Z_B > 0.97$ or $U_B > 0.29$ remains constant under other conditions.
- Application of foam "A" may gain an economic advantage if $Z_A > 1.93$ or $U_A > 0.54$ remains constant under other conditions.

Table 10— Conditions of the efficiency of the foam "A" and "B" to each other

$Z_A < \frac{Z_B U_B}{U_A}$	Z_A<1.93	Z_B>0.97	$Z_B > \frac{Z_A U_A}{U_B}$
	Z_A=1.25	Z_B=1.5	
$H_A = Z_A U_A$	H_A=0.438	< H_B=0.675	$H_B = Z_B U_B$
	U_A=0.35	U_B=0.45	
$U_A < \frac{Z_B U_B}{Z_A}$	U_A<0.54	U_B>0.29	$U_B > \frac{Z_A U_A}{Z_B}$

Based on the previous reasoning it is still valid in this case, that enhancing the unfavourable features from two directions could be simpler or more beneficial than improving a single factor significantly.

7.3. **Comparative index**

We can get the qualifier comparative index (B) in two ways. Either by multiplying the comparative indexes of the professional effectiveness of the extinguisher by that of the logistics (34) or as the quotient of the standard qualifier indexes of the two extinguishers (35). Both build on the previous reasoning.

$$B = GW \quad (34), \text{ and } B = \frac{H_A}{H_B} \quad (35)$$

The two mathematical processes must yield the same results. The result reveals the difference between the economic efficiency of the two extinguishers, which can be higher or lower than 1, depending on which extinguisher is the divisor and the dividend in the relation. Obviously, it has no significance in multiplication. The farther the value is from 1, the bigger the difference is between the economic efficiency of the two extinguishers. If the result is 1, there is no difference between the extinguisher and the related aerial firefighting in terms of economics despite the dissimilar partial results.
It does not affect our calculations with the qualifier indexes which data (the extinguisher and the related aerial firefighting) we use as the divisor or the dividend (35). Naturally, we get a higher quotient by dividing the higher value, so that extinguisher is more effective professionally. On the basis of the values of the example, foam "B" performed better in the test (B=0.68/0.44=1.54), its effectiveness is 1.54 times or 54% higher than that of foam "A". We get the same product in multiplication, too (B=1.2x1.29=1.54). Figure 11 presents the comparative indexes of qualifying the aerial firefighting efficiency.

Table 11— Comparative indexes of qualifying the aerial firefighting efficiency

	B	
From standard qualifier indexes	$\frac{H_A}{H_B}$ (1.54)	
From comparative indexes		GW (1.54)

The two types of relationship between the comparative qualifier indexes are presented in Figure 5. On the one hand, the indexes of economic efficiency are quotients of the professional indexes of the extinguishers and the related logistics needs. On the other hand, they are the products of multiplying the standard qualifier indexes of the two extinguishers.

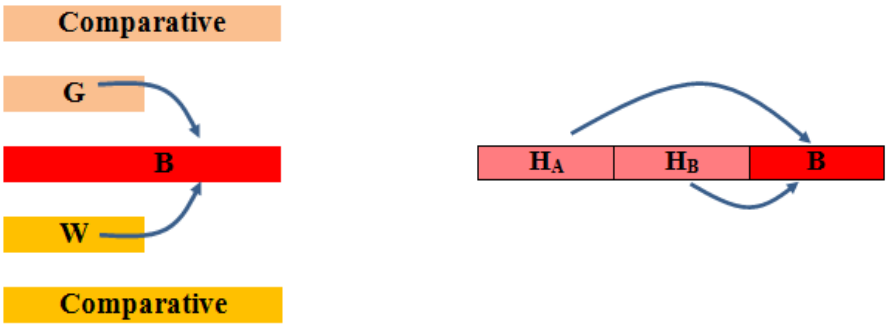

Figure 5. Logic of the comparative index of qualifying the efficiency of the aerial firefighting by two different ways

8. Summarizing

The creation of indexes and the calculations can be looked upon as a kind of mathematical game. It can be clearly seen how one consequence generates another one and also that, by keeping the basis of correlation, the new relations do not necessarily yield new results but rather a new approach to the results. The relationship between the indexes are summarised in Figure 6.

Despite the above, the creation of the indexes was not for their own sake. The paper has drawn attention to the fact that the extinguisher ability of extinguishers and the cost of their delivery can be examined together and that the separate analyses of their effectiveness do not necessarily lead to the correct conclusions. According to author's approach, it is possible - however difficult it is - to analyse and evaluate the effectiveness of aerial firefighting beyond the producers, distributors of the extinguishers and the marketing tricks of service providers of aerial firefighting even if the paper does not discuss each and every factor in detail.

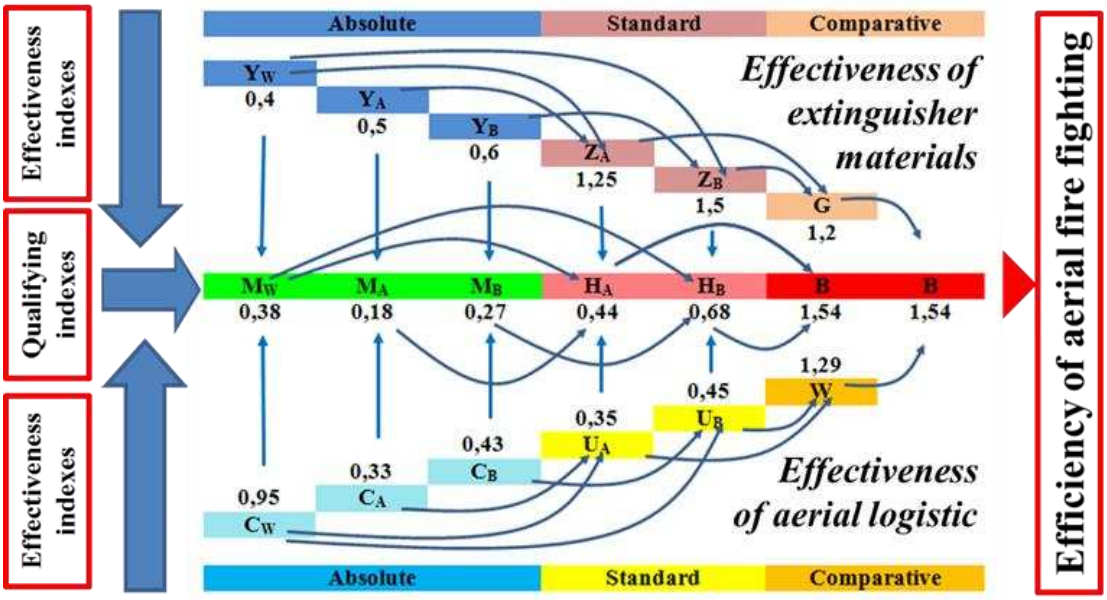

Figure 6. Complex logic of the indexes

The reasoning in the paper obviously changes with the modification of the influencing factors. We might assign different delivery means to the various extinguishers or even increase the number of extinguishers to be compared. We can get the results by expanding the formulas above or by interpolating the already existing results.

Crossing the crossroad: challenges for the implementation of a collaborative wildfire management program in Portugal.

António Patrão

Institute for Interdisciplinary Research, University of Coimbra (IIIUC),
uc1997105312@student.uc.pt

Abstract
Wildfires represent the main natural risk in Portugal. Since 2003 the territory has been affected by extreme wildfires which have consumed more than 1.2 million ha. Following those events, several modifications were introduced in wildfire policies to preserve forest and increase the resilience of communities facing wildfires. These modifications suggest that the wildfire management strategies in Portugal are changing from a response based paradigm (wildfire combat capability) to a paradigm based on prevention and community collaboration. The goal of this paper is to identify this set of transformations, analysing the main features of the wildfire management program between 2003-2013 and the challenges for the implementation of a collaborative wildfire management framework. Wildfire policies and legislation created since 2003 were collected and submitted to content analyses to identify the main resolutions and strategies for wildfire management and to explore the extent of community involvement and participation. Results suggest that since 2003 many changes were implemented in the system, setting a positive context for wildfire prevention. But these measures still reveal a low potential for community participation and empowerment towards wildfire risk. New models of risk communication and information sharing with communities that increase their involvement in the decision process are needed.

Keywords*: wildfire management, collaborative framework, wildfire policies, community.*

Introduction

Wildfires represent the main natural risk in Portugal. Since 2003 the territory has been affected by extreme wildfires which have consumed more than 1.2 million ha and destroyed and many tangible and intangible resources, including human lives. These great wildfires, with catastrophic features, highlight the need for reviewing the policies of wildfire management and to develop systematic actions to preserve forest, guarantee the security and increase resilience of communities (adaptative capacity) when facing wildfires. Therefore, following a tendency common to other countries such as the United States of America or Australia, where catastrophic wildfires are common, wildfire management strategies in Portugal are changing from a response based paradigm to a more collaborative/resilience oriented framework based on prevention and community participation (Pearce, 2003). After 2003 several changes were introduced in the national system for the defence of forest against wildfires, focusing in creating more resilient and safe territories. However, recent studies indicate that wildfire risk is still very high and that there is an urgent need to work on prevention issues and with communities: individual risk behaviours continue high and the collaboration of people/communities has been identified as one of the major factors to the success of the wildfire national policies (Viegas *et al*, 2012; Tedim & Paton, 2012). This paper analyses the main legislative and policy context of wildfire management framework in order to understand the changes that emerged following the 2003 wildfires and analyse at what extent these measures are favourable to the new paradigm based on prevention and community participation.

Objectives

The goal of this paper is to identify and analyse the main modifications in wildfire policies following the catastrophic wildfires of 2003. Specifically it characterizes the framework of wildfires management, from 2003-2013, identifying the main resolutions and strategies for wildfire management, and exploring the degree of community involvement and participation involved on it. Results highlight the legislative framework, its main principles and orientations, suggesting the challenges facing professionals and other stakeholders in the implementation of a more collaborative orientation within the wildfires management cycle.

Methods

In order to understand the main orientations of the policies following the 2003 wildfire catastrophic events legislative instruments (policies and legislation) focusing on wildfire management, between 2003 and 2013 were selected using wildfire as key-words and submitted to content analysis (Miles & Huberman, 1994). The data base of the national forestry services-ICNF (http://www.icnf.pt/portal/icnf/legisl/lex-flor/flor-incen-agric#dfci) which contains the majority of legislative documents connected to the Portuguese forestry sector, since 1901, was used. Legislative instruments (law, decree-law, resolution of the council of ministers and parliamentary resolution and ordinance, decree, order and legislative order) were selected on the basis of their aims and field.

Data analysis

The selected documents were integrally read and then submitted to content analysis (Miles & Huberman 1994) within the emergency management cycle framework (NFPA 1600) (Figure 1).

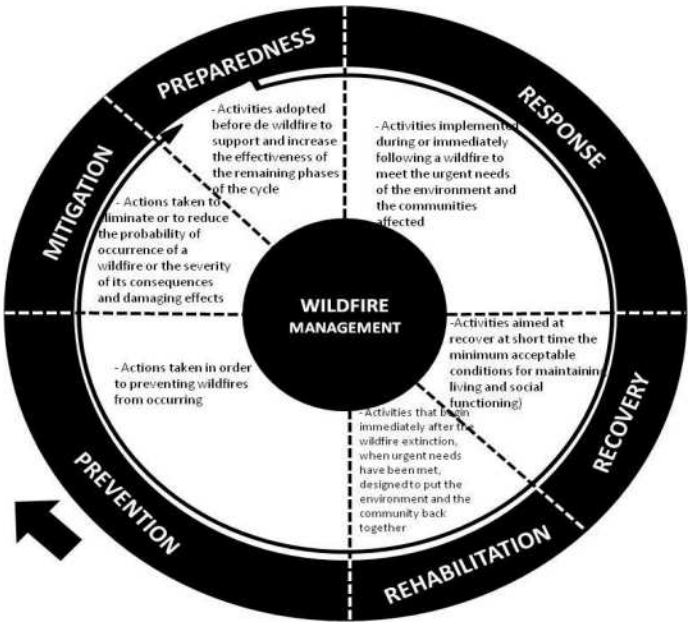

Figure 1. Wildfire Management cycle

The analysis aimed to describe and characterize the main features of the wildfire management framework: core themes, strategies used within the emergency cycle, amount of attention devoted to each of the cycle phases. Categorisation system was gradually refined by two independent judges. Each judge read the legislative documents and drew up a list of categories and subcategories based on the phases of the wildfire management cycle (Figure 1). The inter-judgment agreement score (number

of agreements / total number of agreements plus disagreements) was 80%; this reliability may be considered high (Miles & Huberman, 1994). A list of categories and sub-categories, which included definitions was produced (Table 2). Then the legislative documents were classified to the (sub)categories (judges were in full agreement) (table 3).

Results

4.1. Main topics/themes within the wildfire management cycle

Prevention /Mitigation is the most frequent topic within the Portuguese wildfire management cycle (Table 3). Forest management strategies (plans for sustainable management of wildfire hazardous areas at regional, local and operational level) are the most significant topics within this matter. Funding and support and the reinforcement of agents, organizations and human resources to work on prevention and mitigation actions were also underlined by the legislative instruments. Public education (focused on education to the correct use of fire and wildfire risk awareness) and prescribed burning are also present but are a lot less expressive.

Rehabilitation is the second most recurrent category (Table 3). Most common issues are support programs and funding to face the effects of wildfires, which emerged from a Disaster Declaration in August, 2003. Rehabilitation issues also emphasize operational/technical procedures (e.g. reforestation programs; harvest burned timber; control erosion; preserve water resources) to recover the burned areas, specially following the wildfires occurred in 2003-2006. The regulation of burned timber trade market was included but is less expressive.

Table 2. Themes and contents of wildfire policies and legislation: categories and subcategories within the emergency cycle

Category/	***subcategory***	***Definition***
Prevention/Mitigation: Reducing the chance of occurrence and the damaging effects of wildfires.	1.1. Forest management and planning strategies	Plans for sustainable management of wildfire hazardous areas (regional, local and operational level).
	1.2. Fuel management tools	Fuel reduction techniques (e.g. prescribed burning).
	1.3. Funding and support	Financial support (from European Community and fuel taxes) for prevention and education campaigns and plantation programs
	1.4 Reinforcement of agents, organizations and human resources. (prevention specialists)	Specialized entities and committees; specialized forest brigades; and volunteers programs.
	1.5. Public education/communication	Warning systems, definition of critical risk periods, reinforcement of the legal framework.
Response/Immediate Recovery: meeting the urgent needs of the environment/communities affected;	2.1. Reinforcement of human resources(combat specialists)	Special fire fighters; coordination between fire-fighters and civil protections agent in combat.
	2.2.Communication systems/technology	Communication systems to improve combat and the interaction/connection between entities involved.
	2.3. Special combat/response equipment	Special funding conditions to rent forest fire combat aeroplanes.
Rehabilitation: putting the environment and the community back together	3.1. Support programs (financial, social and operational)	Criteria for the attribution of financial support to repair the damages; special credit lines (preservation of pine and eucalyptus timber; *Quercus suber* plantations and cork extraction).

	3.2. Reinforcement of agents, organizations and human resources (Rehabilitation specialists)	Agents and procedures and to cope with wildfire consequences and recovery of burned areas (reforestation programs; harvest burned timber; control erosion; preserve water resources).
	3.3 Regulation of burned timber trade market	Creation and establishment of burned timber points.
System for forest defence against wildfires: setting the frame	4.1. General framework	Interventions related to the prevention and defence of forest against wildfires accomplished by the public entities and private agents (public education and awareness, conservancy and land use planning, forestry, surveillance, detection, combat and aftermath of wildfires).

Response/Immediate recovery is the third category (Table 3). Most frequent issue within this topic is the reinforcement of organizational and human resources involved in combat. It centres on the coordination between national forestry services, the national civil protection services and the law forces in combat scenarios and in the specialization of professionals to work on the field (fire-fighters, law forces, forest workers and fire specialists). The allocation of special services, like combat aeroplanes and the acquisition of communication systems are also contemplated.
System for forest defense (general framework) is the fourth general category (Table 3). It contains documents related to the definition, implementation and adjustment of a National Wildfires Defense System, which were publicized in the immediate sequence of the great wildfires (years 2004, 2005, 2006).

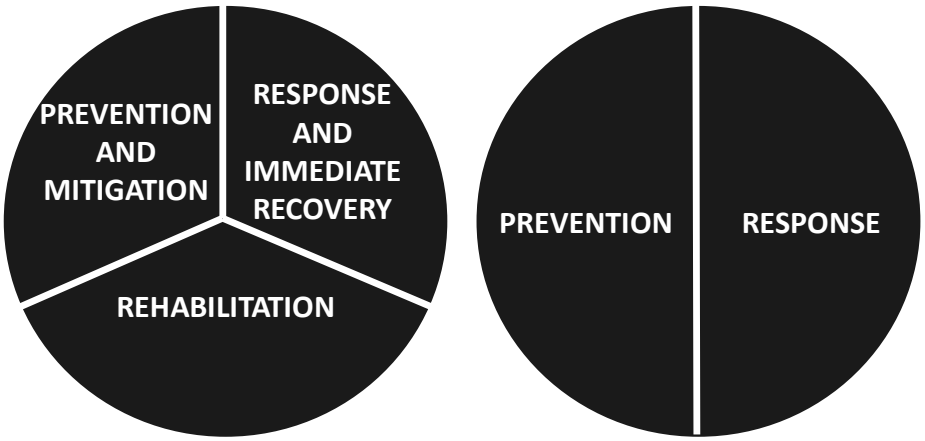
Discussion

5.1. General framework of the wildfire management (context)

The results of this study suggest the embracing of two major topics for wildfire management in Portugal: prevention /mitigation and rehabilitation. Together both areas integrate nearly 85% of all legislative publication, mostly issued between 2003 and 2009. This seems to point out to a turning point on the wildfire management framework, towards a more preventive/resilience orientation. However recent data evidence that funding and financial support continue to reinforce response and combat over prevention. Decision makers centre the discussion on prevention vs. response, dismissing other phases of the emergency management cycle, namely preparedness (Figure 2). Moreover, nonetheless the results suggest that public policies put an emphasis on rehabilitation the guidelines of the legislative instruments are not being successfully imported and transferred to those who implement recovery actions on the field.



a) legislative frame *b) perspective of decision makers (action on the field)*

Figure 2. Features of the wildfire management framework:

Therefore, recent studies and reports continue to point out to a deficit on prevention, structural problems connected to individual property and land use (large areas of abandoned or unattended lands with unmanaged or inadequately managed flammable vegetation), individual risk behaviours (high number of human-caused ignitions) and to the need to persist on community involvement and participation (Tedim & Paton 2012; Viegas *et al* 2012).

5.2. Community involvement and collaboration (challenges)

Content analysis suggests that the degree of community involvement and collaboration provided by Portuguese policies for wildfire management is still low. The contents analysed referred mainly to education and risk communication based on the diffusion of general information (e.g. pamphlets, media advertisements) and to the increase of the legal framework as an instrument of regulation (define what to do and how to do in a top-down orientation).

These measures represent passive forms of communication that fail to address the diversity of needs and expectations within a community and also fails to engage people in ways that facilitate their ability to make decisions (Prior & Paton, 2008). They share the assumption that providing the public with information on wildfires and the protective measures to prevent it will automatically translate into preventive behaviours, which is a wrong assumption (Paton 2003). Behaviour change in wildfire risk situations demands for the active engagement of community members within the risk communication process and the use of interactive risk communication procedures. Professionals and agencies connected to wildfire management should act as facilitators or consultants to communities rather than directing the change process in a top down manner. One possible approach would involve invite

representatives of community groups and stakeholders to review wildfire scenarios in regard to the potential challenges, opportunities and threats they could pose for each group.
Another important dimension of participation is related to the sharing and construction of knowledge between people and specialists (Callon, Lascoumes & Barthe 2001). Results suggest that the framework gives a great emphasis to the specialization of human resources (creating specialists) but less to the acknowledgment and integration of local knowledge. Within these circumstances people tend to rely on the action of the specialists, placing the responsibility of change on their shoulders and disconnecting from the field (Patrão 2010). This is important because such an orientation has the potential to increase the sense of conflict, rivalry and distrust that historically has been characterizing the relationship between the sate and the communities within the forest management (Soares e Oliveira 2006; Mendes & Tavares 2009). Community participation requires the use of strategies to promote the articulation between the scientific community, the political actors, professionals and the citizens (Mendes & Tavares 2009). Socially Fire Regimes framework (Goldstein & Hull, 2008) represent an innovative intervention on this subject.

Conclusions

Since 2003, Portugal has implemented many (and mainly positive) changes in its wildfire management program. However the framework for action includes only three (3) of the six (6) steps of the emergency management cycle, developing in a triadic structure around mitigation/prevention-response-rehabilitation, mainly in a mandatory and directive orientation (top-down). Moreover giving their structural features, many of these changes are still maturing and may take several years to bear fruit. This is special relevant in the process of community collaboration.
The framework is in a period of transformation and transition between paradigms: the system aims at a more collaborative stance but remains trapped in a top-down orientation. It demands new forms of communication, networking and deliberation to foster learning, transform values and cultivate new identities among the communities, the fire professionals and specialists (Goldstein & Butler 2012). It is necessary to develop a culture that embraces the value of empowering communities.
This exploratory study highlighted the legislative framework of the wildfire management in Portugal, its main principles and orientations, summarising some of the obstacles professionals and other stakeholders are facing in the implementation of a more collaborative wildfire management framework.. Future studies are needed to study people (communities) and fire professionals´ attitudes towards different risk communication techniques and to deepen the knowledge about collaborative processes in wildfire management, namely through action research methodology.

Abstract
The economic evaluation of damage and losses of the areas affected by forest fires requires comprehensive studies covering a wide range of natural resources. The assessment of fire impacts requires the individualized study of each resource, such as timber resources, fruit production and hunting activity, and the analysis of their net value change based on fire intensity and ecosystem resilience. As a consequence, this concept of net value change extends the study beyond an economic valuation, integrating two concepts, the value of the resource and fire behavior. However, field sampling on large fires becomes complex because of the costs involved in field tasks and the time that will elapse before the assessment is available.
The incorporation of satellite imagery to the economic valuation of fire impacts provides a new tool of undoubted interest. This paper details the methodology and the results obtained in the economic assessment of two medium (between 200-500ha) and two large fires (more than 500 ha) in the south of Spain. MODIS data were suitable for mapping medium and large fires (more than 200 ha). The advantage of using MODIS satellite images in relation to other remote sensors lies in the free download (zero cost) and temporal resolution. As other studies have shown, the normalized vegetation index was not presented as the best identifier of the burned area. However, RdNBR index allowed us to obtain reliable relationships between its value and the depreciation ratio for each resource due to the differences among resources based on fire intensity.
Economic resources valuation and MODIS images (pre and post-fire) can be integrated into Geographic Information System (GIS), in order to obtain, in a geo-referenced way, the economic value per hectare resulting from fire impact. This tool should provide a procedure to help improving fire management and take more appropriate decisions about budg*et al*location and rehabilitation of areas affected by fires. Given current economic constraints, the use of a geo-referenced tool with free download and regular update (MODIS) allows us to the inclusion of changes, improvements and temporal or spatial adaptations according to the needs of forest managers. The methodological approach for assessing the economic impact of forest fires provided allows the application of this simple and flexible technique to any territory by previous economic valuation of natural resources presented in the interesting area.

Keywords*: Economic losses; net value change, vegetation indices, remote sensing, fire management*

Introduction

Forest fires are a major factor of environmental transformation in a wide variety of ecosystems (FAO, 2007). Although fire has been used since ancient times in crop rotation, agricultural plowing and pasture creation for the purpose of livestock use, socio-economic changes have led to an abandonment of traditional uses. This neglect results in a greater accumulation of scrub (Perez, 1990; Rodriguez y Silva and Molina, 2010), which, along with the accentuation of climate conditions (Piñol *et al*., 1998), are transforming fire into a threat to the biodiversity and conservation of Mediterranean ecosystems (Brook *et al*., 2003).
Remote sensing is commonly used for monitoring wildfires using various space-borne sensors, such as Landsat and MODIS (Chuvieco *et al*. 2005; Devineau *et al*., 2010). MODIS (Moderate Resolution

Imaging Spectroradiometer) data were suitable for mapping medium and large (50-500 ha) burn scars that accounted for the majority of all fire-damaged forests (Morton *et al*., 2011). MODIS makes up to four daily observations from each of the Terra and Aqua satellites providing consistent data on fire development with high temporal frequency. The use of MODIS satellite images enabled us to map wildfires at a national scale due to the high temporal resolution of the sensor (Levin and Heimowitz, 2012). In other works, MODIS has been used to the classification of fires into headfire and backfire types in assessing pollutant emissions to the atmosphere (Smith and Wooster, 2005). The incorporation of satellite imagery to the economic evaluation provides, in a novel way, a tool of undoubted interest to accurately identify the natural resources affected by fire (Rodríguez y Silva *et al*., 2009, 2012a). The advantage of using MODIS satellite imagery lies in the availability of real-time information at zero cost.

The economic evaluation of damage and losses of the areas affected by forest fires requires comprehensive studies covering a wide range of natural resources. The valuations of natural resources tend to underestimate the real value of the forest (Constanza *et al.*, 1997). Unlike traditional economic activity, the forest environment is characterized by the extraordinary relevance of externalities that involve harm or benefits of considerable magnitude to others (Riera, 2000). From forest management standpoint, it is necessary to express all the natural resources in monetary terms. The economic valuation requires the identification of the "net change value" of the resources affected by fire. As a consequence, this concept of "net value change" extends the study beyond an economic valuation, integrating two concepts, the value of the resource and fire behavior (Rodríguez y Silva and González-Cabán, 2010).

Wildfires are the most important disturbance in the Mediterranean area causing damages to tangible assets, environmental services and landscape goods. The spatial assessment of fire impacts is indisputable in the identification of effective rehabilitation actions. However, this evaluation becomes complex when the size of the affected area makes gathering the information unfeasible, mainly because of the costs involved in obtaining the information and the time that will elapse before the final assessment is available. The aim of this paper is to assess the economic fire impacts of medium and large fires based on satellite images and fire intensity level. One of the most difficult concepts to value the economic impact of fire on natural resources is determining the net value change or economic value loss. MODIS images identify value change based on the differences in spectral information based on fire behavior. The socioeconomic vulnerability model was incorporated into a Geographic Information System (GIS) that facilities the development of spatiotemporal tracking cartography, at both the individual resource level and the integrated ecosystem vulnerability level. The impacts valuation using satellite images and GIS achieves in a versatile geo-referenced tool understanding of the forest system vulnerability to wildfires, at virtually real time.

Methods

The economic evaluation of fire impacts by MODIS images has been carried out for four large fires in Andalusia, in the south of Spain. These four fires provide a wide range of Mediterranean ecosystems and topographical characteristics: burned area from 275 to 7,300 ha, range of altitudes between 423 and 1,200 m meters above sea level and different stand areas (*Quercus ilex*, *Castanea sativa*, *Alnus glutinosa*, *Pinus pinea* and *Pinus pinaster*) and treeless (chaparral, *Cistus* genus, *Pistacia lentiscus*, *Rosmarinus officinalis* and *Juniperus oxycedrus*).

The economic impact assessment of a large forest fire requires the following phases of analysis and development:

a) Economic valuation of natural resources
b) Spatial identification of different damage levels
c) Identification of the net value change in the resources
d) Economic valuation of fire impacts

Economic valuation of natural resources

Although economic valuation of natural resources must incorporate three types of resources: tangible assets, environmental services and landscape goods, this paper only includes tangible assets covering timber and non-timber resources. The methodology for the evaluation of timber resources consists of an algorithm integrating the method in the National Fire Management Analysis System (NFMAS) developed by the USDA Forest Service and the method used by the Spanish Forest Service (Rodríguez y Silva *et al*., 2012b). NFMAS is based on the concept of natural restoration while Spanish system considers artificial restoration based on stand development stage and rotation age of the species.

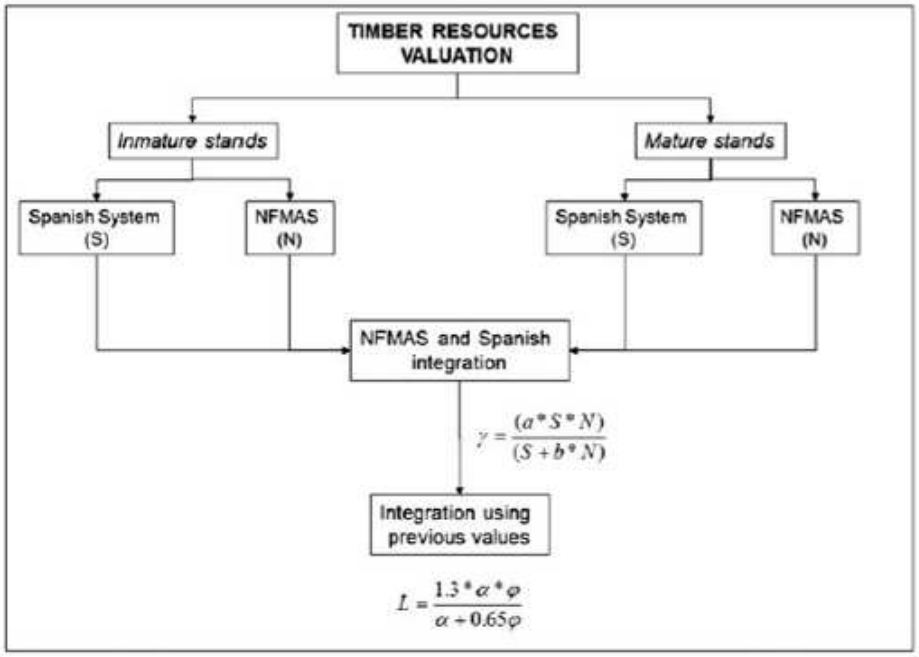

Figure 1. Methodological scheme for the valuation of timber losses (Rodríguez y Silva et al., 2012b)

Non-timber losses should be calculated depending on the generated annual income from resources production, such as pasture, acorn and pine nut production (Table 1). A problem exists because of the number of years without resource production or vegetation resilience (Molina *et al*., 2011; Roman *et al*., 2013). Valuation of grassland impact requires information on the available production, nutritional value of the grass and the carrying capacity of the area. On the other hand, fruit production per hectare is given by the tree production and the canopy closure adjusted for site index and phytosanitary condition. Finally, the hunting resource is based on the acquisition of a hunting assessment by updating the annual profit plus the stock or replacement value of the reproductive wildlife (Zamora *et al*., 2010).

Table 1. Mathematical formulations used for economic valuation

Resource	Formula	Potential status	Source
Timber	$\gamma = (a*S*N)/(S+b*N)$	Immature and mature stands	Rodríguez y Silva *et al*. 2012
	$S = C_0*t\,[r^e + i(r^e - 1)] + F*(r^e - 1)$	Immature stands	
	$N = [(P*V*1.025^y)/1.04^y]*\,[1-(1.025/1.04)^e] * [1 + M*c*t]$	Immature stands	
	$S = [P*V - P_1*V_1] + P*V\,[(r^{(R-e)} - 1)/(r^{(R-e)})]$	Mature stands	
	$N = V*c*t[C*P + (1 - C)*P_1]$	Mature stands	
Firewood; fruit production	$L = A_p*P_r*[((1+r)^y - 1)/(r*(1+r)^y]$	Mature stands	Martínez, 2000; Molina *et al*., 2011
Pasture production	$L = V*[((1+0.06)^n - 1)/(0.06*(1+0.06)^n]$	Livestock and/or game area	Martínez, 2000; Molina *et al*., 2011
Hunting activity	$L = V*[((1+0.06)^n - 1)/(0.06*(1+0.06)^n] + S$	Game area	Zamora *et al*., 2010

where " γ " is the timber valuation (€/ha), "S" is the valuation according the Spanish system (€/ha), "N" is the valuation adapted from NFMAS (€/ha), "a" takes the value of 1.7 or 2.6 according to protection or recreational function, or timber forest respectively, "b" takes the value of 0.85 or 0.25 base on the same reasons, "C_0" is the reforestation cost per hectare (€/ha), "t" is the percentage burned stand based on fire behavior, "r" is the compound annual interest rate and depends on species growth rate: fast growth (1.06), medium growth (1.04), slow growth (1.025) and very slow growth (1.015); "e" is the estimated stand age, "i" is the annual silvicultural cost factor and depends on species growth rate: fast growth (1.27), medium growth (1.1) slow growth (1.1) and very slow growth (0.93), "P" is the price of the timber (€/m^3), "V" is the timber volume (m^3/ha), "y" is the time or years remaining in the harvesting rotation or senescence age, "M" is the tree mortality coefficient depending on fire intensity, "c" is the percentage of immature or mature timber in stand, "P_1" is the price of affected timber with commercial use (€/m^3), "V_1" is the volume of burned timber (m^3/ha), "R" is the rotation age, "C" is the percent of non-commercial timber, "L" is the resource loss (€/ha), "A_p" is the annual production (kg/ha), "P_r" is the estimated resource price (€/kg), "V" is the annual income given the carrying capacity of the site (€/ha), "n" is the estimated number of years until recovery (vegetation resilience), "S" is the reproductive stock (€/ha)

Spatial identification of different damages levels

The spatial and spectral information from satellite images before and after fire let us to identify fire severity (Chuvieco *et al*., 2008). MODIS images were assessed in order to characterize fire impacts and to relate them with land cover. The spatial identification of the different damage levels was performed using MODIS images (Terra and Aqua) for a previous date as well as for a post-fire date. The MODIS products (both pre and post-fire) were downloaded from the United States Geological Service's LP DAAC Server (https://lpdaac.usgs.gov/get_data/data_pool). These images were already geometrically corrected. The original reference and coordinate system was transformed to the ETRS89 30N system making the overlapping of the images with the fire perimeter in vector format. The identification of damage levels was obtained based on the spectral and spatial differences between pre and post-fire images. Figure 2 shows a framework for the methodology proposed in this paper.

The surface reflectance, both for the Terra and Aqua platforms, was identified in the electromagnetic spectrum of 620-670nm (Red-NIR) for band 1, and 841-876nm (NIR) for band 2. In the case of images with a spatial resolution of 500 meters, the band 7 used ranged from 210-215nm. Geo-referencing and adjusting of the final fire perimeter was performed with ArcGIS© software, keeping a 150-meter tolerance buffer in order to include the effect of the proximity to the burned area. In order to harmonize MODIS bands (1, 2 and 7) and land use cartography for the calculation of the fire impacts, all inputs were resampled from original spatial resolution to 25 m (cell size = 0.625 ha).

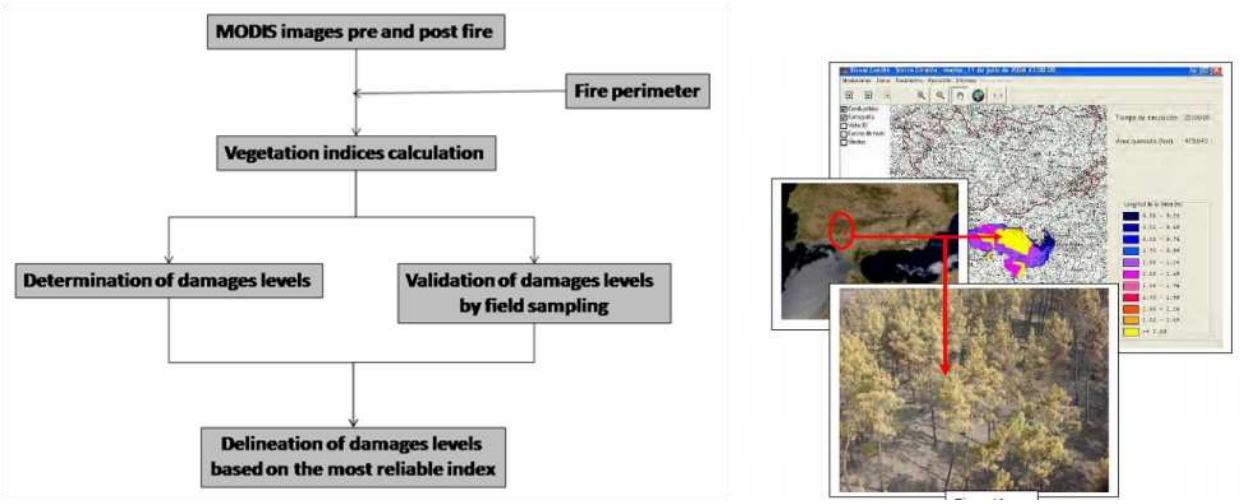

Figure 2. Framework of the methodological proposed in this paper

Three vegetation indices were considered: Normalized Difference Vegetation Index (NDVI), Normalized Burn Ratio (NBR) and a relative differenced Normalized Burn Ratio (RdNBR).The calculation of these indices requires mid-infrared (MODIS band 7) and near infrared (MODIS band 7) information. MODIS band 7 was very important due to its intrinsic ability to identify fuel moisture.

At the Red-NIR spectral space, NDVI (Chuvieco *et al*., 2002) was computed as follow:

$NDVI = (\rho_{NIR} - \rho_R) / (\rho_{NIR} + \rho_R)$
where ρ_{NIR} is the reflectance in the NIR (MODIS band 2) and ρ_R is the reflectance in the RED (MODIS band 1).

In the NIR-SWIR spectral space, NBR (Key and Benson, 1999) was calculated as follow:

$NBR = (\rho_{NIR} - \rho_{LSWIR}) / (\rho_{NIR} + \rho_{LSWIR})$
where ρ_{NIR} is the reflectance in the NIR and ρ_{LSWIR} is the reflectance in the SWIR (MODIS band 7).

In both vegetation indices the value range oscillates between -1 and 1. While values close to zero generally correspond to bare soil areas, positive values represent shrublands or grasslands (lower positive values) and forest lands (values close to one). The identification of the damage level of each "cell" (0.625 ha) was estimated by the differences in the values of vegetation indices, pre and post fire:

dNDVI = PreFire NDVI – PostFireNDVI
dNBR = PreFire NBR – PostFire NBR

Since chlorophyll contents vary due to vegetation type and density, each absolute differenced image should ideally be stratified by pre-fire vegetation type and independently calibrated. Therefore proposed the creation of a relative differenced NBR (RdNBR) to remove the biasing of the pre-fire vegetation by dividing dNBR by the square-root of the pre-fire NBR as follows (Miller and Thode, 2007):

RdNBR = dNBR / [Square Root (ABS (PreFire NBR/1000)]

We scale NBR by 1,000 to transform the data to integer format (Key and Benson, 2005); therefore the pre-fire NBR must be divided by 1,000 in the RdNBR formula. Positive RdNBR values remain

representing a decrease in vegetation cover, while negative values represent an increase in vegetation cover.

2.3. Identification of the net value change in the resources

The economic assessment of fire impacts on natural resources requires knowledge of the fire severity. The net value change in the resources is computed as a function of fire severity, which is determined by Fire Intensity Level (FIL) (Molina *et al*., 2011; Rodriguez y Silva *et al*., 2012b). To estimate the rates of depreciation for each resources based on fire behavior we used the following 13 large fires (year of fire in parenthesis) in Andalusia: Huétor (1993), Aznalcollar (1995), Los Barrios (1997), Estepona (1999), Cazorla, Segura and Las Villas Natural Park (2001, 2005), Ojen (2001), Aldeaquemada (2004), Minas de Río Tinto (2004), Alajar (2006), Obejo (2007), Cerro Catena (2009) and Cerro Vértice (2011). For the valuation of hunting activity, information from Monfragüe National Park, Aldeaquemada and Minas de Río Tinto were used to test the annual hunting profit and number of years until recovery (vegetation resilience) (Zamora *et al*., 2010).
Different sampling plots (10 and 15 m square plot) were established according to forest characteristics and average flame length in each fire event. We used flame length as a simple parameter "in situ" for fire severity. The creation of a direct relationship between fire severity and flame length increases the flexibility and simplicity of this methodological approach. In addition, a photographic overview was taken as a virtual key to identify vegetation resilience.

2.4. Economic valuation of fire impacts

We used Geographic Information Systems (GIS) to assess the socio-economic impacts on natural resources. The use of GIS allows us the option to link the economic value of natural resources and damage levels obtained by MODIS images. An extrapolation of sampling depreciation rates for each damage level could be extrapolated to large burned area with the help of remote sensing. The depreciation rate is estimated individually for each resource based on damage level depending on fire intensity. The integration of both economic value and real fire impacts provides the economic vulnerability of each resource. Final economic vulnerability is the sum of the vulnerabilities of the resources present in each burned area. Economic vulnerability cartography was developed showing fire impacts by hectare.

Results

3.1. Economic valuation of natural resources

It was necessary to characterize vegetation (combination between stand cover and understory association) to identify the natural resources presented in each area. In stand areas, immature and mature condition could be determined from the rate of growth and rotation length, as well as approximate stand age that is necessary for some resources valuations. Once the vegetation structure was characterized, a spreadsheet was used to identify the economic vulnerability of each area based on the mathematical formulations (Table 1). This characterization was related to dominant species, as a consequence, to the ecosystem resilience, that can be defined as the time needed by a species to recuperate to its original condition as a result of fire. Resilience was assigned based on restoration planning (large fires in Andalusia) and the experiences in the maintenance of the preventive infrastructure in wildfire risk areas (Zamora *et al*., 2010).
As an example of the application of this methodological approach, we incorporated the economic valuation of natural resources from "Catena fire" (Table 2). Economical results indicated that timber is the most important resource (€ 194,093.17), given the natural condition of the *Pinus pinaster* and their longevity (over 100 years in some stands). Tangible assets valuation reaches to € 263,568.69, showing a value per unit area of 1,261.1 €/ha.

Table 2. Tangible assets valuation for one example fire

Resource	Valuation (€)	Valuation per unit area (€/ha)	Representativeness (%)
Timber	194,093.17	928.68	29.35
Non-timber resources	60,771.17	290.77	9.19
Hunting activity	8,704.35	41.65	1.32

Spatial identification of different damages levels

MODIS images were assessed in order to characterize fire damages levels based on field sampling plots. In order to the size of the fire, we can identify four or six fire intensity levels according to the flame length (directly related to the fire line intensity) and spatial resolution. In this sense, four fire intensity levels were differentiated by medium fires (between 200 and 500 ha):

- Damage level I: this level corresponded to a flame length lower than 3 meters
- Damage level II: this level corresponded to a flame length between 3 and 6 meters
- Damage level III: this level corresponded to a flame length between 6 and 10 meters
- Damage level IV: this level corresponded to a flame length exceeding 10 meters

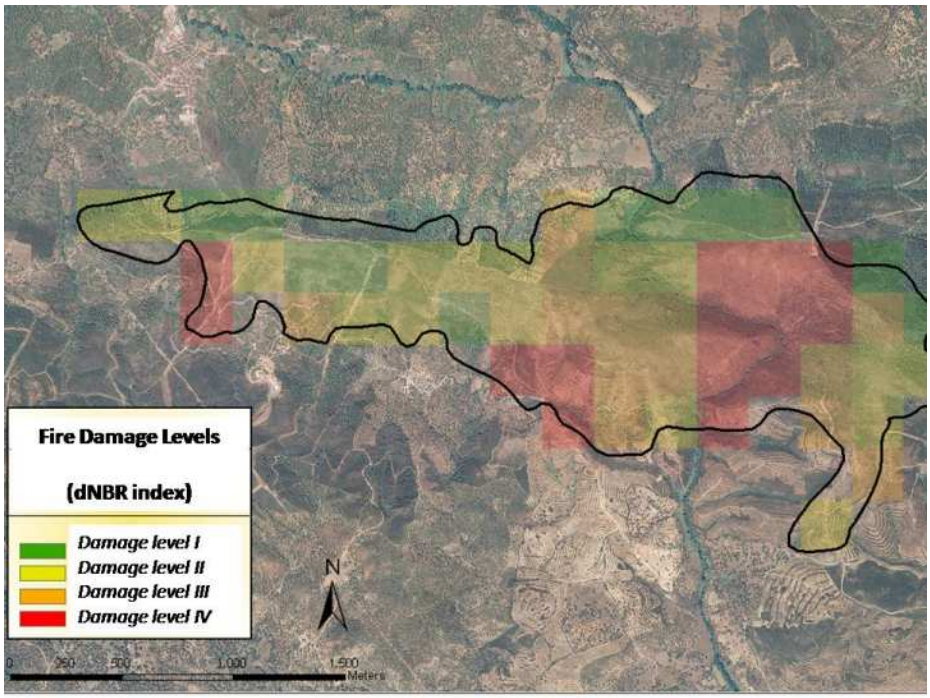

Figure 3. Fire damage levels from medium fire (275 ha)

In the case of large fires (more than 500 ha), the damage scale was extended to six categories due to the large sampling area and the most different fire behavior:

- Damage level I: this level corresponded to a flame length lower than 2 meters
- Damage level II: this level corresponded to a flame length between 2 and 3 meters
- Damage level III: this level corresponded to a flame length between 3 and 6 meters
- Damage level IV: this level corresponded to a flame length between 6 and 9 meters
- Damage level V: this level corresponded to a flame length between 9 and 12 meters
- Damage level VI: this level corresponded to a flame length exceeding 12 meters

The selected index should have adequate differences among damage levels, to avoid potential omission error in the automatic remote sensing process. The observed behavior of the different indices, regarding the identification of different damage levels, was heterogeneous. In general, better results were obtained with NBR index in relation to NDVI indices, since it allowed better discrimination and contrast of the fire impacts (Figure 4). Pre-fire and post-fire values (dNDVI) showed a difference (0.128) higher than dNBR (Terra bands 2 and 7) due to the post-fire photosynthetic activity. The indicator RdNBR allowed eliminating existent correlation between the result of the ratio and the pre-fire NBR value showing the most reliable relation between reflectance fire response and damage levels.

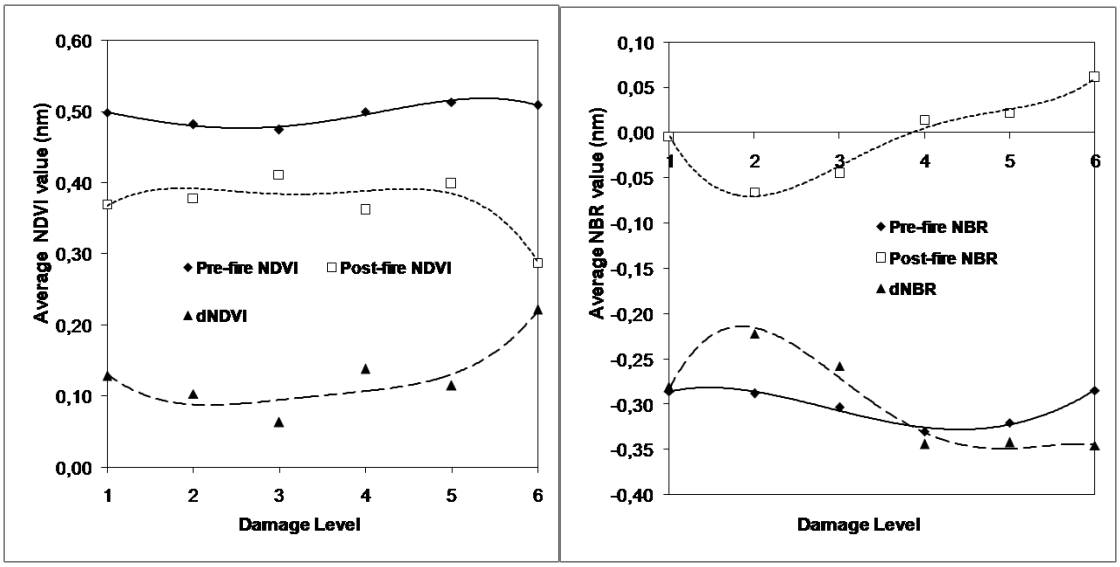

Figure 3. Comparison between dNDVI and dNBR for the same large fire

3.3. Identification of the net value change in the resources

The economic impact was determined by the fire intensity level. Therefore, a relationship had to be established between fire intensity level (directly related to flame length) and resource depreciation caused by the fire. The net value change expressed as different percentage intervals were from the result of some research projects and direct experiences from large fires in the region of Andalusia (Figure 4 and Table 4).

Figure 4. Sampling plots inventory on burned stand to determinate the net value change

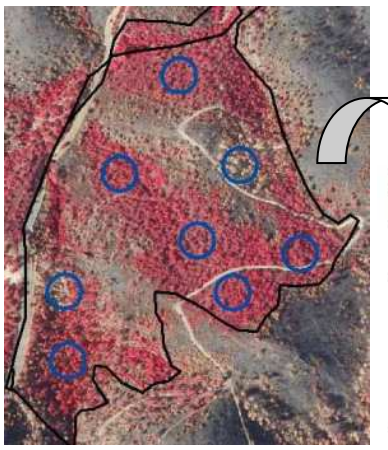

Table 1
Timber resource deterioration by fire intensity level.

Average flame length (m)	Fire intensity levels (FIL)	Timber resources deterioration (%)	Tree mortality coefficient (x)
< 2	I	8.33 (±6.58)	0
2–3	II	16.65 (±5.89)	0
3–6	III	38.58 (±6.27)	0.5
6–9	IV	57.85 (±13.74)	0.5
9–12	V	82.79 (±1.81)	1
>12	VI	89.41 (±2.82)	1

Table 4. Depreciation matrix (net value change for each resource based on fire intensity level)

Resource	Fire Intensity Level			
	I	II	III	IV
Timber	16.65 (±5.89)	38.58 (±6.27)	57.85 (±13.74)	89.41 (±2.82)
Firewood/fruit production	6 (±3.53)	14.2 (±5.03)	44.1 (±26.62)	73.40 (±5.65)
Hunting activity	40 (±17.67)	65 (±19)	84 (±15.27)	99 (±3.53)

*Depreciation matrix was more-detailed by other scientific papers: Rodríguez y Silva *et al*., 2012 (timber resource); Molina *et al*., 2011 (non-timber assets) and Zamora el al., 2010 (hunting activity)

Each resource change o depreciation value was adjusted with RdNBR index (the best index for the identification of the four damage levels) showing greatest correlation. We chose the logarithmic approach since it provides a reliable and easy way for the valuation of fire impact. In this sense, it is possible to provide the deterioration ratio (depreciation caused by fire and the residual economic benefits of vegetation unaffected) for each resource based on the spatial identification of the RdNBR index by MODIS images.

$y = a \ln(x) - b$
where " γ " is the net value change or depreciation ratio (%) and "x" is the value of RdNBR index

3.4. Economic valuation of fire impacts

MODIS data were suitable for mapping medium and large fires (more than 50 ha) similar to other studies (Morton *et al*., 2011). The spatial identification of damage levels with satellite imagery supported by a field inventory facilitates the extrapolation of the field information to the burned area (Devineau *et al*., 2008). The final step in the process, once the losses were determined and damage levels map was complete, was the preparation of a GIS-based data layer portraying the economic impacts to each studied fire (on a 25 x 25 m spatial resolution).

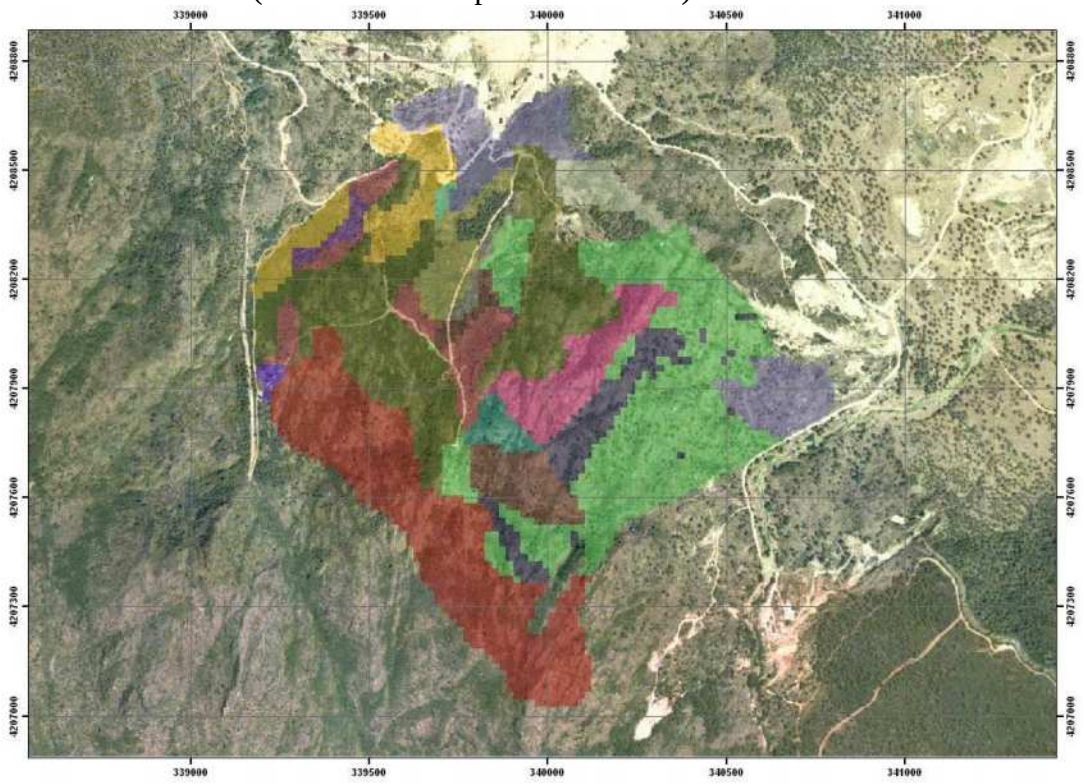

Figure 5. Economic valuation of burned area based on the socio-economic value of each ecosystem and the fire behavior

Conclusions

The integral valuation of forest ecosystems is essential for spatiotemporal planning conducted by forest managers. It is necessary to express non-timber resources in monetary terms. The incorporation of satellite imagery to the economic valuation of fire impacts provides a new tool of undoubted interest. The model should provide a sound procedure to help improving pre-fire management and take more appropriate decisions about rehabilitation of areas affected by fires.
The increasing demand for thematic mapping by government agencies with management responsibilities implies the need to develop tools and products based on Geographic Information Systems (GIS) and remote sensing. The use of GIS and remote sensing in spatial economic valuation provides flexibility when doing spatial ordination of the territory and increases the dynamisms of planning and systems protection tools. Given current economic constraints, the use of a geo-referenced tool with free regular updates (MODIS) allows us to the inclusion of changes, improvements and temporal or spatial adaptations according to the needs of forest managers.

Fire extremes and the triangle of climate, fuels and people

Timothy J. Brown[a] and Tamara U. Wall[b]

[a] *Desert Research Institute, Reno Nevada USA, tim.brown@dri.edu, tamara.wall@dri.edu*

Abstract
Over the past decade or so, statements by fire personnel claiming unusual fire behaviour beyond training or experience levels seem to be increasing. This is occurring globally. Concurrently, climate and weather extreme events have been increasing, fuel loads have notably increased due to both natural occurrence and management practices, and the people have been expanding into the wildland and rural interfaces. All of these factors appear to be intersecting causing an increase in "extreme" fire events based on another fire triangle of climate, fuels and people. Megafires (for those comfortable with the term and lack of official definition) could be considered the extreme of the extremes, but many large fires can be categorized as extreme events. But for these extreme events to occur, not all three factors on the triangle need necessarily be extreme simultaneously. For example, strong winds need not be out of the ordinary (e.g., Santa Ana in southern California), but combined with continuous and heavy fuel in a highly populated area can lead to "never seen before" occurrences. Sometimes fire personnel are surprised at how large a fire becomes. In some cases, the extreme event is truly a surprise; in other cases, while seemingly a surprise at the time, upon further reflection perhaps it should not have been. In either event, personnel safety can easily be at higher risk during extreme events, as these situations tax critical thinking given they are outside the common fire experience.
This presentation discusses a project that draws upon quantitative assessment of physical observations (e.g., climate, weather, fuels) along with qualitative assessment of firefighter claims to 1) determine if indeed there is a common trend and intersection of these factors; 2) determine if situational awareness factors can be identified to lessen the surprise of these events; and 3) provide recommendations that incorporate knowledge of extreme events into fire management training.

Keywords*: Fire extremes, large fires, human factors, climate, fuels, fire behaviour*

Introduction

This project is driven by the phrase “I’ve never seen fire do that before” and the concern that fire fighters in the US are being surprised by wildfire behaviour, which then raises concerns about fire fighter safety and if levels of training and situational awareness are sufficient to address current patterns of fire behaviour. Fire is inherently a complex environment, and by extension, almost all questions related to the intersection of fire and people will be equally complex. Added to this is a convergence of climate (hotter and drier), fuels loading (high in many areas), and expanded residential areas in fire-prone areas. In summary, by any measure, addressing the question of fire extremes, both in terms of a quantitative assessment of climate, weather, and fuels and a qualitative assessment of fire fighter perceptions of extreme wildfire behaviour, requires a method that can absorb the variability in this complex problem.

2. Methods & Timeline

Our methodological approach in this project uses a software developed by Cognitive Edge, SenseMaker®, which uses narrative story prompts to ask for “microstories” about an event or experience in someone’s life (Figure 1). Once a person has either dictated or typed a brief narrative into the collection device (using either a app or website using a smartphone, tablet, or computer), they then answer a series of questions about the event or experience, applying context and meaning to their story. The questions employ a level of ambiguity to 1) deter “satisfying” or giving the “right answer”

to a question and 2) to provide the storyteller the ability to respond with complex answers—if you ask specific questions, you will get specific answers. While that may be advantageous for some questions, it does not provide the complexity needed in this situation. Survey's, for example, tend to provide averages of responses to a question. In this problem, an average is exactly the wrong metric to use—what we need are a diversity of stories that provide an array events across geographies, timescales, and situations in response to surprising, unexpected, or extreme wildfire behaviour. This diversity and quantity of stories/context questions will provide us with an authentic reflection of reality that can then be analysed for weak signals and patterns to identify factors involved with fire fighters responses to these situations. The primary data in this methodology is not the stories themselves, but rather the responses to the questions that apply the context and meaning of the story to create a quantitative dataset that can then be analysed statistically.

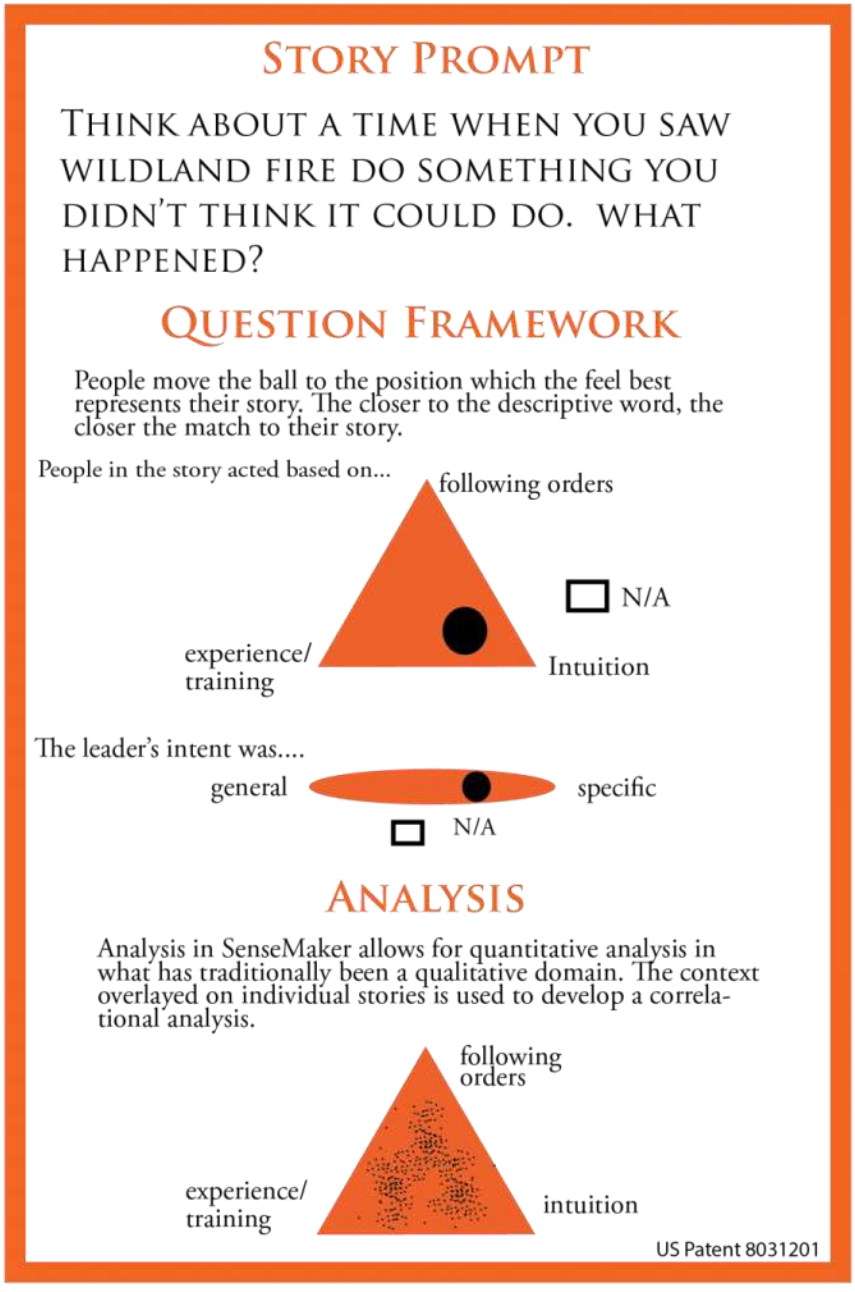

Figure 1. SenseMaker framework.

For this project, we worked iteratively with several groups of expert fire fighters and supervisors, as well a consultant experienced in SenseMaker® to develop the initial question framework. SenseMaker® uses a series of questions that are framed as triads and dyads (Figure 1). Once a preliminary framework was developed, we tested pen/paper versions with several different fire crews to finalize the framework. At this point the framework was coded, and uploaded to a demo server where it was tested again on the website, as well as both iOS and Android operating systems, and the mobile apps.

Quantitative analysis of the physical side of fire - fuels, weather and climate - will be done in association with the stories and other analyzed case studies. This quantitative analysis will assess the extent that fuels, weather and climate are associated with firefighters view of extreme fire. The data for this project component includes weather observations, climate background (e.g., extent of drought), fuels conditions (e.g., moisture, fire danger), and atmospheric synoptic characteristics that might be associated with the fire.

Summary

At the time of this writing, we are about to launch the data collection system and are developing and deploying an extensive outreach strategy to reach both current and past wildland fire fighters in the United States. We hope to gather approximately 1000 stories through December of this year. Analysis of the data will occur simultaneously with the data collection. We will also develop a workshop and/or series of webinars to explore the data themes and results with the fire community early in 2015. Following the U.S. analysis, we would to begin collecting stories in Australia, Canada and Europe.

Flexible design of a cost-effective network of fire stations, considering uncertainty in the geographic distribution and intensity of escaped fires

Abílio Pereira Pacheco[a], Richard de Neufville[b], João Claro[a], Hèctor Fornés[b]

Abstract
This paper proposes an improved strategy for allocating fire-fighting vehicles to Local Dispatch Centers (LDCs) over a region. By considering the uncertainties in fire location and intensity, and a flexible design, it develops a plan more cost-effective than that from a traditional deterministic approach, reducing the number and cost of required vehicles.
While small fires occur regularly and call for 'first response' equipment to be available close to susceptible fire-prone areas, large fires occur rarely and take time to develop. Thus the 'extended attack' equipment needed for larger fires can be held in reserve over a larger area, serving in effect as insurance against rare events. A layered strategy removes specialized equipment from the front lines and locates it in strategic reserves located in some of the pre-existing fire stations. The proposed solution thus reduces specialized equipment.
Innovatively, the analysis applies simulation to the management of fire-fighting resources, in order to deal with uncertainty in the number of deployments and location of fires over time. The approach first uses location algorithms to calculate optimal sets of fire stations. It then uses simulation to determine the probability distributions of outcomes of several performance measures (e.g., distance run by vehicles, vehicle utilization, or fire access time). The simulation implements flexibility by considering decision rules to open and close LDCs, according to recent observations of leading parameters. The outcomes of the simulation allow decision-makers to evaluate the performance of the flexible design in four different scenarios: as-is, intensification through wildland urban interface expansion or climate change, and attenuation (i.e., surveillance investment and law enforcement).
Finally, we use data available from ANPC and AFN/ICNF to compare the current design with the proposed flexible design, in a case study of the district of Porto, in Portugal. The results show that this design (a partially centralized strategy) leads to a cost-effective allocation of equipment and could reduce investment costs up to about 68 percent.

Keywords*: forest fire suppression, flexibility, network design, capacity planning, operations strategy*

Introduction

Portugal has an old and hardly used fleet of fire-fighting vehicles. These vehicles have more than 34 years on average and their underutilization is reflected by the mere 80 km they travel every year on average. The main goal of this research is to define a flexible design for the location of this fleet, to improve vehicle utilization efficiency without compromising its effectiveness.
We propose the centralization in Local Dispatch Centers (LDC), located in pre-existing fire stations (*Corporações de Bombeiros*), of some of the vehicles used in extended attack, deployed well after the initial emergency call, when containment by initial attack fails. These vehicles do not need to be immediately close to potential fires to ensure current levels of protection.
The model carries out a simulation to compare the current design with a proposed flexible allocation of equipment to LDCs, which can adjust to the changing location and nature of the forest fires. To deal with the uncertainty in the number and location of fires, a flexible approach opens and closes LDCs, according to recent observations of leading parameters - some of the current fixed locations as the

LDCs are selected to be open each year, according to the severity of the past three seasons and the number of LDCs open in the previous year.
Using the district of Porto, one of the eighteen districts of Portugal, as a case study, four envisioned trends are also analysed in independent scenarios: business as usual, evolution of the Wildland-Urban Interface, increased forest surveillance and law enforcement.

Methodology

Our model combines optimization and simulation to assess the flexible design in each of the four scenarios, over a 20-year period, considering one-year time-steps.
First, for each possible number of LDCs in a given range, and using historical data, we determine the set of LDC locations that minimizes the total distance run by vehicles (Cooper 1963; Kotian *et al.* 2009; Aravind *et al.* 2010). The potential locations are the currently existing firehouses, to decrease the costs of implementing the new design.
Second, in the simulation component, the model uses the locations of LDCs and the uncertain XY coordinates of fires to calculate the distance run by vehicles. The main driver of uncertainty is the total number of deployments per year, which depends on fire weather, modeled as an independent mean reverting process (Chow and Regan 2011). Empirical data is used to obtain this parameter and generate grid-based spatial distributions of vehicle deployments for each scenario, i.e., specific 2D distributions for each time-step, accounting for the uncertainty in the location and intensity of fires (Figure 1).

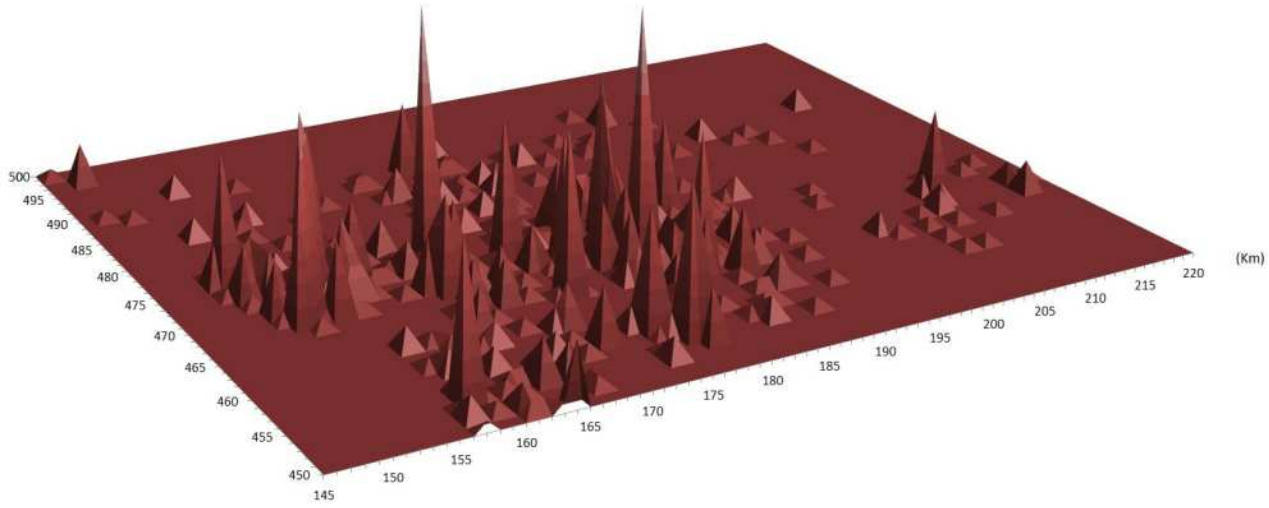

Figure 1. Graphical representation of a 2D distribution of escaped wildfires in the district of Porto, generated from a grid of one square kilometre

The model includes flexibility by applying, at each time-step, two decision rules to determine whether LDCs should be opened and/or closed given the new fire scenario conditions. Once the LDCs are fixed, the model calculates trip distance, time required to access fires, and thus extra time spent. The same procedure is repeated for the current network of firehouses, to compare the current and the proposed flexible design.

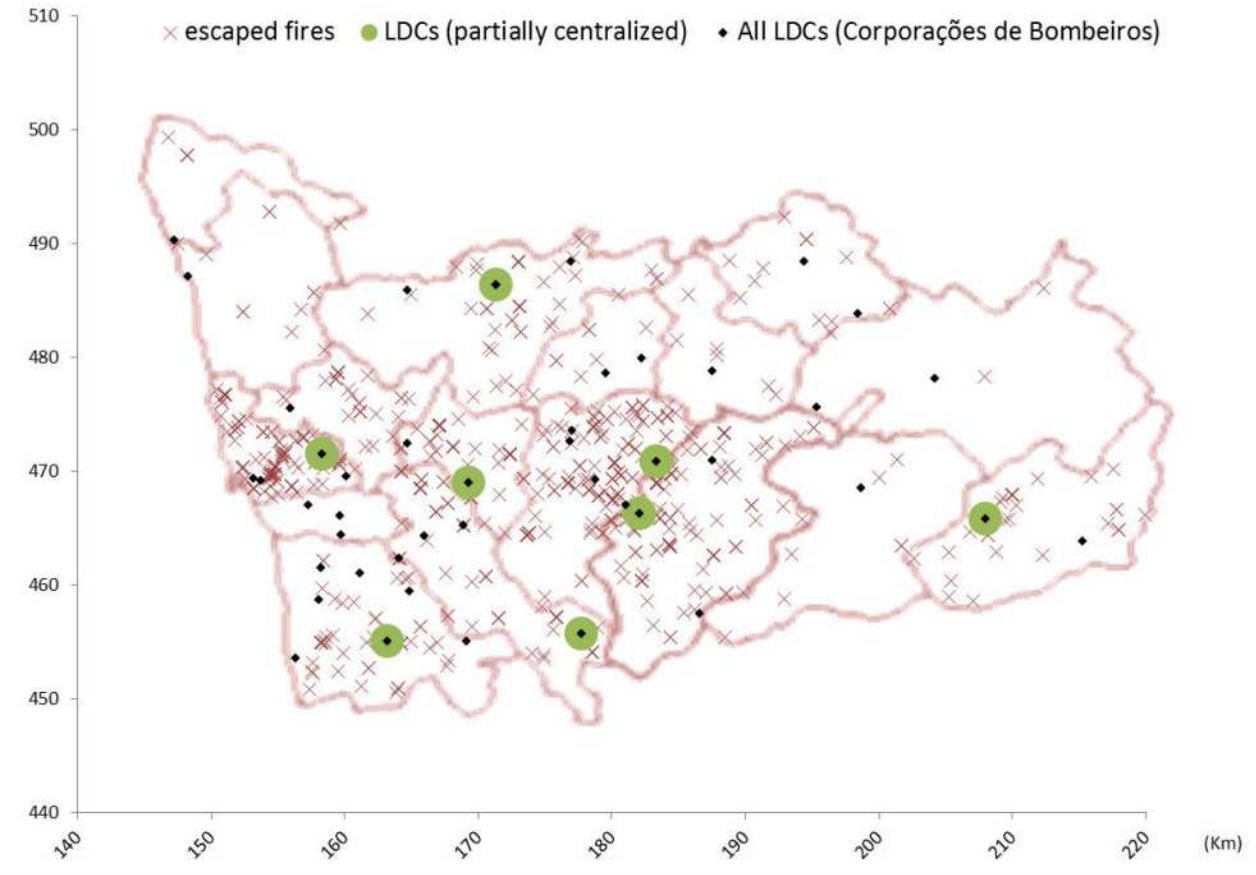

Figure 2. The best 8 (out of the current 45) LDC locations and randomly generated escaped fires, preserving the spatial pattern of historical forest fire data

For all the parameterizations, we use the Portuguese official fire databases, from ANPC and AFN/ICNF, the latter being the largest such database in Europe in terms of total number of recorded fires in the 1980–2005 period (Pereira *et al.* 2011).

Findings

Using one of the eighteen districts of Portugal as a case study (Porto, Figure 2), in the flexible design, the current fixed 45 locations were reduced to no more than 16 in the four scenarios. This design leads to a cost-effective allocation of equipment. Indeed, just in the case of the Porto district, it could reduce the investment in vehicles by about 6.5 M€, for a potential fleet reduction of up to 68%.
Additionally, the protection levels remain constant by keeping 90% of the potential fire-events within 10 km of the closest LDC and an average extra access time of sixteen minutes: these two indicators are reasonable given that they concern vehicles that are deployed after the fire escapes the first containment.

Contribution

This research tackles the issue of how to manage fire-fighting resources more cost-effectively. Analysis of empirical data of 2003 through 2005 provided by ANPC and AFN/ICNF, shows that Portugal has a very old and hardly used fleet of fire-fighting vehicles.
Our results show that a partial centralization by applying the proposed flexible design improves vehicle utilization efficiency while maintaining its effectiveness. The increased utilization reduces the number of vehicles needed and thus the cost of renewing the fleet (by about 100 M€). Policy makers might

consider using this new design as a strategy to address the lack of a management plan to procure equipment, since it eases the modernization of the current fleet.

Abstract
We model intra-annual management as a multistage capacity investment problem, considering a portfolio of resources enabling fuel treatment and fire suppression, and having fires as the demand.
The solutions are spatially explicit and our Mixed Integer Programming model considers two types of flexibility: capacity commitment postponement (prevention, pre-suppression, and suppression) and spatial flexibility (ground crews and aerial resources).
The results confirm that higher volatilities in weather conditions lead to commitment postponement, and we have found that the prevention/suppression balance changes qualitatively according to the burnt hectare value. The changes in the investment mix correspond to real world behaviors and challenge several myths. We have also found that above a certain threshold for the burnt hectare value, fuel treatments are always needed.

Keywords*: forest fire management, risk management, multi-resource investment, stochastic optimization*

Introduction

There are few natural phenomena with the scope and complexity of wildland fires (Van Wagner 1985). Highly unpredictable factors, such as weather, suppression performance, or fire behaviour, spread, and effects, have to be addressed in most Forest Fire Management (FFM) decisions. With limited financial funds, equipment, and human resources, policy makers must decide their most efficient and effective distribution among alternative FFM options, such as community prevention, fuel treatment, pre-suppression, suppression, and restoration (Mavsar *et al.* 2010).
In Portugal, forest fires are a severe problem, accounting for more than half the fires in the EU Mediterranean region (San-Miguel-Ayanz *et al.* 2013). In recent years, the consequences of forest fires have been particularly severe, with multiple catastrophic fire seasons (2003, 2005, 2013), and every year, on average, close to 2.5% of forestland burned, total direct losses near 250 M€, and more than 120 M€ spent in fire prevention and suppression.
To help tackle some of the challenges raised by the complexity and the large uncertainties in FFM systems, we use optimization to study the relationship between different types of operational flexibility, when used to mitigate exposure to uncertainty.

Methods

Using data and insights from our previous studies and fieldwork, we propose a Stochastic Mixed Integer Programming (MIP) model focusing on fuel treatment planning, but taking into account escape and suppression costs. We model intra-annual FFM as a multistage capacity investment problem, considering a portfolio of resources (Chod *et al.* 2010) enabling fuel treatment and fire suppression, and having fires as the demand.

Demand uncertainty has two origins: inter-annual weather variability (oscillations in fire season severity); and uncertainty in micro-scale factors (ignition, time, place, escape probability, and specific fire severity). We focus our analysis on mismatch risk (the cost of supply differing from demand): over-investment in FFM capacity will lead to unused capacity costs, whereas under-investment will lead to forest value loss. We model inter-annual weather variability with a scenario tree (considering conditions for winter, and spring) and micro-uncertainty with a spatial grid, each cell characterized by maximum ignition probability.

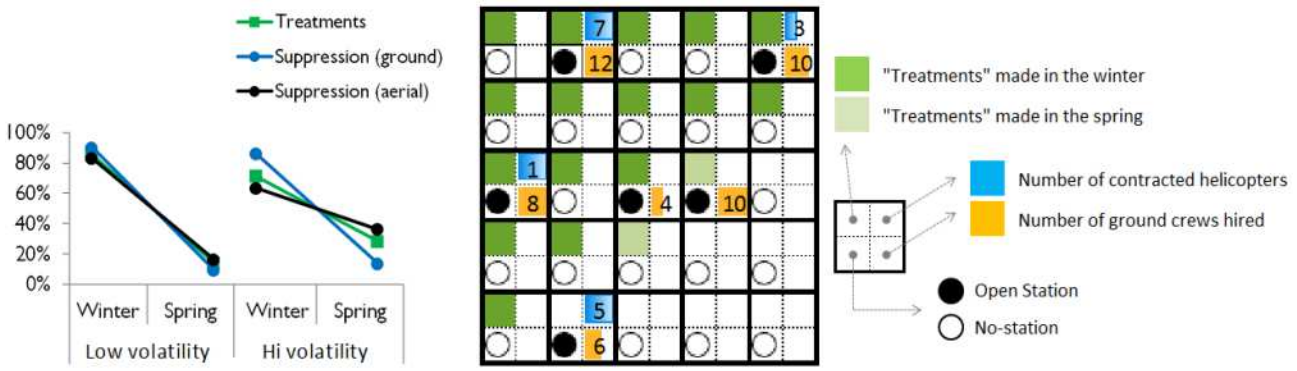

Figure 1. Low/high volatility vs. investment postponement % (left); spatial solution example (right).

We consider two types of flexibility (the ability to adapt to change): postponement of the commitment to each type of capacity (prevention and suppression), fine-tuning the capacity mix as the year evolves (and the weather conditional probabilities change); and spatial flexibility in a trade-off with the costs of the different suppression resource types (e.g., helicopters and ground crews).

3. Findings

Preliminary results point in three promising directions. First, the evolution of the investments along the year confirms that higher volatilities in weather conditions lead to their postponement (figure 1, left), and the results provide an estimate of the value for this source of flexibility. In addition, the solutions are spatially explicit (figure 1, right).
Second, we found that the balance between prevention and suppression changes qualitatively in the system (figure 2), according to the expanded cost attributed to each escaped fire (i.e., ignitions for which the initial attack fails, and come to be big or catastrophic fires), resulting in three system states.
Finally, fuel treatments are always of value above a certain cost per hectare. Indeed, independently of how the escape cost rises above that threshold, the optimal absolute value of the budget for fuel treatments remains almost constant (figure 2, solid green line).

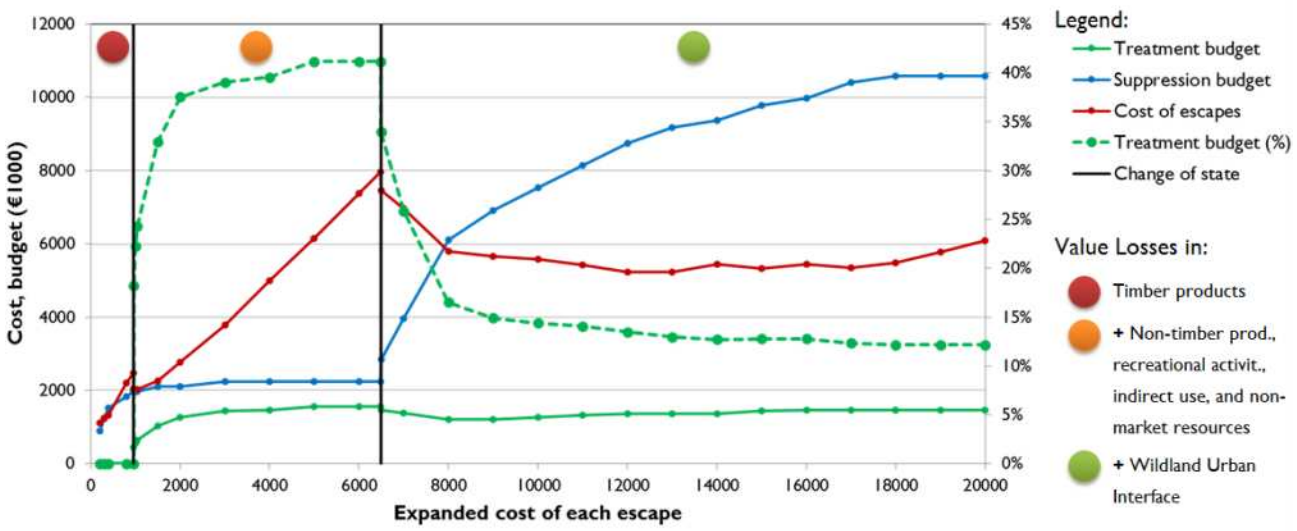

Figure 2. Global system behaviour and change of state (no prevention, prevention focused, and suppression dominance) according to the cost of each escaped forest fire.

Contribution

Studies addressing fuel treatment and fire suppression within the same model are scarce (Rideout *et al.* 2008), even more with the use of MIP, as in Minas *et al.* (2013), or Mercer *et al.* (2008). The latter inspired our model, which in turn modifies the standard-response model of Haight and Fried (2007) to include the effects of fuel treatment; in addition, we use insights from some of our previous studies (Collins *et al.* 2013; Pacheco *et al.* 2014).
Our results show that an integrated intra-annual FFM leads to a cost-effective allocation of the budget reducing the losses with catastrophic fires. In addition, the investment mix in each system state corresponds to different real world behaviours, challenging several FFM myths (e.g., prevention is always good; the prevention budget proportion should be at least one third; the utilization of helicopters is always a waste). Moreover, after a certain threshold the investments in fuel treatments are stable and always needed.

Abstract
Despite enhanced fire suppression efforts the number of fires has increased in Europe and in North Africa, above all in Portugal, and the extinction oriented model of fire control is no more suitable to change the trend. Hence, the need of shifting from a reactive model grounded on a fast and strong reaction, to more pro-active procedures supported by prevention, aimed not only to fuel reduction but also to gradually intervene on the causes of fires. In this perspective, a fair knowledge of man-caused fire outbreak motives is a crucial point. This paper intended to compare and interpret those motives in Portugal, Italy and Algeria obtained through the perception of experts (forest experts and other practitioners). In this research new data was collected in the North Region of Portugal and data already available for Algeria and Italy was commented.
The results of the research highlighted great similarities of the main fire causes and motives identified by the experts from the case-studies in the three countries. Fire outbreak motives are not related with deliberate fire setting but, mainly, with the use of fire in rural activities. Fire is a manageable tool that is still needed in many agro-forestry systems. One of the findings of this study pointed out the need to design and develop specific prevention programs able to reduce fire incidence and promote practices more respectful of the tradition and needs of rural communities, often criminalized for their habitudes of using fire as a multipurpose tool. Deliberate fire can represent isolated and sporadic actions however, some of them result from organized and even criminal interests. Finally, this paper argues that improved fire prevention to address the roots of fire problems cannot be achieved without a deep knowledge of the complexity and diversity of the fire outbreak motives.

Introduction

Each year burned area continues to be substantial in Europe and in other Mediterranean countries (Table 1). Enhanced fire suppression efforts and investments in human and technical resources (e.g. important aerial fleets; updated methods and technology to fight fires; emergency response organization, coordination and support) limited the damages but did not solve the fire problem which is far from being controlled. The incapacity of reducing the number of ignitions, the apparition of events that grow to previously unheard sizes, and more frequent and complex fires in the wildland urban interface, are alerting signals of the need to improve and change forest fires policies. A mainly extinction oriented model of fire control seems not well adapted to cope with new forest fire scenarios (Molina *et al.* 2010; Montiel and Herrero 2010; Sebastián López *et al.* 2011).

Source: *European Commission, 2013; **Annual Average Risk (AAR) i.e. the percentage of the wooded area burnt each year (FAO, 1999)

Even though forest fires have not usually been considered as a natural hazard by the scientific community (McCaffrey 2004), since the last decades of 20th century they have been recognized as natural hazards (e.g. floods, earthquakes) by the state agencies and institutions, such as NASA or European Union (EU) (Leone and Lovreglio 2003) and, consequently, as a problem to be covered by Civil Protection (or Civil Defence in some countries). Forest fires are a civil protection/defence problem in the moment of suppression, but they are the result of complex interrelationships between society-environment-economy, thus requiring a rather different approach shifting from the reactive model, typical of Civil Protection, to more pro-active procedures supported by a prevention strategy (EFIMED 2012; Xanthopoulos 2012; Marino *et al.* 2014; Raftoyannis *et al.* 2014).

A symptomatic solution dealing with problems, as they arise, but failing to address the underlying causes, can increase the chance that the same problem will crop up in the future. In the case of forest fires, this means to allocate resources to short-term fixing of symptoms, increasing emphasis on fire suppression, instead of dealing with the causes of problems (Collins *et al.* 2013), so neglecting fire prevention. The "*firefighting trap*" metaphor as used in business domain (Collins 2012; Collins *et al.* 2013) well depicts such a short sighted cycle of problem-solving.

Policy makers and fire managers should pursue a balanced approach to suppression and prevention activities (Collins *et al.* 2013) aimed not only at fuel management but also to intervene on the causes of forest fires which are predominantly the result of anthropic activities (FAO 2012).Thus, actions must effort to change individual, social and institutional behaviours, but they meet a weak point in the general lack of in-depth knowledge of causes and forest fire outbreaks motives which according to FAO (1999) is a "*precondition for the implementation of prevention adapted solutions*" (p. 41). It is actually biased by the relevant incidence of unknown causes [e.g. 95% in Morocco (European Commission 2013), 80% in Algeria (Meddour-Sahar *et al.* 2013), 60% in Tunisia (Ben Jamaa and Belhaj 2011), 16% in Italy (CFS 2012), 49% in Portugal (ICNF 2012)]. This is due to the current system of producing forest fires statistics through an a-critical processing of individual forest fires reports, compiled soon after control activity is over. The task is difficult without appropriate surveys, which are impossible in the presence of a great number of events, most of them of less than 5 ha, and without the identification of each ignition point.

This study intended to interpret the motives (i.e. "the intentional state which prompts or moves one to act"; Wrathall 2005: p. 118) of forest fires outbreaks in Portugal through the perception of forest experts, and compared the results with previous studies realized in Italy and Algeria, by a method which consistently reduces the incidence of unknown motives. This paper argues that improved fire

prevention to address the roots of fire problems requires a deep knowledge on the complexity and diversity of man-induced fire causes and motives and should be sensitive to their spatial variation.

Methods

In the absence of sufficient data and/or complete knowledge in regard to forest fires motives the Delphi technique, grounded on a structured process to collect opinions from a group of experts, can be used. This collective judgment, although made up of subjective opinions, is considered to be more reliable than individual statements and is thus more objective in its outcomes.

In Portugal, a research of forest fires causes using Delphi method was conducted in the North Region (NUT 2), with about 3.6 millions of inhabitants (INE 2012) and a surface of 21,278 km^2. It is among the most fire prone regions of the country where, between 1980 and 2011, a total number of 351,550 fires was recorded which burned 1,219,609 ha. The North Region encompasses 86 municipalities, but the urban municipalities of Porto and S. João da Madeira were excluded from the analysis. To the 84 selected municipalities a questionnaire was sent by email to be answered by the Forest Fire Technical Division of each municipality which is responsible for the Municipal Plan for the Defence of the Forest Against Fire, as established by the Decree-law 17/2009. The questionnaire contained the Portuguese official list of the three level structure of fire causes reporting 68 motives (http://www.icnf.pt/portal/florestas/dfci/Resource/doc/estatist/dgrf-codificacao-causas.pdf; Camia *et al.* 2013), divided into seven main categories (i.e. *negligent usage of fire, accidental, structural causes, incendiary, natural, unknown, and rekindle*) with their identification codes. Experts should identify the fire outbreaks motives in their territories, classifying them by a Likert scale from 1 to 5 (ranging from *not important* to *extremely important*); successively, they were asked to rank the six most important motives in decreasing order of importance from 1 (the *most important*) to 6 (the *least important*). Sixty nine valid answers were received (i.e. a return rate of 82% of the contacted sample). The information from the questionnaire was analysed and a fire motive rank-ordering was established as the mode of rank-scores. The early results of this procedure are presented and discussed in this paper. The following step will be the organization of meetings in different municipalities of the North Region to circulate, validate and discuss the results from the questionnaire.

The procedure used in Portugal was slightly different from the one used in Algeria and Italy concerning the two rounds interspersed with a feedback and the number of ranked motives, only six in Portugal instead of the eight in Algeria and Italy. These differences did not have implications in the comparative study. Detailed information on the methodology used in Algeria and Italy can be found in Meddour-Sahar *et al.* (2013) and Lovreglio *et al.* (2006), respectively.

In Algeria, the Delphi method was used to identify forest fires causes and motives in the three most affected *wilayas* (equivalent of NUTS 3, Departments) i.e. Bouira, Boumerdes, and Tizi Ouzou (Meddour-Sahar *et al.* 2013; Meddour-Sahar 2014).

In Italy, the same method was used in the 29 most affected provinces in the Centre and South of the country, in two National Parks (NP) in the South of the Country (NP of Gargano, NP of Cilento and Vallo di Diano) and in some minor administrative units such as Mountain Communities (MC) (Lovreglio *et al.* 2006; De las Heras *et al.* 2007; Lovreglio *et al.* 2008; Leone and Lovreglio 2009; Lovreglio *et al.* 2010a,b; Marciano *et al.* 2010; Regione Puglia 2012).

Although it was interesting to consider Spain in this study, the data obtained also using Delphi method (APAS and IDEM 2003, 2004; Dolz Reus and Franco Irastorza 2005; Franco Irastorza and Dolz Reus 2007) were not comparable for methodological differences.

3. Results

The frequency analysis of forest fires outbreak motives reported as extremely important by the panel's members in North Region of Portugal showed a large variety of motives, where just five of 68 possible reasons were not identified as extremely important by the experts. The most mentioned were rekindle

(considered by 54% of the municipalities) and management of forestry or agricultural vegetation (e.g. renewing pastures, 48% of the municipalities' responses; clearing of forest areas, 45%; clearing of agricultural areas, 41%). Other motives were related with conflicts in the use of resources (e.g. hunting conflicts, 30%), influence on economic/market activities (e.g. pressure on wood market, 20%), social and interpersonal tensions (e.g. conflicts between neighbours, 26%; revenges and retaliatory actions, 24%), and antisocial behaviours (e.g. pyromania, 38%; vandalism, 32%).

The rank obtained from the modal values of the extremely important motives classified from 1 to 6 by the panel's members highlighted the same reasons although presenting them in slightly different order (Table 2). Thus, the most important fire ignition motive in the North Region of Portugal was renewing pastures which was identified as the first one in 16 municipalities and the second one in another nine municipalities. Still related with management of forestry or agricultural vegetation cleaning the agricultural lands and cleaning forest lands appeared in rank 2 and 3, respectively. Pyromania appeared in rank 4, being the main motivation in eight municipalities. In rank 5, appeared vandalism as well as rekindle. Conflicts between neighbours were classified in rank 6.

The results of the rank ordering in North Region of Portugal were not very different from the ones found in Algeria and Italy. Furthermore, in these countries fire, as a manageable tool needed in many agro-forestry systems, appeared as the main reason for fires outbreaks. In Algeria (Table 3), the use of fire in agricultural works was the main motive in the three wilayas together with vegetation management activities (i.e. creation or renewal of pastures, forest works, and wild honey hunting). Illegal garbage dumping and burning, mentioned in the three wilayas although in different rank position, is an "inevitable ´problem solving´ solution by inhabitants, who have no other more sustainable alternative for waste disposal" (Meddour-Sahar *et al*. 2013: p. 251). Other negligent reason was cigarettes remains. Deliberate fires (i.e. intentionally caused by human, according to the harmonized classification scheme of fire causes in EU, Camia *et al*. 2013) were mainly related with interests in land use changes. Rekindle appeared important in Algeria too, where it is caused by fire crews who do not always ensure the mopping up of controlled fires but as well as by the so called "security fires" (Meddour-Sahar *et al*. 2013).

In Italy (Table 4), with the exception of the Province of Bari, the negligent motives are also more important than deliberate use of fire. Multiple motives in the same rank order reflect the

difference of experts' perspective. The main negligent reasons (classified in rank 1) in all the study-areas were agricultural burnings (e.g. *stubble burning, creation or renewal of pastures, burning of fallow, burning of rests, agricultural land cleaning after harvesting*). Also considered in the rank of the six most important fire outbreak motives appear: *fire-crackers and bottle-rockets, careless use of*

machinery, *cleaning of road/railroad*, *hot vehicle exhaust pipes*, *cigarettes remains,* and *illegal garbage dumping and burning*. *Garbage dumping and burning* is a negligent action in the current EU causes classification (Camia *et al.* 2013), where it is considered a form of waste management. Anyhow, mainly in the South of Italy, it is related to illegal dumping and successive burning by organized criminality, for which illegal waste and garbage traffic and disposal represent an important eco-business; for this it must be classified as voluntary, related to illegal profits.
Deliberate fires motives in the Italian case-studies appeared very diverse and with different profiles. The most important motives are profit activities to obtain goods, job or even money (e.g. *hunting products in areas scorched by fire passage as mushrooms and wild asparagus; building speculation; vegetation burning to earn agricultural land; fire lit to depreciate tourist area; fire caused with the intent of being included in fire-fighting crews*). Social and interpersonal tensions (e.g. *hunting conflicts and poaching*, *ownership controversies*) can also explain some fire setting. Some forest fires events could be attributed to negligent behaviours (e.g. *fire-crackers and bottle-rockets*; *careless use of machinery*; *hot vehicle exhaust pipes*). The experts also identified fire outbreaks as a mean of protest and contestation against public or installed powers (e.g. *retaliation against public administration* and *protest of seasonal fire-fighters)* as well as *noncompliance with regional regulations*. Antisocial behaviours (e.g. *pyromania, vandalism*) did not appear as relevant as happened in Portugal. *Rekindle* was not considered significant in Italy, and was just mentioned in Sardinia Region.
Forest fires outbreaks motives hotspots in all the case-studies were related with the fire use in agriculture burnings and vegetation management. The representativeness and the profile of deliberate fire motives are distinctive between the case-studies.

Discussion

Forest fire outbreaks motives are not a fixed and immutable concept being used through the centuries. "*Fire's definition has changed with its cultural circumstances. It takes its character from its contex*t" (Pyne 2006: p.1). Main motives behind fire outbreaks found in the study-areas can be categorized in three main groups: traditional fire use (TFU) which refers to communities using fire for land and resources management purposes, based on traditional know-how (Lázaro 2010); deliberate fires; and rekindle, each of them putting different challenges in developing measures to reduce their incidence.
TFU explains most of the fires in Portugal, Italy and Algeria as it is a deeply-rooted tool for land and resources management purposes, namely *agricultural or forest residues burning* and for *creating or renovating pastures*. TFU has been facing a very restrictive legal framework (Lovreglio and Leone 2010) resulting from the incapacity to understand that "*fire for humanity is more than a problem or a process. It is a relationship*" (Pyne 2006: p.6). The illegal use of fire is often carried out as a *hit-and-run* practice (e.g. by shepherds setting fires during the night and escaping to avoid prosecution) many times taking place even in days of high fire danger which can provoke the occurrence of large and severe fires. TFU still represents an efficacious way of "problems-solving" by aged rural societies, whose members persist with practices now considered with disdain by the dominant urban society; the latter sometimes adopts a top-down approach deciding plans and programs in the rural context without concertation nor listening the rural communities. For decades state agencies ignored this reality and the criminalization of TFU in land management activities and the lack or absence of alternatives just aggravated the problem. Problems solving through the use of fire fits with the relevant concept of "*man responsible, but not guilty*" as theorized by Dumas *et al.*(2013) and well indicates a possible direction for prevention measures based on the scientific knowledge, respect and wise re-utilization of T.E.K. (Traditional Ecologic Knowledge: Ribet 2002) in rural areas. The criminalization of TFU and the public strategies to deal with high impact fire events, mainly through subsidies to overlap property damages, can inhibit the TFU and transform it in deliberate fire. Considering the high representativeness of the negligent use of fire in agricultural and forestry works in the investigated fires with known causes (46% in 2012 in Portugal, according to ICNF 2012), an improved action on

TFU could have a significant contribution for a sustained reduction of fire occurrence. The concept of integrated fire management offers the framework to enhance TFU (FAO 2006; Silva *et al.* 2010) which implies making communities part of the solution requiring a community-based fire management (CBFiM) approach i.e. "*an approach to fire management in which local communities are actively engaged in the development, and in some instances the implementation, of fire management strategies designed to prevent, control or utilize fires in ways that will improve their livelihood, health and security*" (FAO 2011: p.4).

Deliberate fires in all study areas represented only a part of the arson motive classification as proposed by NCAVC (National Centre for the Analysis of Violent Crime) of FBI Academy (Icove and Estepp 1987; Douglas *et al.* 1992), namely: *vandalism*, *excitement*, *revenge*, *crime concealment*, *profit*, and *extremist*. These classes were also proposed by the new classification scheme of fire causes in EU (Camia *et al.* 2013). In the study-areas the classes retrieved were mainly *vandalism*, *revenge*, and *profit* (including some cases of deliberate fires by organized crime, e.g. *fire lit to depreciate tourist area* as was mentioned in Italy).

"Logics" behind deliberate fires can be a consequence of processes acting: (i) at different spatial scales (e.g. some fires are related with local conflicts that originate revenges; others can be associated with the constraints of a top-down approach by state agencies, interest of non-local groups or even criminal organizations); (ii) with different frequency (i.e. some fires are isolated events; others can have a high frequency reflecting the repetition of the same fire outbreak motive). The representativeness and the profile of deliberate fire outbreak motives resulted distinctive between the case-studies. Most of the motives identified in the case-studies appeared as a consequence of local dynamics reinforcing the importance of adopting CBFiM approach with adapted strategies of intervention. A small part of deliberate fires can be interpreted as a reaction from the peasantry to the exclusion from their environment imposed by the urban society (Zarraga Moreno 1988) and the top down approach used by the state supporting policies that affect the forms of local life (e.g. forestation of commons, too restrictive nature conservation policies, precluding hunting). Others can be related with taking profit of sectorial policies (e.g. hunting law, nature conservation law) or spatial planning (e.g. urban sprawl planning). Others can result from the management of resources imposed without assessing the impacts on the economic dynamic, environment quality and social relationships in each territory. In some cases they can represent a reaction against benefits established by law which can create conditions favourable to the exploitation of local resources by people from outside the communities, for instance changes of land use. Antisocial behaviours in Algeria and Italy (e.g. *pyromania, vandalism*) did not appear as important as happened in Portugal where *pyromania* can be related with the misuse of the term. There are different solutions to deal with deliberate fires. Law enforcement is important not only to penalize behaviours but mainly to control business opportunities related with fires. However it is not the only solution mainly because "a one fits all" strategy more than solving a problem can develop it.

The importance of *rekindle* is different among the case-studies considered in this paper. The frequency of fire restart is higher in Portugal and the situation has aggravated over the years (Pacheco *et al.* 2012). "*The high number of rekindles results from the pressure on the suppression system which works at constantly very high levels of capacity utilization, and is constantly requested to immediately combat all the new fires*" (Pacheco *et al.* op. cit.: p.10). *Rekindle* is important in Algeria too and can be explained by the pressure on the suppression apparatus, adding to the specific lack of security in some forested areas due to problems of terrorism, which make dangerous working in forests (Meddour-Sahar *et al.* 2013). In Italy, *rekindle* is not present in the official list of motives, with the exception of the autonomous Region of Sardinia where it appeared in the second rank. Reducing the incidence of *rekindle* could be achieved directly by enhancing suppression effectiveness (e.g. better training in mop-up operations), active surveillance, increased crew capacity and by adjusting dispatch rules (Pacheco *et al.* 2014). Indirectly, it could result from the reduction of the number of fire outbreaks which implies a decrease of the pressure on suppression apparatus. Pacheco *et al.* (2013) presented

quantitative evidences of the advantages of investing in prevention to reduce *rekindle* as well as "*to invert the vicious circle of more fire, more teams*" (p.53).

Conclusion

It is a common place to say that addressing current forest fire problems requires more balanced suppression and prevention policies. The "*firefighting trap*" pointed out for the need to increase fire prevention clearly identifying the pitfalls of a single suppression approach. However, it is not possible to enhance prevention without a deep knowledge on the complexity of fire causes and outbreaks motives. This study showed the importance of adopting a cause-based approach focusing on the underlying reasons that induce specific negligent or deliberate behaviours.

Fire occurrence cannot be understood if disconnected from the social environment in which is produced (Zarraga Moreno 1988).The theoretical knowledge of the cultural and social construction of fire outbreak motives based on empirical studies is one of the requirements of paramount importance to enhance prevention. Without this scientific knowledge and its integration with local knowledge and the interests of the communities, the development of prevention programs can be misleading and contribute to discrediting the indisputable role of prevention. However, the immediate consequence should not be the design of a general model indistinctly applied in all contexts even with similar characteristics. From an operational point of view the theoretical framework should support prevention plans using a place-based approach, taking into account that more superficial is the knowledge of forest fire outbreak motives more inefficient and dangerous can be the transfer of findings from one context to another even with the same profile. An improved knowledge on fire ignitions motives can enhance forest fire prevention as implies a collaborative effort and communication between state agencies and local communities, thus necessarily adopting a CBFiM approach. However, it does not mean "a "*one size fits all" approach, but rather it must be tailored to meet specific needs and circumstances to be an effective and sustainable approach to fire management*" (FAO 2011: p.1-2).

Fire prevention oriented to the reduction of fire outbreaks is a complex issue comprising three processes: (i) knowledge of man-caused ignition motives; (ii) the development of specific targeted awareness campaigns promoting communities' engagement to change attitudes and behaviours; (iii) and concertation between communities and public organizations. The latter is a very complex and ambitious goal. It needs to accommodate several interests and solve conflicts between several actors (e.g. forest services, shepherds, farmers) through proper communication, finding concerted and socially acceptable solutions, defining new relations between public policies, administration, and communities.

Acknowledgment

The first author would like to thank the experts from the North Portugal municipalities for their collaboration in this research and CEGOT – Centre for Geography Studies and Spatial Planning, a research unit funded by FCT- Portuguese Foundation for Science and Technology, (PEST-OE/SADG/UI4084/2014) for funding the participation in the VII International Conference in Forest Fire Research.

Abstract

Wildfires statistics for Sardinia (Italy) exhibit a very high number of unknown causes: all merged, they account for about 78%. In order to reduce their number, which really hinders any preventive approach, we tested Delphi method, the structured communication technique which relies on a panel of experts.. Results, obtained in collaboration with the Regional Forestry Service (CFVA), put in evidence the concordance among the highest frequency of motifs in regional statistics, as from CFVA databases and those resulting from Delphi survey. Our study reveals a modest prevalence of intentional causes (53 % of total number), also on a provincial basis, v. unintentional ones (46%). All of them can be classified as negligent use of fire in agriculture, namely stubble (or other agricultural wastes) burning, inappropriate or uncontrolled mop-up , negligent use of motors, open flames, electric or mechanical devices, non compliance with regional reglements concerning fire prevention and control. Voluntary fires are also related with agriculture and a traditional rural society, in which fire is a well rooted tool.

Keywords*: Delphi method, fire causes, fire smart, forest fire protection plans, individual fire report, integrated fire management, negligent behaviour, panel of experts, traditional ecological knowledge.*

Introduction

In this paper, we deal with the implementation of a Delphi survey in the eight provinces of the island of Sardinia (Italy), aimed to produce statistics on wildfires causes mainly avoiding unknown causes which represent about 78% (1998-2011) of the total.
Sardinia is a real hotspot for wild fires, which are a recurrent presence.The second largest island in the Mediterranean Basin after Sicily, with a surface of about 2,408,989 hectares, Sardinia is prevalently hilly; 13.6% of the island is mountainous, 18.5% is flat and 67.9% is rugged and hilly.
Forests cover a total of 1,213,250 hectares of which forest cover respectively 583.472 hectares, i.e 24,22%,; other woodland cover 629.778 hectares i.e. 26,14%; thus Sardinia has a forestry index of 50,36 % (Salis *et al*., 2013).

1.1. Climate and territory of Sardinia

The climate is inner Mediterranean (Chessa & Delitala, 2012; Vacca *et al*., 2002), or dry summer subtropical (*Subtropical Csa* type after Köppen, 1936) with an exceedingly long summer and a short humid winter interspersed with three short rainy seasons.
Maximum temperatures of 35-40 °C are repeatedly recorded and peak temperatures climb occasionally well above 45°C as in 2003 and 2009. An absolute maximum of 48,0 °C was recorded in 1965 in Macomer (Chessa & Delitala, 2012).
Wind speed can largely exceed 13,5 m/s (Chessa & Delitala, 2012) with a maximum registered speeds of 64 knots for NW winds in Cagliari and 59 for W winds in Alghero (respectively 118 and 109 km h^{-1}; Osservatorio Industriale della Sardegna, 2000).

1.2. Fires: number and surfaces

About 600,000 ha of woodland were burned in Sardinia in the last 120 years (D'Angelo & Enne, 2000). In the period 1970-2010 fire occurrence is documented (Regione Autonoma della Sardegna, 2011) by the following data (mean ± S.D. and CV, coefficient of variation) :

Number of fires *3,341 ± 1,113 (0.34)*
Burned surface (ha) *38,336 ± 27,619 (0.70)*
Burned forested surface (ha) 7,701 ± 6,847 (0.87)

Sardinia exhibits the highest incidence of wildfires among Italian Regions.

1.3. Fire suppression effort

To counter such a recurrent calamity, since the '80s the autonomous Region of Sardinia has improved its fire suppression apparatus. Despite relevant investments in human and technological resources, results are apparently acceptable. If burned surfaces diminished, due also to improved suppression procedures which insure initial attack within 14' as an average, thus containing 97% of fires under 10 hectares, the number of events (a yearly average of 2,800-3,000) remains accordingly unchanged along time (Boni, 2004).

1.4. Fire causes

There are a variety of motivations for wildfires in Sardinia and their recognition is the key to finding a solution for a more efficacious control (Jollands *et al*., 2011).
It is actually accepted (Birot, 2009; Montiel & Herrero, 2010) that facing the increasing wildfire threats demands a shift from suppression-oriented policies to preventive and integrative policies aimed at removing the structural causes of wildfires. But this pro-active approach requires a good knowledge of the causes contributing to wildfires.
Forest fire statistics, yearly compiled by CGVA (The Sardinian Forestry Rangers Corps) on the basis of individual fire reports, confirm that agropastoralism still plays a major role among the causes of fires, with a positive correlation between sheep number and burned surfaces.
In Tab. 1 motifs, as assessed by CFVA for 1998-2011 and stored in its databases, are reported with their statistical code, where C stays for involuntary, D for voluntary or deliberate. Only motifs with a frequency > 2.00% are considered.

Tab.1 - Motives in order of importance for provinces (1998-2011) through the official statistics by CFVA

Statistical code	Description	Frequency	Frequency in %	Province where frequency is maximum
C09	Fires caused by agricultural and forest activities (burning of stubble and agricultural wastes)	47	12.40	Oristano
C05	Fires caused by inappropriate or uncontrolled mop-up	28	8.70	Oristano
C11	Fires caused by the careless use of machinery	33	7.80	Sassari-Olbiatempio
C08	Non compliance with the the Regional Ordinance relating to the Prevention and Control of Fires	25	7.60	Oristano
C01	Fires caused by cigarette stubs or matches	27	6.80	Sassari-Olbiatempio
D12	Fires caused by behavioural disturbance (pyromania)	28	6.70	Ca-Carbonia Iglesias

C15	Fires caused by poor power line maintenance	27	6.30	Sassari-Olbiatempio
D02	Fires caused by agricultural and forestry activities for the clearing of uncultivated land	21	6.10	Oristano
D03	Fires caused by conflicts or revenge among private owners (for pasture)	32	6.00	Ca-Carbonia Iglesias
D17	Fires caused with the intent of creating an alert situation in firefighting structure	26	5.90	Nuoro-Ogliastra
D13	Fires caused by revenge or retaliation referable to poaching	15	4.20	Oristano
D04	Fires caused by conflicts or revenge among private owners or shepherds and public agencies (for pasture)	15	2.70	Nuoro-Ogliastra
D18	Fires caused by arson (not otherwise defined)	11	2.60	Nuoro-Ogliastra

Such statistic are based on less than 23% of the 8,428 fires occurred in the period 1998-2011.In many cases motifs are classified as unknown voluntary or unknown involuntary, without a specific motive. All merged, unknown causes account for 77.65% and therefore do not give the sufficient information deemed necessary for a more preventive approach.
In order to reduce the number of unknown events, in collaboration with CFVA we tested the Delphi method.

Materials and methods

The Delphi method

The Delphi method (Dalkey & Helmer 1963, Linstone & Turoff 2002) is an iterative process based on the principle that *"a group of experts usually performs better than any one expert because the group possesses at least as much knowledge as its most knowledgeable member"* (Henderson, 2008).

The panel of experts and the questionnaire

For our Delphi survey, carried out in 2012, experts were the non commissioned officers working for CFVA. As from their statement, their knowledge of wildfires is very good for 54% of them, excellent for 14%. They were convened in four successive sessions from one or several neighboring provinces. Number of experts per session varied from 14 for the merged provinces of Nuoro-Ogliastra to 30 units in the provinces of Cagliari-Carbonia/Iglesias, for a total number of 98. Number of experts was balanced among areas and, in addition, well above the minimum (at least 10, Delbecq *et al*., 1975). Structured questioning was achieved through the use of *ad hoc* questionnaires, reporting the motives of forest fires for Sardinia as used by GFVA in official statistics (Saba, 2004). Experts were asked to recognize the four most relevant fire motives in their area of duty and were then invited to rank such motives in order of decreasing importance, giving a score ranging from 1 (maximum) to 4 (minimum). In previous works we used a range of 1 to 8 (Lovreglio *et al*., 2006, 2008, 2010, 2012 ; Meddour-Sahar et a.l 2013). Reducing rank score range to 1 to 4 obliges respondents to make a more severe selection in their responses. Controlled feedback was achieved by discussing responses, and then asking the panel members whether they wanted to change their judgements.

Results

Rank-ordering is the mode of rank-scores. Causes, from our survey, result involuntary for 46%, voluntary for 53 %, natural for 1 %; values are coherent with the general opinion that voluntary fires are often overestimated or overemphasized (Vélez, 2000).

A comparison between the voluntary/involuntary motifs as detected by CFVA in the period 1998-2011 and the motifs identified by the panel of experts was carried out.
In some provinces voluntary fires are clearly prevailing in CFVA official statistics, with the exception of Cagliari-Carbonia Iglesias, where Delphi assesses a majority of voluntary fires.
Motifs issued from Delphi survey and arranged following the mode of rank-scores are presented in Fig.1. Identification codes in the bar chart reflect the official list of causes as proposed by CFVA (Saba, 2004).

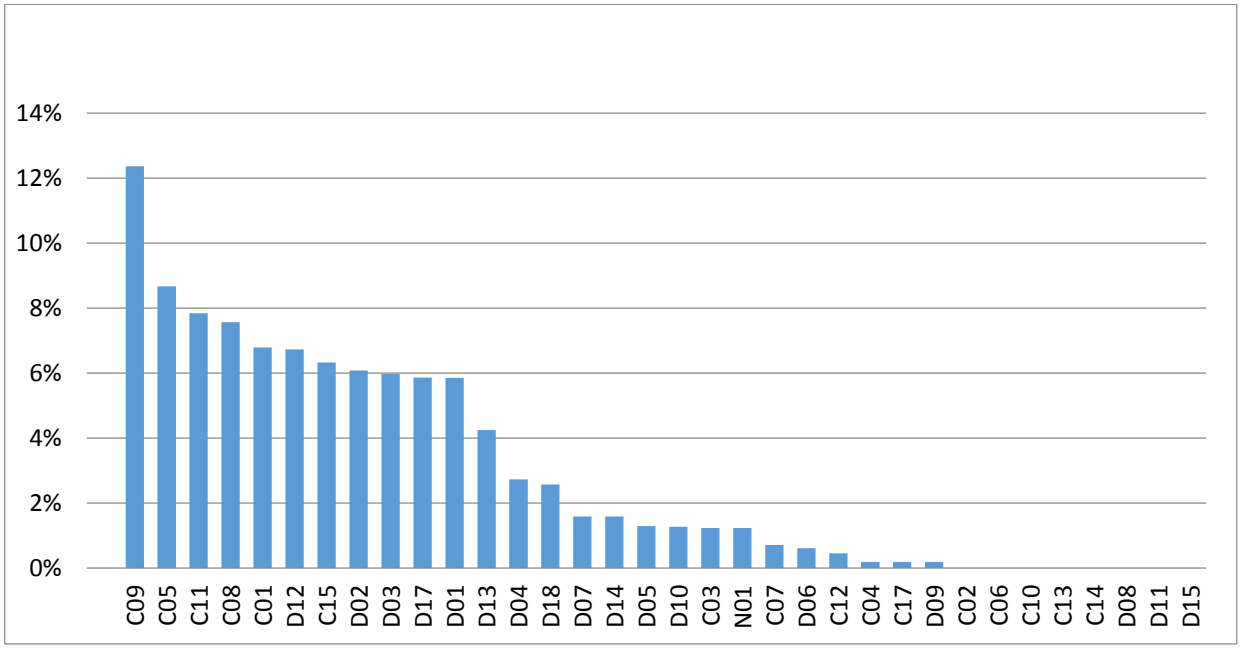

Figure 1 Frequency (%) of the motifs on a regional scale as a result of Delphi method

In Tab. 2 we present the motifs as assessed in the regional wildfires databases and results of our Delphi survey, in terms respectively of frequency and rank order.

Tab.2 - Motives at regional level: comparison between data from regional databases and data from Delphi survey

Motives frequency Data from regional databases		Motives frequency Data from Delphi survey		Motives rank order (1 to 4) Data from Delphi survey	
C09	Fires caused by agricultural and forest activities (burning of stubble and agricultural wastes)	C09	Fires caused by agricultural and forest activities (burning of stubble and agricultural wastes)	1	C09 Fires caused by agricultural and forest activities (burning of stubble and agricultural wastes)
C05	Fires caused by inappropriate or uncontrolled mop-up of fires	C05	Fires caused by inappropriate or uncontrolled mop-up of fires	2	C05 Fires caused by inappropriate or uncontrolled mop-up of fires
C11	Fires caused by the careless use of machinery	C11	Fires caused by the careless use of machinery	3	C11 Fires caused by the careless use of machinery

C08	Non compliance with Regional Ordinance relating to the Prevention and Control of Fires	C08	Non compliance with Regional Ordinance relating to the Prevention and Control of Fires	4	C08 Non compliance with Regional Ordinance relating to the Prevention and Control of Fires

Results put in evidence the full concordance among the highest frequency in regional statistics, as from CFVA databases and the motifs as perceived by the experts in Delphi survey:
In the following Tab. 3 we present the top motives, i.e. those ranked 1 to 4, through the Delphi method, on a provincial scale.

Tab. 3 - Rank order of motifs by Province

Rank	Oristano	Sassari-Olbiatempio	Ca-Carbonia Iglesias	Nuoro-Ogliastra
1	C.05 Fires caused by inappropriate or uncontrolled mop-up	C.11 Fires caused by the use of machinery (motor, flame, electric or mechanical devices)	C.09 Fires caused by agricultural and forest activities (burning of stubble and agricultural wastes)	C.09 Fires caused by agricultural and forest activities (burning of stubble and agricultural wastes
2	C.09 Fires caused by agricultural and forest activities (burning of stubble and agricultural wastes	C.15 Fires caused by poor power line maintenance	D.03 Fires caused by conflicts or revenge among private owners (for pasture)	D.02 Fires caused by agricultural and forestry activities (clearing of uncultivated land)
3	C.08 Non compliance with the Regional Ordinance relating to the Prevention and Controll of Fires and Abusive stubble burning	C.03 Fires caused by cigarette stubs or matches	D.12 Fires caused by behavioural disturbance (pyromania)	C.11 Fires caused by the use of machinery (motor, flame, electric or mechanical devices)
4	D.02 Fires caused by agricultural and forestry activities (clearing of uncultivated land)	C.08 Non compliance with the Regional Ordinance relating to the Prevention and Control of Fires and Abusive stubble burning	D.17 Fires caused with the intent of creating an alert situation in firefighting structure	D.17 Fires caused with the intent of creating an alert situation in firefighting structure

Discussion of results

The results represent only the collective informed opinion and judgement of the experts participating in the panel about fire motives but, at our opinion, there is no alternative way to produce better results,

with the exception of information issued from sentences beyond recall for identified culprits (Leone *et al*., 2009).
Our research was based on the opinions of professionals with an interest, knowledge and field experience in wildfires, assuming that replies are frank and well meditated.Their responses should however be taken to be truth-as-observed by experts not exact science (Jollands *et al*., 2011).
By the Delphi method, unclassified causes of wildfires in Sardinia are eliminated, thus allowing to express more clear information on the possible roots of the phenomenon.
Our results reveal the relevant importance of unintentional causes, which are prevailing also on a provincial basis. All of them can be mainly classified as negligent use of fire in agriculture (burning of residues, stubble burning, negligent use of agricultural machinery, non compliance with regional regulations concerning use of fire..).
A closer analysis of motifs reveals only two cases of voluntary reasons: creating an alert situation in fire fighting structure, though ranked at 4th position, and pasture conflicts; the latter recalls the importance of traditional pastoral activities in the island. If we exclude from analysis pyromania, all others motifs are directly or indirectly connected with agricultural activities and a rural society. In many cases the threshold between voluntary and involuntary is rather fuzzy, such as the case of stubble burning behind official date fixed by regional regulations. Voluntary fires, on the contrary, are more limited but they also partly refer to the use of fire in agriculture.
In the province of Oristano inappropriate mop-up is referred to extinction operations not carefully carried out. Limited to Sassari and Olbia-Tempio province, we notice fire caused by lack of maintenance of power lines. Both situations give a clear info about possible solutions, respectively improving suppression procedures and ensuring power lines efficiency through maintenance.
Results reflect a society accustomed to using forest and rural spaces, with scarce respect and care and without concern for its preservation (Thirgood, 1981; Dimitrakopoulos and Mitsopoulos, 2006).
Causes and their motives, as issued from our research (involuntary for 46%, voluntary for 53 %, and natural for 1 %, as percentages of respondents' judgments), are well consistent with the general trend reported in current literature (Catry *et al*. 2010).
In Sardinia, traditional abilities and know-how of fire use represent a deeply rooted tool for agricultural activities (Silva *et al*., 2010b), a true *TEK, traditional ecological knowledge* (Ribet, 2002) well used by a still fire-relying community (Lazaro & Montiel, 2010).

Conclusions and final remarks

Delphi method for the identification of the major causes and reasons of forest fires exploits the good level of panellists' expertise and their knowledge of the territory and of local socio-economic scenarios behind the phenomenon of wildfire, in a rather quick and easy way (Lovreglio *et al*., 2006, 2008, 2010, 2012; Meddour-Sahar *et al*. 2013).
As in the case of Sardinia, where official info about wildfires is rather poor, Delphi method is intended for use in stuations where statistic method are not possible due to the lack of appropriate data.
Understanding the most frequent causes and reasons in different social contexts can definitely help the prevention measures and the efforts in modifying the behavior of individuals in complex social contexts.In our study area recognizing the presence of a fire-relying community, as from Delphi results, could suggest an approach locally based on a different and fire-smart application of the traditional use of fire, rather than the conventional and regulatory, restrictive measures of prevention. This could represent a fair example of integrated fire management, sensu Fire Paradox.

Acknowledgements

The authors wish to thank dr. C. Masnata, regional head of CFVA and dr. G. Delogu, head of Cagliari provincial CFVA bureau, whose help and collaboration permitted this research. A special thank is also due to all the foresters who accepted to participate in the different Delphi sessions.

Abstract
In 2004 one of the most devastating forest fire started since we have official records and statistics of fire occurrence in Spain. On a fire prone context on July 27, 2004, in Minas de Ríotinto (Huelva, Spain) the largest forest fire of the last century and the third largest in the statistical history of Spain initiated. It was extinguished more than three weeks later. The combination of exceptional meteorological, topographic and vegetation conditions resulted a four hours free fire behaviour that burned 4.000 hectares in a 27.000 hectares final perimeter. The economy of the affected settlements and towns was severely damaged not only by the loss of the production of cork, but by the loss of much of its agricultural and livestock production as well as other silvicultural activities, logging and hunting. It was one of the first fires with problems in wildland urban interfaces at large scale because of more than 1000 people evacuated from their homes. Inside this fire prone area, one of the most affected places was the small town of Berrocal which saw how more than 90% of the territory in the municipality was seriously affected by fire. Also, one of the most active firefighting crews working in the fire belonged to this town.

Introduction

In 2004 one of the most devastating forest fires started since we have official records and statistics of fire occurrence in Spain. On a fire prone context on July 27, 2004, in Minas de Ríotinto (Huelva, Spain) the largest forest fire of the last century and the third largest in the statistical history of Spain initiated. It was extinguished more than three weeks later. The combination of exceptional meteorological, topographic and vegetation conditions resulted a four hours free fire behaviour that burned 4.000 hectares in a 27.000 hectares final perimeter. More than 1.000 people were evacuated from the towns of Berrocal, Escacena del Campo, Minas de Riotinto, Nerva, Paterna del Campo y Zalamea la Real (Huelva province) and from Aznlacóllar, El Castillo de las Guardas, El Garrobo, Gerena y El Madroño (Seville province). The economy of the affected settlements and towns was severely damaged not only by the loss of the production of cork, but by the loss of much of its agricultural and livestock production as well as other silvicultural activities, logging and hunting.
The catastrophic fire among other material and human damage caused the death of two citizens disoriented by the smoke in the interior of his car. They tried to run out but they were achieved by fire. Some horus later the pilot of one of the extinction helicopters was seriously injuried during the approximation maneuvers to take water.
The Minas de Riotinto Fire was one of the first wildland fires with serious problems in wildland urban interfaces at large scale because of more than 1000 people evacuated from their homes. Inside this fire prone area one of the most affected places was the small town of Berrocal. This area saw how more than 90% of the territory in the municipality was seriously affected by fire. Also, one of the most active firefighting crews working in the fire belonged to Berrocal.

Methods

The present paper researches through personal interviews and analyzes the situation of these people, firefighters (brigade members) and citizens, in 2014, ten years after the fire.
The study work was intended to extract information in order to try to understand one of the most overlooked realities within the human dimension of fire as it is the condition of people who have suffered these losses. A series of interviews was conducted in Berrocal (Huelva, Spain), a 300 habitants towns, with key actors related to the process. It took place at the beginning of 2013.
During the interviews to 25 people (1 wildland firefighting technician, 5 firefighters, 1 mayor and 13 civilians), the goal was to known to the persons affected directly by 2004 fire or not directly affected by suffering the effects ten years later. Among other things, the interviews touched on the so-called message of natural resources but also childhood at Berrocal, memories and future plans. Interviewed were treated sensitively in the interviews, taking into account their serious suffering from the event and even trauma (some cases).
Most of older people in Berrocal were older than 70 years old in 2004 (80 years old in 2014). At this study time there was a part of the population aged below 40 years and other part below 13-15 years.

Results and discussions

Many of citizens of Berrocal feel completely abandoned by regional instituions. The view shared by the majority of participants was indifference from the point of view of refussing to discuss the fire topic (again).
Some of the interviewed belonging to the elder group have not preserved a clear memory of this past situation.
Because they were too young in 2004 the members of the 13-18 years old didn't have memories of those unforgettable days from almost the rest of the population.

Conclusions

This fire events permited an effective learning from past wildland fire incidents and important safety lessons. Also permited a large number of lesson learned from wildland fire incidents from the point of view of managers. However, the human part not belonging to firefighting services felt abandoned a few years after the fire.
The media have contributed in some cases to create a growing excess of pressure in the popolation during the first years focusing on the past not their present even their future.
It seem not to be clear for civilians the human factors in wildland fire safety, including impact of legal and institutional responses on wildland fire.

Abstract

Management of wildfire incidents involves trade-offs over risks to firefighting personnel, private property and infrastructure, ecological values, public exposure to harm, and the costs of management. Trade-offs, non-linear probability weighting, and risk preferences among wildfire managers are investigated using a multi-attribute lottery choice experiment. The survey-based experiment asks managers to make strategic choices with varying levels of risk to aviation personnel, property damage, and suppression costs. A latent-class model is estimated to identify two classes of respondents with varying degrees of non-linear probability weighting. Differences between the two classes, explained by differences in educational attainment, suggest that expected outcomes of wildfire can vary depending on risk preferences and individual characteristics of managers.

Keywords*: risk management, decision biases, wildfire outcomes, lottery experiment*

Introduction

Wildfire incidents present a complex risk management environment. Wildfire managers must often make decisions that balance multiple potential outcomes, long-term and short-term risks, and social and political pressures. However, relatively little attention has been paid to how differences in risk preferences among managers affect management decisions and wildfire outcomes. Risk-related decision biases – including risk aversion, probability weighting, and status quo bias, among others – have been demonstrated in a wide variety of decision environments, including wildfire management (Maguire and Albright 2005; Wilson *et al*. 2011; Wibbenmeyer *et al*. 2013). This paper builds on previous work by investigating the role of heterogeneity of risk preferences in determining outcomes on individual incidents and the fire management program.

Of primary interest in this paper is the degree to which risk preferences vary within the population of fire managers. Previous research has established that probability weighting, risk aversion, and information framing drive choices of fire managers that depart significantly from an expected loss-minimization baseline. However, the degree to which managers exhibit risk biases may vary in the population. Differences in risk preferences within the target population can have implications for the expected outcomes of strategic choices made by managers and the extent that choices depart from expected loss-minimizing choices.

Risk preferences are examined using insights from a survey-based experiment administered to Federal wildfire managers in the United States in 2012. The experiment presented managers with a series of strategy choices to respond to a hypothetical wildfire scenario. A random utility model of risky strategic choices is adapted to allow for non-linear probability weighting and risk preferences (e.g., risk aversion). We estimate a latent class model of risk preferences to distinguish between different types (or classes) of respondents in the sample. Latent class models are a way to describe heterogeneity in the sample by identifying different response patterns (usually by estimating some unique parameters for each class) and the factors that are associated with respondents being members of each class

(Greene and Hensher 2013). In this application reported educational attainment is used to identify groups of managers that exhibit varying degrees of risk biases.

A survey-based lottery choice experiment

The primary method used to estimate risk aversion and probability weighting parameters is a multiple-attribute lottery choice experiment. Single-attribute lottery choice (also called multiple price list) experiments have been used to identify risk preferences in a variety of settings, e.g., Holt and Laury (2002) and Taylor (2013). In this study, managers are presented with a series of multi-attribute lotteries; respondents are asked to select strategies that reflect potential responses to a hypothetical wildfire scenario.

Each choice set (i.e., lottery) offered a relatively ``safe'' strategy and a relatively ``risky'' strategy. Both strategies are defined by potential good and bad outcomes that occur with probabilities that vary in the experimental design. The safe strategy represents a situation with moderate use of suppression resources to contain the hypothetical wildfire. The risky strategy involves monitoring the fire with minimal commitment of suppression resources; such strategies are used when potential values at risk are low or favorable conditions are expected to continue for the foreseeable future. As in lottery experiments with financial outcomes, the risky strategy yields good outcomes that are better than the good outcomes in the safe strategy, but bad outcomes that are worse than the bad outcomes in the safe strategy.

The lottery choices require respondents to make tradeoffs over three outcome attributes that are hypothesized to enter the fire manager utility function: Exposure of aviation personnel to the risk of a fatality, damage to private property, and total suppression expenditures for the incident. Potential outcomes for each of the attributes under both the safe and risky strategies are given in table 1. Attribute levels for the good and bad outcomes under the safe strategy and good outcomes under the risky strategy were held constant across all of the choice sets seen by each respondent. The attribute levels in the risky strategy--bad outcome were varied using an experimental design to test risk preferences of respondents across a range of utility values.

Table 1. Attribute levels used in the experimental design

	Safe strategy		Risky strategy[a]		
Attribute	Good outcome	Bad outcome	Good outcome	Bad outcome – low	Bad outcome – high
Aviation exposure	50 hours	75 hours	10 hours	300 hours	1,200 hours
Private property damage	$600,000	$1.25 mil.	$700,000	$3 mil.	$14 mil.
Suppression cost	$300,000	$500,000	$25,000	$2 mil.	$12.5 mil.

[a] Each attribute has two potential bad outcomes under the risky strategy. The Risky-Bad outcomes were varied systematically among the choice sets using a full-factorial design.

To identify how managers respond to lotteries over a range of probabilities, the probability (p) that the good outcome obtains is varied in the experimental design, taking six different values: 0.7, 0.85, 0.9, 0.95, 0.98, and 0.995. Respondents saw probability information displayed as both a percentage (e.g., a 70% chance the good outcome results) and as a frequency (e.g., 700 out of 1,000 fires where the good outcome results).

The risky strategy--bad outcome attributes (two for each of the three attributes) and the outcome probabilities are combined to form choice sets using a 2x2x2x6 full-factorial design, resulting in 48 unique choice sets. A framing experiment was also incorporated into the experimental design. Half of

the sample saw the aviation exposure attribute expressed in expected fatalities per 1,000 incidents (the treatment group) rather than hours of aviation use (the control group). Based on historical accident and fatality rates for the U.S. Forest Service, the aviation exposure attribute was converted to a fatality rate using an average of 4.801 fatalities for every 100,000 flight hours (USDA Forest Service 2010). The econometric models used to analyse the data are estimated separately on the control group sample and the treatment group sample.

The choice sets were blocked into six blocks of eight choice sets, with potential respondents randomly assigned to one of the six blocks. Details of the survey administration can be found in Wibbenmeyer *et al*. (2012). Figure 1 displays sample choice sets for the control and treatment groups.

Strategy A			Strategy B		
90.0% 900 of 1000 wildfires	Aviation Exposure	50 hours	90.0% 900 of 1000 wildfires	Aviation Exposure	10 hours
	Private property damage	$600,000		Private property damage	$700,000
	Suppression cost	$300,000		Suppression cost	$25,000
10.0% 100 of 1000 wildfires	Aviation Exposure	75 hours	10.0% 100 of 1000 wildfires	Aviation Exposure	1200 hours
	Private property damage	$1.25 million		Private property damage	$14 million
	Suppression cost	$500,000		Suppression cost	$12.5 million

A: Control frame

Strategy A			Strategy B		
90.0% 900 of 1000 wildfires	Aviation Exposure	2.4 deaths in 1000 fires	90.0% 900 of 1000 wildfires	Aviation Exposure	0.5 deaths in 1000 fires
	Private property damage	$600,000		Private property damage	$700,000
	Suppression cost	$300,000		Suppression cost	$25,000
10.0% 100 of 1000 wildfires	Aviation Exposure	3.6 deaths in 1000 fires	10.0% 100 of 1000 wildfires	Aviation Exposure	58 deaths in 1000 fires
	Private property damage	$1.25 million		Private property damage	$14 million
	Suppression cost	$500,000		Suppression cost	$12.5 million

B: Treatment frame

Figure 1. Sample choice sets for the control (A) and treatment (B) frames

Econometric specifications

Analysis of the observed lottery choices is conducted using a modified version of a random utility conditional logit model. In this case, assuming that the random component of choices has a type I extreme value distribution (Train 2009, ch.3), the conditional logit model expresses the probability of selecting the "safe" strategy over the "risky" strategy as:

$$(1) \qquad Pr(Safe) = \frac{e^{V_S}}{e^{V_S} + e^{V_R}}$$

where V_S and V_R represent the deterministic component of utility associated with the "safe" and "risky" strategies, respectively. The utility functions are specified using a linear-in-attributes form, modified to accommodate probability weighting and risk preferences. Similar recent examples of this approach include Hensher *et al*. (2011), van Houtvan *et al*. (2011), Sun *et al*. (2012) and Wibbenmeyer *et al*. (2013). Probability weighting is specified using a single-parameter non-linear weighting function of *p* drawn from Prelec (1998): $\pi(p) = exp - (-\ln p)^{\gamma}$. Risk preferences are specified using a constant relative risk aversion form as in Hensher *et al*. (2011). Incorporating probability weighting and risk preferences results in the following utility function for strategy *m*, which is defined by the good (*G*) and bad (*B*) potential outcomes, attribute preference parameters (β_k), the probability weighting parameter (γ), and the risk preferences parameter (α):

$$(2) \qquad V_m = \pi(p_G)\left(\frac{1}{1-\alpha}\right)(\beta_{AE} AE_{mG}^{1-\alpha} + \beta_D D_{mG}^{1-\alpha} + \beta_C C_{mG}^{1-\alpha}) + \big(1 - \pi(p_G)\big)\left(\frac{1}{1-\alpha}\right)(\beta_{AE} AE_{mB}^{1-\alpha} + \beta_D D_{mB}^{1-\alpha} + \beta_C C_{mB}^{1-\alpha})$$

where *AE* is the aviation exposure attribute, *D* is the property damage attribute, and *C* is the suppression cost attribute.

To examine heterogeneity among managers, a latent class model is developed following the approach described in Sun *et al*. (2012) and Greene and Hensher (2003). The latent class model assumes that two distinct classes of strategy choosers exist in the population of managers. The likelihood of belonging to one or the other class is determined by reported educational attainment.[1] The probability that individual *i* is a member of class *q* is specified as a conditional logit:

$$(3)\ H_{iq} = \frac{e^{Z'_i \Theta_q}}{e^{Z'_i \Theta_1} + e^{Z'_i \Theta_2}}, \Theta_1 = 0$$

where *Z* is a vector of educational attainment indicator variables, and Θ is a vector of parameters that describe the relationship between *Z* and the likelihood of membership in class *q*. Θ_1 (corresponding to class 1) is normalized to zero to identify the parameter vector.

Separate choice probabilities (equation 1) are specified for each class. In this application, the choice probability specifications include common attribute preference parameters (βs) and risk preferences parameter (α), but the probability weighting parameter is allowed to vary between the two classes (γ_1 and γ_2 for class 1 and 2, respectively). Although it is possible that other parameters besides those in the probability weighting function vary between classes, holding the other parameters constant

[1] A variety of variables and question responses was used to test class membership probabilities. Educational attainment provided the best fit of candidate regressions.

allows us to isolate differences among managers in responses to probabilities and limits the complexity of the maximum likelihood estimation.[1]

Results

Results from the latent class model suggest that there are at least two classes of respondents in the sample, and that the classes respond to probability differences in distinct ways. Two sets of results are presented in table 2, one each for the control group and the treatment group.

4.1. Latent class model estimates

For both the control group (who saw the aviation exposure attribute expressed as hours of aviation use) and the treatment group (who saw the aviation exposure attribute expressed as expected fatalities), one class exhibited severe probability weighting ($\gamma_1 < 0.2$) and the other class exhibited significant but more moderate probability weighting ($\gamma_2 \sim 0.7$). This suggests that some differences in strategic choices observed in the respondent sample can be attributed to variations in the sample in how managers weight different outcome probabilities.

Table 2. Latent class model parameter estimates by treatment frame

Attribute/parameter	Control frame	Treatment frame
Aviation exposure (flight hours or fatality rate)	-.878***	-2.22***
Private property damage ($)	-1.01***	-.875***
Suppression costs ($)	-.590***	-.192*
Θ_2 (class 2 membership)	-1.08**	-2.06**
Some college education	.906	2.26**
Bachelor's degree	1.76***	2.68***
Graduate degree	1.65***	2.72***
γ_1 (prob. weighting for class 1)	.165***	.137***
γ_2 (prob. weighting for class 2)	.703***	.672***
α (risk preference)	1.02***	.951***
Choice obs (N)	4,097	4,059
Number of respondents	516	511
ln(L)	-2,241	-2,179
AIC	4,501	4,307

*, **, and *** indicate significance at the 90%, 95%, and 99% level respectively.

The observed pattern of probability weighting indicates that managers over-weight low probabilities and under-weight high probabilities. In the case of the extreme probability weighting class (class 1), estimates imply that some managers perceive outcome probabilities to be in the 0.3 to 0.5 range over a large portion of the probability spectrum. Over-weighting low probabilities has the consequence of encouraging managers to avoid strategies with low-likelihood bad outcomes more than they would if they chose according to expected loss minimization, i.e., they appear to avoid taking "good bets" on

[1] The models that allowed additional parameters to vary between the classes, and models with more than two classes, exhibited significant difficulty with maximum likelihood convergence.

low-likelihood bad outcomes. Conversely, under-weighting high probabilities encourages managers to avoid good bets with high-likelihood good outcomes.

Model estimates also show that educational attainment helps explain the likelihood of a respondent belonging to either class. Compared to respondents with a high school diploma or less education, those with a bachelor's or graduate degree are more likely to be members of class 2 (the moderate probability weighting class). For the treatment group, having any amount of college education or more is associated with class 2 membership. This suggests that greater educational attainment is associated with strategy decisions that are more closely aligned with expected loss minimization (at least in terms of probability weighting). However, we cannot assess from the results whether this represents a causal mechanism (i.e., obtaining more education results in less severe probability weighting in decision making), or whether educational attainment is associated with other unobserved characteristics that may drive differences in probability weighting.

4.2. Expected attribute outcomes by educational attainment

The lottery choice experiment was designed such that the (hypothetical) outcomes for each attribute that result from a choice are determined probabilistically. Further, the experimental design and attribute levels were calibrated to ensure that for some lotteries the "safe" option will result in lower expected attribute outcomes, whereas for other lotteries the "risky" option will result in lower expected attribute outcomes. To examine the potential consequences of probability weighting and risk preferences on expected attribute outcomes, we calculated the expected outcomes under an expected loss minimization (ELM) choice pattern (with linear probability weighting and risk neutrality). These were then compared to expected outcomes calculated based on likely strategy choices for the estimated latent class model.

Table 3 displays expected attribute outcomes under ELM choices and under estimated latent class model choices for the control and treatment groups. Under modelled choices, expected outcomes are calculated for each educational attainment category, with choice probabilities for each class weighted by each respondent's likelihood of class 2 membership (note that under ELM there is no difference between classes because all individuals are assumed to exhibit no probability weighting). Attribute preferences (which in part determine choice probabilities) are assumed to be the same for ELM choices and latent class model choices.

Table 3. Average expected attribute outcomes under ELM and modelled choices, by educational attainment.

	Control frame	Treatment frame
Expected loss minimization choices		
Aviation exposure (fatalities per 1,000 fires)	2.6	2.7
Property damage (mil. $)	.785	.815
Suppression costs (mil. $)	.339	.388
Modelled choices		
HS diploma or less		
Aviation exposure (fatalities per 1,000 fires)	4.1	3.3
Property damage (mil. $)	1.25	1.02
Suppression costs (mil. $)	.659	.514
Some college education		
Aviation exposure (fatalities per 1,000 fires)	3.9	3.3
Property damage (mil. $)	1.16	1.06
Suppression costs (mil. $)	.640	.535
Bachelor's degree		

Aviation exposure (fatalities per 1,000 fires)	3.8	3.2
Property damage (mil. $)	1.10	1.05
Suppression costs (mil. $)	.585	.518
Graduate degree		
Aviation exposure (fatalities per 1,000 fires)	3.6	3.1
Property damage (mil. $)	1.12	1.06
Suppression costs (mil. $)	.639	.545

For both the control and treatment groups, modelled choices result in an increase in the number of expected fatalities of between 40 and 60 percent (which represents approximately an additional fatality per 1,000 fires) compared with ELM choices. The amount of expected property damage is also higher under modelled choices by a similar factor, and expected suppression expenditures are higher by between 50 and 100 percent.

The differences in probability weighting between the two classes have implications for expected attribute outcomes. For those respondents with the greatest likelihood of membership in the moderate probability weighting class (class 2), the differences in expected outcomes between ELM and modelled choices are smaller. In the control frame, greater educational attainment in the sample is associated with attribute outcomes that are closer to expected loss minimization, i.e., fewer expected fatalities, less property damage, and less suppression expenditures. In the treatment frame, where the negative consequences of aviation use were highlighted, educational attainment is only associated with reduced expected aviation fatalities. This may be due to respondents in the treatment group exhibiting a greater preference for reducing aviation fatalities than property damage or suppression costs relative to the control group.

Conclusion

Responding to wildfire incidents requires careful consideration of risks and potential outcomes associated with available strategies. This paper has examined how Federal wildfire managers respond to risk by observing hypothetical choices over strategies that involve risk to fire outcomes. An econometric analysis of a survey-based lottery choice experiment indicates that respondents tend to be risk averse and exhibit non-linear weighting of outcome probabilities. Specifically, respondents on average over-weighted low probabilities and under-weighted high probabilities relative to linear probability weights.

Using a latent class model of strategy choices, we discovered that at least two classes of respondents exist in the sample. One class is characterized by extreme non-linear probability weighting, and the other class exhibits non-linear but more moderate probability weighting. The likelihood of class membership is significantly associated with educational attainment; respondents with more education are more likely to be members of the moderate probability weighting class.

Probability weighting, risk aversion, and latent classes have implications for the expected outcomes of the hypothetical wildfires respondents were asked to manage. Compared to an expected loss minimization strategy baseline (i.e., linear probability weighting and risk neutrality), respondents made decisions that on average resulted in greater expected aviation fatalities, property damage, and suppression costs. That is, risk and decision biases tend to result in increased losses to outcome attributes thought to be important to fire managers when they make strategic decisions. However, a portion of the respondent sample exhibited less-severe biases, which tends to mitigate these losses.

It is important to note that the results were obtained using a hypothetical choice scenario, and it is unclear how the quantitative results would apply to real-world fire management scenarios. However, the results suggest that how managers respond to risk can be an important determinant of fire outcomes. Also, a better understanding of heterogeneity of risk preferences among managers could assist training and after-action review efforts to improve risk management skills. Although there is not currently a

reliable way to generate empirical probabilities of strategy outcomes, future research would benefit from a focus on more realistic management scenarios, particularly those that incorporate a temporal dimension of strategic decision making.

Abstract
Forest fires in the Mediterranean Europe are mostly related to human activities. More than 90% of fires are originated from either deliberate or involuntary causes. Socio-economic changes occurring in Europe in the last decades (e.g., abandonment of agricultural lands, depopulation of rural areas, changes in agriculture and forestry policies, etc.) have driven landscape transformations affecting fire risk levels through processes like e.g., increase of unmanaged lands, dead and live biomass accumulation, new uses of the forest and natural lands. In this work we analysed and attempted modelling the influence of socio-economic factors and their change over time on forest fire occurrence in the Mediterranean Europe (EU-Med).
Three 6-year time periods were considered (1988-1993, 1998-2003, 2004-2009). Fire data was extracted from the European Fire database of the European Forest Fire Information System (EFFIS). Our analysis was performed in the most fire-affected area of Europe, the European Mediterranean region covered by Portugal, Spain, France, Italy and Greece. Fire data were analysed according to their main fire cause (accident-negligence and deliberate). Both, fires and socio-economic variables, which represent anthropogenic factors related to fire activity, were mapped on a 10 km x10 km grid. Models of forest fire density were derived separately for each period and per cause category using ordinal regression statistical methods. The best predictors by period and fire cause category were assessed and differences between time periods analysed. Our result show that the variable wildland-urban interface (WUI) is related to higher ratings of fire density. This result was consistent for all periods and for the two type of fire cause analysed in our study. The overall fit of the models was 40-50%.for accident-negligence and 50% deliberated caused fires. Despite the relatively homogeneous socio-economic characteristics of the Mediterranean Europe, differences are found at regional level and by fire cause category. The anthropogenic drivers of forest fires are a challenging yet fundamental factor to understand and model the European Mediterranean fire environment.

Keywords*: fire density, fire causes, socio-economic drivers, Europe, EFFIS*

Introduction

Mediterranean ecosystems cannot be fully understood without the role of fires. Natural fires have been essential to maintain biodiversity. Fire has also been a widely used tool to manage territory. In Mediterranean Europe fire regimes have been set directly and indirectly by humans for thousands of years (Pyne, 2009). However, in the last decades, natural fire regimes have experienced significant alterations (fire frequency, intensity and severity), which have aggravated their negative ecological, social and economic consequences (Westerling *et al*., 2006; FAO, 2007). In Mediterranean Europe nowadays, fire does not form a significant part of traditional systems of life; however it continues to be strongly tied to human activity (Leone *et al*., 2009). Socio-economic changes which are occurring in Europe (abandonment of agricultural land, depopulation of rural areas, priority shifts in forestry policy, etc.) result in an increase of unmanaged shrubs and biomass, which increases fire risk (Vélez Muñoz, 2007). Fire risk is also aggravated by the climate conditions in these Mediterranean areas (e.g. hot and dry summers) (Leone *et al*., 2009). Furthermore, research on climate change has indicated that increased fire hazard is likely to arise from global warming (Westerling *et al*., 2006).

Forest fires in the Mediterranean Europe are mostly related to human activities. More than 90% of fires of known cause are originated from either deliberate or involuntary causes (Ganteaume *et al*., 2013).
Fire data were extracted from the European Fire database of the European Forest Fire Information System (EFFIS). EFFIS is the European Commission (EC) focal point for information on forest fires in Europe (San-Miguel-Ayanz *et al*., 2012). It was established by the Joint Research Centre (JRC) and the Directorate General for Environment (DG ENV) of the European Commission to support the services in charge of the protection of forests against fires in the EU and neighbour countries, and also to provide the EC services and the European Parliament with information on forest fires in Europe (San-Miguel-Ayanz *et al*. 2013). Following the recommendations of the European Parliament to further develop the European Forest Information System (EFFIS), a common classification scheme of fire causes was established. This harmonized classification scheme was accepted in 2012 and is currently being adopted by the countries as a common means to record fire causes when reporting national data to EFFIS (Camia *et al*., 2013). This classification was used in our analysis. .
We analysed and attempted modelling the influence of socio-economic factors and their change over time on forest fire occurrence in the Mediterranean Europe (EU-Med). Data from the European Fire database in the European Forest Fire Information System (EFFIS) related to three 6-year time periods were considered: 1988-1993, 1998-2003 and 2004-2009. These three periods will be referred to in the text as 1990s, 2000s and 2006s. Fires were mapped on a 10 km x 10 km grid starting from their location at NUTS3 (Nomenclature of territorial units for statistics, level 3 - province) level resolution using GIS tools. NUTS regions are used by the countries to report national information to the European Commission. Fire density was separated into two cause categories, accident-negligence and deliberate. Socio-economic variables representing anthropogenic factors related to fire activity were also mapped using the same 10 km x 10 km grid.

Methods and materials

Study area

The Mediterranean Europe (EU-Med) area considered for the analysis includes the EU countries Portugal, Spain, Italy, Greece and the Southern provinces of France, with a total area of more than 1 million km^2. Figure 1 shows the area analysed by NUTS3 administrative level (province) and by fire regions agreed by expert knowledge (Camia A, personal communication). Landscape differences between the Mediterranean Basin and the rest of Europe are mainly related to climate, the long and intense human impact and the role of fire (Pausas and Vallejo, 1999). Reflecting the prevailing climate, Mediterranean forests are frequently characterized by fire climax species, i.e. those dependent on the presence of fire in the reproductive cycle (FAO, 2007). Forests, including shrub formations and other semi-natural categories (e.g. transitional woodlands, sclerophyllus vegetation) occupy about 50% of the area. The area is populated by about 137 million people (Eurostat, 2011).

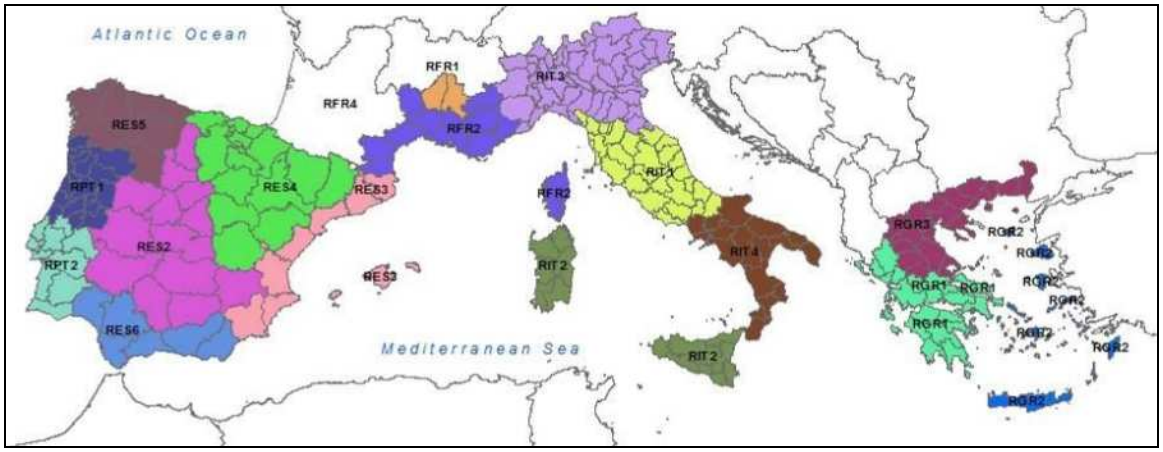

Figure 1- Extent of the analyzed area, separated by NUTS3 administrative level boundaries and fire regions

Data

2.2.1. *Fire occurrence data*

Fire occurrence data was obtained from the European Forest Fire Information System (EFFIS). Three 6-year periods of time were extracted: 1988-1993 (1990s), 1998-2003 (2000s) and 2004-2009 (2006s). The fire records were at NUTS3 (province) level, and included fire occurrence data for months March to November. Fire data was analysed by main fire cause category (accident-negligence and deliberate). Fires of unknown cause were assigned to a known cause on the basis of the proportion of known caused fires in each NUTS3. Also, the number of fires was referred to the wild-land area in the NUTS3. After the pre-processing and selection, the fire data were mapped on a 10 km x 10 km grid (LAEA projection reference grid) following the INSPIRE specifications (EC and EP, 2007). This resulted in fire density values by cause (accident-negligence and deliberate) by grid cell and by period (1990s, 2000s and 2006s). These variables were used as response variables in our modelling. Figure 2 shows as an example the fire density (fires/km^2) by 10 km x10 km grid of deliberated fires in 2000s.

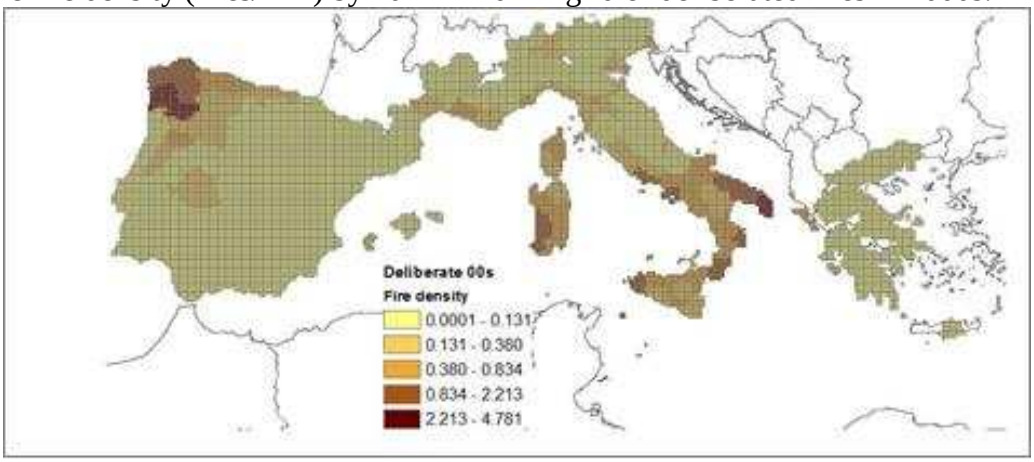

Figure 2- Fire density (fires/km^2) by 10 km x10 km grid. Deliberated fires in 2000s

2.2.2. *Socio-economic factors*

Fire density is influenced by socio-economic factors. These include socio-economic changes in rural and urban areas, traditional activities in rural areas, accidents or negligence, fire prevention activities and other factors that can lead to social unrest (e.g. land use disputes or high unemployment rates) (Martinez *et al*., 2009; Vilar del Hoyo *et al*., 2008; Leone *et al*., 2003). To analyze the impact of these factors on fire density in the EU-Med region, available spatially explicit socio-economic variables

related to the different factors were obtained from different cartographic and statistical sources for the three selected periods of time (1990s, 2000s and 2006s).. All the variables were spatially referred and mapped on the 10 km x 10 km grid. Different spatial analyses were carried out using Geographic Information System (GIS) tools (ArcMap 10, ESRI 2011), including format conversion, re-projection, re-clasification, overlay, calculation of areas, buffer zones and other distance operations such as quantification of different land use interfaces. The variables considered in the analysis are shown in Table 1.

Table 1. Socio-economic variables tested as predictors in the models

Variables [abbreviation]	Unit
Population density [pop_den]	[number/km^2]
Density of labour force in economic sectors *(agriculture, industry, services)* [agri, indus, serv]	[number/km^2]
Agrarian holders older than 55 [holders55]	[number/km^2]
Road network *(road, motorway*) [road, motow]	[total lines/ km^2]
Wildland-Urban interface [WUI]	[km^2]
Number of heads of livestock [bovine, goat, sheep]	[number/km^2]
Full farm time workers (WT) [farmw]	[number/km^2]
Total AA (Agricultural area) Owner Farmed [ofarmed]	[km^2]
Grassland-forest interface [FGI]	[km^2]
Agricultural-forest interface [FAI]	[km^2]
Railway network [railway]	[total lines/ km^2]
Protected areas [NATURA00]	[km^2]
Landscape fragmentation [RPC_A] [RPC_W]	[-]

2.3. Modelling the role of socioeconomic drivers of forest fires

Scientific approaches which include human factors in fire risk assessment were commonly based on statistical models that attempt to explain historical, human-caused fires from a set of independent variables (Vilar del Hoyo *et al*., 2011). Logistic regression analysis was frequently used both to predict and also to explain human-caused fires (Martell *et al*., 1987; Vega-García *et al*., 1995; Chuvieco *et al*., 1999; Lin, 1999; Pew and Larsen, 2001; Vasconcelos *et al*., 2001; Martínez *et al*., 2004; Prasad *et al*., 2008; Martínez *et al*., 2009). Other statistical methods such as linear regression, classification regression trees, neural networks or Bayesian probability were also used in fire risk mapping to generate local risk models (Chao-Chin, 2002; Koutsias *et al*., 2004; Robin *et al*., 2006; Amatulli *et al*., 2006, 2007; Amatulli and Camia, 2007; Syphard *et al*., 2007; Vega-García, 2007; Yang *et al*., 2007; Romero-Calcerrada *et al*., 2008). The response variable in those models always refered to fire occurrence, commonly obtained from information available in forest fire databases.

In order to identify the role of different socio-economic factors on the spatial variation of fire density, the relationships between this response variable and the spatialized socio-economic variables previously described were analized by using regression models for ordinal data, by means of cumulative link models (package ordinal, Christensen, 2012, for R, R Development Core Team, 2011). Fire density was divided into three equiprobable classes (low, medium, high). Models of forest fire density were derived separately for each period and per cause category. A 75% random sample of the input dataset was used to calibrate the models. In particular, the models were initially fitted by a constant and then the relevant socio-economic explanatory predictors were identified by performing a forward stepwise selection procedure, using the Akaike Information Criterion (AIC) as the criterion for variable inclusion. Finally the calibrated model was used to predict the expected fire density class on the 25% of the sample dataset excluded from calibration. The performance of the models was

evaluated by comparing the observed and predicted fire density classes. In particular, a crosstabulation analysis was conducted. This allowed calculating the accuracy by fire density class (user's and producer's accuracy) as well as the overall fit.
The best predictors selected by period and by fire cause category as well as the differences between time periods were analysed.

Results and discussion

Our results in EU-Med study area showed that, for the three periods of time analysed and for accident-negligence and deliberate caused fires, wildland-urban interface (*WUI*) was the variable invariantly selected with positive sign in all periods. For the two types of fire cause analysed the model predicts that the probability of belonging to a higher fire density class increases when *WUI* increases. Tables 2 and 3 show a summary of the results, indicating the significant variables of each model and their signs by period, and by fire cause (accident-negligence vs. deliberated), respectively.

Table 2. Summary of results of ordinal regression models for accident-negligence caused fires in EU-Med: period, variables in the model ordered by AIC step forward, sign and overall fit. In red colour, variables present in all periods with negative sign; in green colour, variables present in all periods with positive sign; in orange colour, variables present in all periods with changing sign

Accident-negligence					
1990s		**2000s**		**2006s**	
Variables (AIC Step forward order)	**Sign**	**Variables (AIC Step forward order)**	**Sign**	**Variables (AIC Step forward order)**	**Sign**
holders55	+	road	+	**bovine**	-
bovine	-	goat	-	**WUI**	+
pop_den	+	**bovine**	-	road	-
sheep	-	pop_den	+	**FGI**	-
FGI	-	agri	+	NATURA00	+
goat	+	RPC_W	-	FAI	+
WUI	+	**WUI**	+		
RPC_W	-	NATURA00	+		
RPC_A	-	RPC_A	+		
		FAI	+		
		FGI	+		
Overall fit	49%	Overall fit	47%	Overall fit	39%

Regarding fires caused by accident-negligence, the variable agriculture-forest interface (*FAI*) enters in the models with positive sign in 2000s and 2006s. This variable is related to vegetation management or agricultural burnings. It must however be noticed that other theoretically important variables show changing signs in the different periods (e.g. *FGI*), and also that high livestock presence (*bovine*) seems to lead to a reduction of expected fire density.

Table 3. Summary of results of ordinal regression models for deliberate caused fires in EU-Med: period, variables in the model ordered by AIC step forward, sign and overall fit. In red colour, variables present in all periods with negative sign; in green colour, variables present in all periods with positive sign; in orange colour, variables present in all periods with changing sign

Deliberate					
1990s		2000s		2006s	
Variables (AIC Step forward order)	**Sign**	**Variables (AIC Step forward order)**	**Sign**	**Variables (AIC Step forward order)**	**Sign**
holders55	+	**goat**	-	**holders55**	+
goat	-	**holders55**	+	**WUI**	+
sheep	-	agri	+	**sheep**	+
WUI	+	**sheep**	+	**FAI**	-
road	+	**WUI**	+	**goat**	-
bovine	-	**FAI**	-	NATURA2000	-
FAI	-	**road**	+	**road**	-
RPC_W90	+	RPC_A	-		
agri	+	FGI	-		
		NATURA2000	-		
		pop_den	-		
Overall fit	56%	Overall fit	53%	Overall fit	50%

Regarding deliberately caused fires, *goat* and *FAI* are the variables that in all periods enter the models with a negative sign, meaning that these variables are less likely to be linked to higher ratings of fire density. *Goat* enters in the models in 1990s and 2000s in the second and first position respectively, while in 2006s in the 5th position. This fact may be related to the loss of the role goats played in the past helping to prevent fire thanks to grazing. *WUI* and *holders55* enter with a positive sign in all periods, meaning they are more likely to be linked to higher ratings of fire density. The overall fit of models was between 40% and 50% for accident-negligence models and above 50% for deliberate fire models. Results were improved when modelling was attempted by sub-country regions, reaching 74% for the best fitting of deliberate fires.

Conclusions

Models show temporal trends in time in the case of the variables *WUI* for both type of fire cause and *goats/FAI* in the deliberated caused fires. For the rest of predictors the models did not highlighted clear trends. This suggests the need to analyse data with larger time span, to include more important socio-economic and territorial changes. The depopulation of rural areas in Europe started after the II World War, being more intense from the 50s and 60s in southern Europe. Changes in regional development have happened since the 60s and 70s. To analyze this issue, homogeneous data would be required for the study area for these periods. The negative sign of some of the variables is non-intuitive. This issue might have a reason related to limitations of the data, lack of explanatory variables or the statistical analysis itself. Further investigation will be needed in these cases. The variables representing the socio-economic issues are an indirect way of measuring the role of socio-economic influence on forest fires. Human behaviour is very difficult to predict and to represent, in particular regarding deliberate actions. Consistent, complete and trustworthy data (both fire data and socioeconomic drivers) is essential to obtain reasonable models.

Generally speaking, the fit is slightly better in the case of the deliberately caused fires. It might be indicative of the influence of fire causality and the scale of the analysis.

Despite the relatively homogeneous socio-economic characteristics of Mediterranean Europe, differences are found at regional level and by fire cause category. The anthropogenic drivers of forest

fires remain a challenging yet fundamental factor to understand and model the European Mediterranean fire environment.

Abstract
The suppression costs represent a significant proportion of the total budget available for forest fire protection programs. The need to make efficient use of available budgets requires directing funding towards areas with the lowest costs and maximum benefits. Accordingly, incorporating econometric tools enables establishing criteria to optimize budg*et al*location. Modelling the fire suppression process and budg*et al*location requires knowing how suppression is managed, how resources are dispatched and how costs are incurred.
The methodological approach presented here allows forecasting fire suppression operations productivity, based on suppression difficulty and cost, as well as records from documented fire suppression operation plans from prior fires. On the other side, the value of natural forest resources and the damage and losses from forest fires assessing, help to determining the change net value to estimate the economics fire impacts. For the efficiency analysis of the fire program, is possible using the VISUAL-SEVEIF (Spanish acronym for System for the Economic Evaluation of Wildfires) software tool, to obtain the knowledge of fire behavior and its direct effect on the depreciation of natural resources value, providing the total costs of the losses in the area affected by the wildfire, and the value of the losses for each of the resources identified within the fire perimeter.
This tool work showing both in real time, simulating the spatial development of ground and canopy fires, and the economic losses. The spatial resolution of work will be conditioned by quality and accuracy of fuel model mapping, as well as the characteristics of the digital terrain model, so that in high-precision models the results of the fire behavior dynamic can be up to a square meter. The information layers required by the tool includes one that incorporates the characterization of the natural resources that exist in the area being analyzed and allows determining the economic value of these resources. The import and export possibilities of geo-referenced perimeters, in both vector and raster formats, allows easy transfer of the information generated to geographic information systems (GIS). VISUAL-SEVEIF enables carrying out diagnostic studies of an area that are aimed at the prevention and strategic management of wildfire defense. This paper showing how using this methodology, is possible obtained the efficiency rate of fire suppression activities.

Introduction

Forest fires are one of the biggest environmental problems facing the world today, generating significant consequences with regard to both damage and deterioration of forest landscape and its depreciation and economic and social valuation. The abandonment of forest settings, as areas inhabited and affected by humans in terms of actions related to subsistence and energy use, has generated an increase in the accumulation of high-energy biomass over the past few decades (Rodríguez y Silva and Molina 2010, Vélez 2009). This circumstance, coupled with worsening climatic conditions (Piñol *et al*. 1998), has caused a rise in the potential energy released by fire and consequently the virulence of forest fires, resulting in an increase in fire damage to natural resources and the surrounding environment.
The need for strategic information, in relation to the dynamic, energy and expansive potential of fire runs, led to the development of both analytical and graphical simulators. Increased knowledge in fire

science has allowed addressing prediction and simulation studies, thus facilitating their application in wildfire defense activities.

Today's technology provides appropriate prediction and simulation tools that allow effectively developing attack plans in which the priority focus is on safety; it can thus be concluded that prediction and simulation are an ongoing need in protecting forest areas from fire. Moreover, the prediction and simulation exercise allows reducing the time required to achieve control, while facilitating cost savings by providing critical information for the efficient distribution of firefighting resources.

While there has been significant progress in the quality and accuracy of fire behavior forecasts over recent years, important uncertainties remain to be resolved in relation to the simulation of complex phenomena such as energy feedback, the effect of turbulence on acceleration, and the transition and spread of ground fire to the forest canopy. Regardless of future advances in our understanding of fire's dynamic behavior, there is another important need in forest fire management, which is quantifying it in monetary and therefore budgetary terms. Indeed, it is indisputable that any application of a wildfire defense management model is inextricably linked to budget availability and therefore the establishment of priority-based criteria to determine investment levels to implement the management model.

This discussion highlights the importance of studies, research and developments that enable applying econometric criteria to decision-making. Currently, new tools are available, such as the SINAMI econometric model, which allow analyzing in the context of the area and as a matter of strategic planning the most efficient budg*et al*location, by taking into account: the historical background in the frequency and distribution of fires, fire behavior conditions, the economic value of natural resources and the operational capabilities of the firefighting resources (Rodríguez y Silva *et al*. 2010). As discussed by Thompson and Calkin (2011) uncertainty is a major component to consider in developing decision support methodologies "… to facilitate cost-effective, risk-based wildfire planning efforts (p. 1895)." However, the availability of this model and of its ECONOSINAMI software (Rodríguez y Silva 2009, Rodríguez y Silva and González-Cabán 2010) does not resolve in an integrated manner the expansive simulation of fire behavior and the economic evaluation of damages that the simulated fire can potentially generate. This paper presents the structure and operational flow line of the first simulation tool that incorporates the assessment of economic losses caused by fire based on the linear intensity level that the fire develops (kW/m) by each pixel of spatial resolution with which the simulation is performed.

The VISUAL-SEVEIF model (Rodríguez y Silva *et al*. 2013) has been determined by performing the integration in the VISUAL-CARDIN program (Rodríguez y Silva 1999, Rodríguez y Silva *et al*. 2010) of the set of algorithms for the SEVEIF model (Molina *et al*. 2008, Rodríguez y Silva and others 2007, 2010), which were developed for determining and assessing the impact of fire on natural resources in terms of intensity levels released by fire spread. This model offers real-time economic evaluation of losses from post-fire depreciation of natural resources affected.

Valuations of natural resources tend to underestimate the real value of a forest (Constanza *et al*. 1997). Unlike traditional economic activity, the forest environment is characterized by the extraordinary importance of externalities that entail damages or benefits to others of considerable magnitude. From the socio- economic standpoint, all the natural resources must be expressed in monetary terms. The valuation of damages caused by forest fires requires individualized study of each of the resources (tangible and intangible) and their change in net value in relation to fire severity and ecosystem resilience (Molina *et al*. 2009).

The recognition and valuation of natural resources is essential for spatiotemporal planning of preventive work and post-fire rehabilitation (Molina, 2008). Incorporating the concept of vulnerability extends the study beyond the sphere of traditional economic valuation work, integrating two concepts, on the one hand the value of the resource and on the other fire behavior. The integration of the two concepts is performed using a matrix of depreciation rates based on flame length, called a "depreciation matrix" (Molina *et al*. 2011, Rodríguez y Silva *et al*. 2012).

The socio-economic vulnerability model was made through the configuration of a mathematical algorithm associated with a geographic information system (GIS), facilitating the development of spatiotemporal tracking cartography, both at the individual resource level and at the ecosystem's integral vulnerability level. The automation of the calculation and management through GIS is being conducted under the INFOCOPAS project (RTA2009-00153-C03-03) funded by the National Institute for Agricultural Research (INIA), in order to attain versatile geo-referenced knowledge in almost real-time of forest system vulnerability to forest fires.

Architecture of simulator

The process followed in the definition and development of the operational architecture of the VISUAL-SEVEIF program consisted of the following phases:

- Review of the VISUAL-CARDIN simulator's software structure in order to locate the assembly position of the economic evaluation module in the program's flow line.
- Selection of natural resources for which losses are to be evaluated based on energy intensity levels that simulated fires can develop.
- Programming of economic evaluation algorithms through C++ computer language.
- Development of interactive windows between the VISUAL-SEVEIF program and the user.
- Determination of input variables, which must be entered in order to perform the calculations.
- Implementation of economic evaluation options included in the VISUAL- SEVEIF program:
  1. Calculation of the monetary value of natural resources located within an area or region (area included inside a polygon, both rectilinear and curvilinear). This option allows determining the economic value of the stocks.
- Calculation of the economic losses and depreciation in the economic value of resources as a result of fire spread. In this phase the procedure followed in the SEVEIF model (Rodríguez y Silva *et al*. 2010) is applied by using the "matrix of economic depreciation factors."
- Assignment of the table of values for the different parameters included in the economic evaluation algorithms, in relation to the types of fuel models.
- Design and final construction of the windows for entering data, performing calculations and showing results. Validation of results with valuations available in the database of recorded fires.

VISUAL-CARDIN component

Technological developments in the field of computer science have enabled the development of simulation software of great versatility and usability, offering many tool options that are of great help in decision-making. In this regard, forest fire protection requires specialized programs that provide information on forecasts of dynamic fire behavior associated with fires that evolve in different forest systems. In this sense, the VISUAL-CARDIN program is structured as a deterministic program that works subject to the following conditions:

Simulation model through cellular automaton using the more nearest neighbor

Considerations:

1. Terrain topography.
2. Fuel model in each pixel (cell).
3. Tree height, crown base height, and crown density.
4. Fuel moisture and degree of protection.
5. Wind direction and intensity.
6. Ambient temperature and humidity.

The speed (V) and direction of maximum spread at each point is calculated from the following expression:

$V=(V_0 + V_i \cdot \cos W)\cdot t$ (1)

Where Vo is the rate of spread with zero wind and slope, Vi is the increase in speed in the direction of maximum spread due to the combined effects of wind and slope, φ is the spread radius from the origin of the fire, W represents the angle formed with the maximum spread direction Vi>Vo,
The geometric figure adopted to model the surface expansion of the fire's figure is a cardioid. The excess width on the elliptical reference figure is corrected by a factor (perpendicular to maximum spread). This factor is the ratio between the maximum width provided by the simulation performed by Behave (Andrews 1986) and the maximum width of the theoretical figure produced by the geometry of the cardioid. The maximum width value is determined by the expression (Martínez- Millán 1990, Martínez-Millán *et al*. 1991, Caballero *et al*.1994):

$F= (3V_0 + (V_0^2 + 8Vi^2)^{0,5}) (4V_i^2 - 2V_0^2 - V_0 (V_0^2 + 8V_i^2) / 16V_i^2$ (2)

The input parameters required by the program for the simulation are entered via the module parameters, which allows including data associated with local characteristics through a set of commands. Through the winds command, the characteristics of wind speed and direction measured at six meters above the ground can be entered. The moisture command offers the ability to assign the moisture of both living and dead fuels, with the latter classified according to their geometric characteristics. Alternatively, dead fine fuel moisture can be obtained from a set of calculations based on data such as the date, effects of weather, terrain and vegetative state. The protection command allows assigning the fuel's degree of protection of against wind, whereas the residence command option establishes the flame and ember residence times, allowing assignations to each of the different fuel models. Adjustment of input data using this command allows simulation of the phenomenon of revival from increases in wind speeds. In the simulation, there are some scenarios in which the conditions of transition from a ground to tree-stand crown fire produce a shift in combustion towards the canopy and therefore the fire spreads through the treetops. That is, the model recognizes the possibilities and if conditions allow it, ground, mixed and crown spread are produced. This feature certainly offers great versatility and accuracy in determining the economic impact of fire, by being able to capture the strong energy increases associated with forest canopy spread and thus be able to relate it to damages and losses generated.
Conducting post-fire analysis, in order to reconstruct the behavior of the fire and corroborate the results obtained by the different attack plans applied to extinguish it, is another feature offered by the simulator. This option allows qualifying the final fire reports while at the same time evaluating the performance of the various resources deployed. In this same option, the possible application of educational and technical training courses in fire suppression and behavior can be incorporated.
From the simulation outcomes, a database can be built that interrelates the affected area simulated in freely-evolving, spread dynamics, i.e. without the inclusion of firefighting actions, and the actual final area obtained after extinguishing the fire. The ratio between the two areas determines the spread rate control. This parameter facilitates the development of information bases on the experiences recorded in attack plans developed and implemented. This allows having a query file on those fires that may occur in the future and evolve under similar environmental conditions.
From this historical knowledge, firefighting simulations can be initiated on the set of resources that must be activated to control and extinguish the forest fire. To the extent that the integration of economic evaluation algorithms in the VISUAL- CARDIN software architecture has enabled the calculation of economic losses, the VISUAL-SEVEIF model opens a window to the possibility of making calculations and relationships that link firefighting operations and their costs with the value of the natural resources and the economic losses resulting from fire spread. Efficiency studies on the

results of firefighting operations will help in defining budget options and the best results in wildfire defense planning.
The current version responds to programming in C++ under the Windows operating system, but it will also soon be available for the Linux operating system, and includes significant improvements in pixel-by-pixel information processing, providing more precise information with regard to spread characteristics (rate of spread, linear intensity of the advancing front and flame length).
The graphical environment has also been taken into account in order to facilitate greater mapping options, as the simulation can be performed on raster coverages of the topographic map at different scales. It allows export of the perimeters in raster and vector format, as well as import of fire or area perimeters, measured with GPS and also in vector format. Shown below is the results window, which includes the area covered by the fire in yellow (Figure 1).

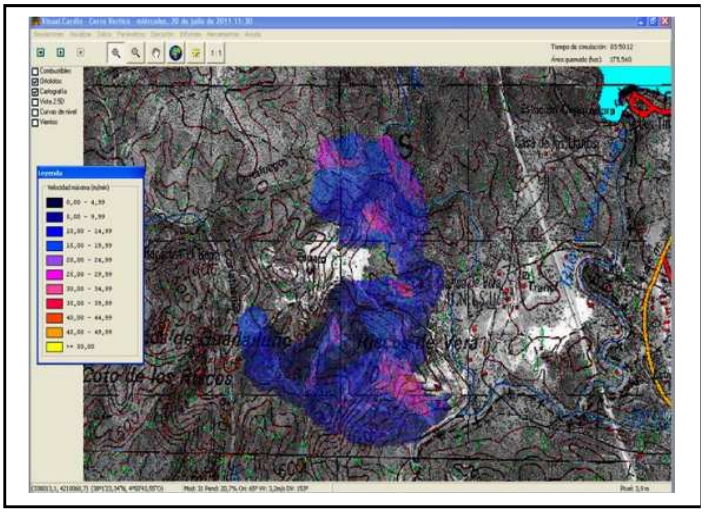

Figure 1—Simulation and analysis of fire behavior using VISUAL-CARDIN software for the Vertice Hill wildfire, 03h:50m after ignition (2011. Cordoba, Spain).

Economic valuation of natural resources: SEVEIF Model

In the first version of the VISUAL-SEVEIF simulator, we have incorporated the most important algorithms corresponding to the natural resources that have high representativeness in forest scenarios and that with the development of the SEVEIF model (Rodríguez y Silva *et al*., 2010) were identified as such.
The natural resources considered for economic valuation are the following: tangible resources, environmental services and landscape assets. The valuation of tangible resources including timber and non-timber products. The methodological approach for valuation of the impact on the timber resource is based on an algorithm that integrates the valuation tools, which include trees of both natural and artificial origin (Rodríguez y Silva *et al*. 2012). The valuation of non-timber resources is based on expressions used in the Manual for the Valuation of Losses and Estimation of Environmental Impact by Wildfires (Martínez Ruíz 2000). The evaluation of the impact on the hunting resource is carried out through the adjustment proposed in Zamora and others 2010.
The valuation of environmental services includes three resources: carbon fixation, erosion control and faunal biodiversity. The valuation of carbon fixation includes both the amount fixed at the time of the fire's occurrence and the amount unfixed from that time on, with prior knowledge of bark, aerial biomass and annual increment volumes being necessary (Table 1). The amount of carbon corresponding to the dry biomass is estimated at 50%. Erosion control will be expressed in economic income loss based on the potential amount of soil lost per unit area. The expression used for the

valuation (Table 1) incorporates a sum in relation to losses incurred during the first rains (bare soil) and a second sum that includes progressive soil losses until recovery of vegetation with similar burn protection (Molina and others 2009). Valuation of faunal biodiversity or unique species is performed using the cost of species recovery programs, or if no specific program is available through the contingent valuation method (Molina 2008).

Resource	Algorithms	Source
Timber	$V_{tim} = (1,7*E*B)/(E+0,85*B)$ $E = C_0*p\ [i^e + g(i^e -1)] + A*(i^e - 1)$ $E = (C_{0/z}*t\ [i^e + g(i^e -1)] + (C_0/z)*0,5*(i^e - 1)$ $E = [P*V - P*V\ ] + P*V\ [(i^{(T-e)} - 1)/(i^{(T-e)})]$ $B = [(V*P*1,025\ )/1,04\ ]*[1- (1,025/1,04)^e]*[1 + X*h*p]$ $B = V*h*t[R*P + (1 - R)*P_1]$	Rodríguez y Silva *et al*. 2012
Firewood us	$V_{firewood} = P_x*R_x*[((1+i)^n - 1)/(i*(1+i)^n]$	Molina *et al*. 2011
Hunting	$V_{hun} = P_x*R_x*[(1+i)^n - 1)/(i*(1+i)^n] + S$	Zamora at al. 2010
Carbon fixation	$V_{carb} = CF*PM + IF*PM*RC*[((1+i)^{T-e} - 1)/(i*(1+i)^{T-e}]$	Molina. 2008
Erosion control	$V_{eros} = R_1*P_1 + R_2*P_2\ [((1+i)^n - 1)/(i(1+i)^n)]$	Molina *et al*. 2009
biodiversity; Landscape; recreation; Unused	$V= Rx*[((1+i)^n - 1)/(i*(1+i)^n]$	Molina. 2008

Table 1. List of the algorithms included in the VISUAL-SEVEIF software, for each different resources considered

where E is the timber valuation based on the traditional Spanish approach (€/ha), B is the timber valuation adapted from the American Model (€/ha), Co is the cost of replanting one hectare of land (€/ha), p is the percentage of the stand affected by fire, i is the annual interest rate, g is annuity dependent on the rotation of the species, A is the value of a hectare of land without trees (€/ha), e is the estimated age of the stand at the time of the fire, V is the timber volume expressed in m^3/ha, P is the m^3 price of felled wood (€), n is the number of years remaining until the hypothetical harvesting rotation, X is the mortality rate dependent on the severity of the flames, h is the percentage of the species in the canopy, z is the reduction in replanting cost due to the self-regenerative phenomenon based on the rotation, P1 is the price of damaged wood with commercial use (€/m^3), V1 is the volume of damaged wood with use (m^3/ha), Px is the price per unit of measurement of the resource (€), Rx is the annual income per unit area, S is the reproductive stock per unit area (€), CF is the amount of CO_2 retained at the time of the fire (t/ha), PM is the price per fixed ton (€/t) , IF is the annual increase in CO_2 retained (t/ha), RC is the income generated by fixing a ton of carbon in a year (€), R_1 is the average amount of soil lost the first year (t/ha), P1 is the estimated price per ton (€), R_2 is the average amount of soil lost until recovery of the original cover (t/ha).

Spatial identification of different damage levels and net change in the value of resources

Determining losses in natural resources, both tangible and intangible, requires knowing the remaining value of the resources, i.e., the "net change in the value of the resources." This concept requires the incorporation of resource depreciation based on fire intensity level. Assigning the depreciation of each

resource based on fire intensity level is made on the basis of depreciation rates or percentage levels, given their greater simplicity and practical applicability.
In the case of the timber and firewood use resources, and under the framework of the FIREMAP, SINAMI and INFOCOPAS research projects, circular plots with a 10-m radius were taken for different plant typologies and degrees of damage in the following fires: Huetor (1993), Aznacollar (1995), Estepona (1995), Los Barrios (1997), Cazorla (2001, 2005), Aldeaquemada (2004), Minas de Ríotinto (2004), Alajar (2006), Gaucin (2006), Obejo (2007), Orcera (2009) and Vértice Hill (2011). For the valuation of losses incurred by the hunting resource, information from Montfrague National Park and the Aldeaquemada and Minas de Ríotinto fires (Zamora *et al*. 2010) was used in order to have not only spatial but also temporal analysis of the natural recovery of reproductive stock and, consequently, of the annual income generated by the hunting resource.
Depreciation levels of the carbon fixation and erosion control resources were estimated based on tree mortality and the consumption level of aerial biomass, from measurements of burned and unburned trees with similar dendrometric characteristics (fires of: Monte Catena, 2009, Obejo 2007, Cazorla 2001, 2005). Economic valuation of erosion damage, or conversion of lost biomass into monetary units, was determined based on the Obejo fire (2007) study, which analyzed the costs associated with the loss of different soil amounts (tons per hectare). In the case of biodiversity, damage valuation is based on the "surrogate value" applied by the Administration (recovery and/or conservation programs) or the value given by the population (contingent valuation methodology). The values obtained for this resource include adjustments based on post-fire costs incurred by the pertinent authorities to prevent the escape and migration of species through the application of food supplementation, predator elimination and competition reduction measures (Molina 2008).
The depreciation rates of landscape assets are very difficult to validate. The aforementioned research projects estimate the depreciation rates for these assets by the technique of social preferences or valuation through indirect landscape perception techniques by pre-fire and post-fire comparison of a territory. Landscape use is affected to a greater extent than leisure and recreational activities. Large wildfires that occurred in Sierras de Cazorla, Segura y Las Villas Natural Park (place where the Catena Hill fires occurred in 2001, 2005 and 2009) provided a good database for quantitative estimates on the impact on landscape assets. It can thus be stated that the 2005 fire resulted in a 40% decrease in the number of tourists and paralyzed numerous business projects for remodeling and expanding recreational facilities. Use of Geographic Information Systems (GIS) allows identification of plant typology and its economic valuation, as well as the availability of information about fire behavior. Based on this, the depreciation rate for each resource is estimated individually. The integration of the two concepts provides the economic vulnerability of each resource present in the burned area. The economic valuation of damages is the sum of the vulnerabilities of the resources present in the burned area.

Classification of fire intensity level from average flame length

Determining the effects of potential fire behavior on the economic valuation of stocks has bee done by identifying the average flame length for each pixel (directly related to the linear intensity of the advancing front). That information is obtained directly from the results provided by the VISUAL-CARDIN program in each of the pixels covered by fire spread. Four fire intensity levels were identified:

Degree of damage I. It corresponds to Fire Intensity Level (FIL) VI or flame length greater than 12 m. Area severely affected. Continuous crown fire is the most representative for this degree.

Degree of damage II. It corresponds to Fire Intensity Level (FIL) V and IV or flame length between 9-12 m and 6-9 m. Moderate affect. Passive crown fire with some crown runs. The ground is left unprotected by clumps due to the intensity. There is almost total surface fuel consumption.

Degree of damage III. It corresponds to Fire Intensity Level (FIL) III or flame length between 3-6 m. Area moderately affected. Ground fire with consumption of surface material. The fire advances with the slope but not the wind. There are isolated scorched trees.

Degree of damage IV. It corresponds to Fire Intensity Level (FIL) II or flame length between 2-3 m. Area slightly affected. Ground fire with consumption of surface material. The fire moves backwards, without slope or wind in its favor.

Identification of net change in the value of the resources and the VISUAL-SEVEIF software flow line

From the experience gained in the large wildfires that occurred in Andalusia during the period 1993-2011 and the scientific results of the FIREMAP, SINAMI and INFOCOPAS research projects, the depreciation matrix was made (Rodríguez y Silva *et al*. 2009), (Figure 2). This matrix is made up of the set of percentage factors based on the fire intensity levels (kW/m) and the corresponding degree of damage, as indicated in the previous section, so that when applied to the initial socio-economic value, it provides both the losses caused by the wildfire and the residual economic value of vegetation unaffected by the fire.

NIF	Vtr	Vfwr	Vhr	Vcar	Verr	Vbir	Vlar	Vler	Vnonr
I	8,33%	5%	20%	10%	10%	20%	5%	2%	4%
II	16,65%	10%	45%	25%	25%	40%	25%	20%	19%
III	38,58%	20%	65%	45%	45%	60%	60%	55%	46%
IV	57,85%	45%	85%	65%	65%	80%	80%	65%	54%
V	82,79%	65%	95%	85%	85%	100%	90%	85%	69%
VI	89,41%	75%	100%	100%	100%	100%	100%	85%	69%

Figure 2—Depreciation matrix ("Vtr", timber resource depreciation (Rodríguez y Silva and others 2012); "Vfwr", firewood use depreciation; "Vhr", hunting resource depreciation; "Vcar"; carbon resource depreciation; "Verr", depreciation of erosion control; "Vbir", depreciation of faunal biodiversity; "Vlar", depreciation of landscape resource; "Vler", depreciation of leisure and recreation resource; "Vnonr", depreciation of non-use resource).

In the VISUAL-SEVEIF software architecture, the depreciation matrix has been integrated in order to provide automatically, and for each pixel concerned, the percentage reduction in the initial economic value as a result of the fire behavior developed in it. The VISUAL-SEVEIF software flow line has been defined by the following sequence of calculation processes (Figure 3):

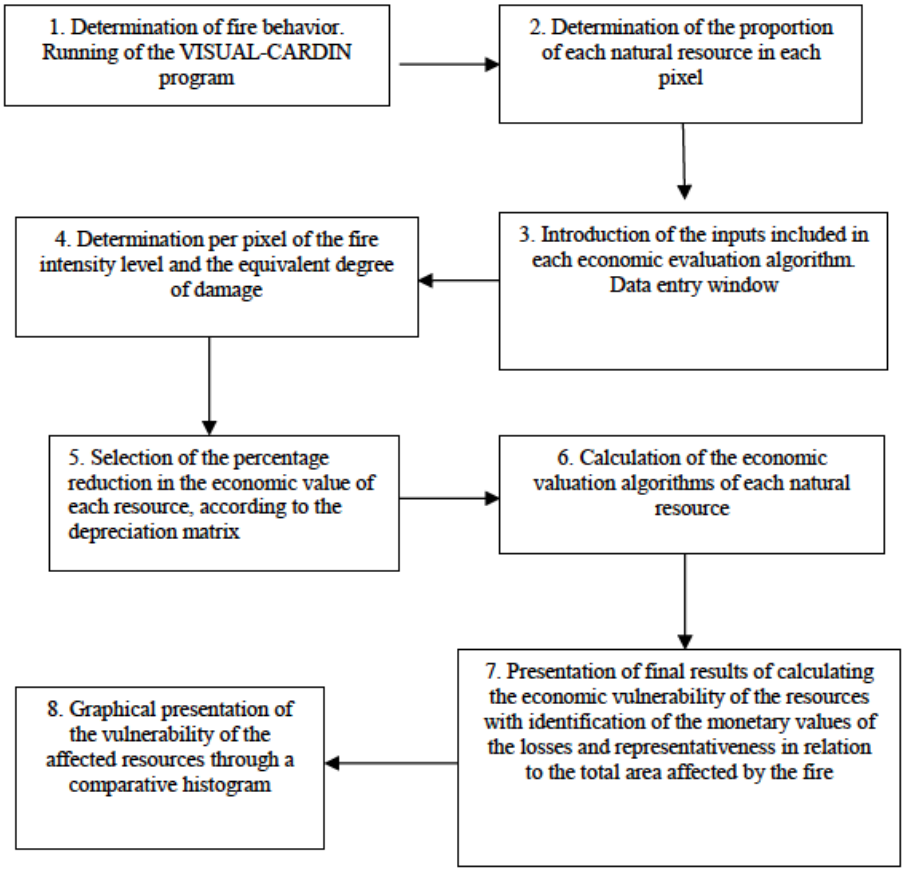

Figure 3—Flow line of the operational process corresponding to the VISUALSEVEIF computer program.

The final windows of the VISUAL-SEVEIF software shown the both report, fire behaviour shape and economic losses affected by different resources (Figure 4).

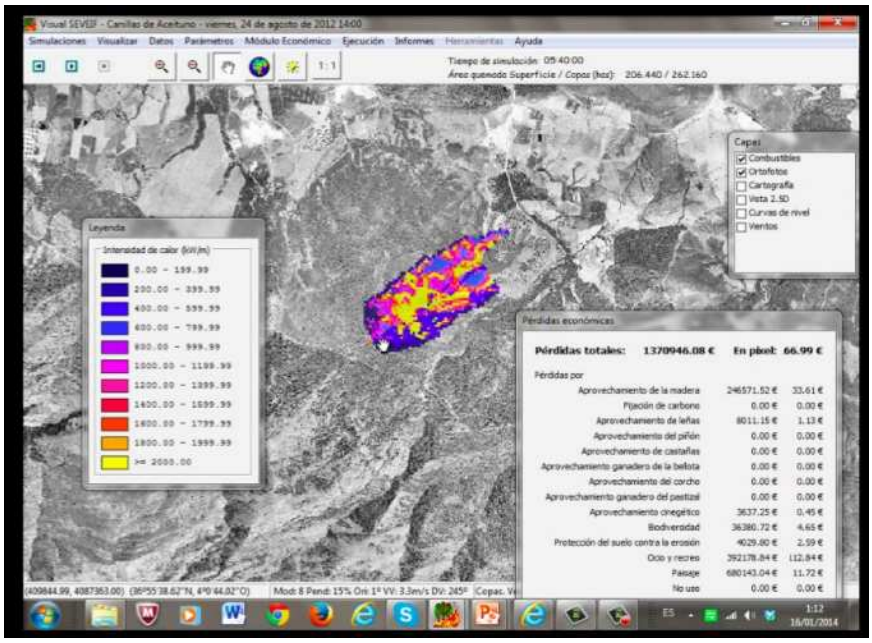

Figure 4. Window of VISUAL-SEVEIF software, showing the fire shape with fire intensity (kw/m) and the economic losses by the resources affected for the fire propagation

7. Estimation of the efficiency of suppression methods using economic losses in natural resources and suppression cost relationship.

Determining the efficiency of production systems, can be understood as an econometric technique through which the existing relationship between the resources employed or assigned and the results obtained, or the target previously set as a goal to be reached, is addressed. That is, it can be understood as the relationship between revenues and expenditures or inputs and outputs generated in a given production system. Conceptually and when evaluating suppression operations, efficiency can be associated with estimating a ratio that allows getting information from the results obtained from using a particular set of suppression resources and their incurred costs on a specific incident or fire (Mendes, 2010).

The efficiency isoquant curve is estimated using data from the fire occurrence database in the forest region or district in which the efficiency analysis is performed. Once the econometric components of the efficiency and its conceptual identification have been achieved the analysis and study of the results of forest fire control and suppression operations can proceed. Using the analysis method for determining efficiency based on econometric model applied to forest fire suppression operations, if necessary to identify for each fire the relationships between the input and the output (Rodríguez y Silva and Gonzalez-Caban. 2013). Inputs refer to the economic value of the area that has been successfully protected based on suppression activities defined when planning the suppression operations. The inputs represents (total economic value saved from the impact of the fire within the fire perimeter), Vr is the economic value of each of the resources in the area where the wildfire has evolved (area bounded by the final fire perimeter), expressed in monetary units (€, $), and Fd is the depreciation factor of the economic value due to the effect or impact of the fire (Molina *et al*. 2009, Rodríguez y Silva and González Cabán 2010, Rodríguez y Silva *et al* 2012). The inputs is obtained using the VISUAL-SEVEIF software.

The outputs or suppression costs are the sum of the individual costs of all suppression resources dispatched to the fire (Ce_j). In terms of efficiency analysis, outputs are the resulting solutions from the combination of suppression resources with a production rate level allocated to the economic value of the resources at risk saved from the impact of the fire. This is the output or suppression costs of the operational suppression system. Accordingly, the efficiency expression can be written as follows, where ET is the efficiency estimator, and all other variables as previously defined (Rodríguez y Silva and Gonzalez-Caban. 2013):

$$ET = 1 - \left[\sum_{j-1}^{j-m} Ce_j / \sum_{i-1}^{i=n} Vr_i\,(1 - Fd_i)\right]$$

From last equation ET values result from the ratio between revenues (outputs) and expenditures (inputs); therefore, it can generalize that:

If 0<ET<1, then the efficiency is low to very high
If ET=1, then the efficiency is in balance

To establish measurement consistency, adjustments are necessary to the ET equation. To do this, weights are introduced that normalize the measurement heterogeneity among the variables in the equation. The weights help put all variables in terms of the ratio of its value to the total overall value for that variable. Thus, for the case of the different suppression resources used (outputs), the weights (β_j) represent the time each resource was used in relation to the total elapsed time from the start of suppression actions until the fire is under control. For the inputs or economic value of each natural resource, the weights (α_i) represents the economic value of each resource relative to the total economic value of all natural resources in the area affected by the fire. By applying the weighting criteria to ET,

we obtain the following equation:

$$ET = 1 - \sum_{j=1}^{j=m} \beta_j (Ce_j) / \sum_{i=1}^{i=n} \alpha_i Vr_i (1 - Fd_i)$$

For simplicity, we suggest a somewhat arbitrary qualitative classification of the results to establish an efficiency ranking (Table 1) by associating the ET estimates to four categorical levels: Low, Moderate, High, and Very High.

Efficiency value interval (ET)	Qualitative classification
0<ET<0.26	LOW
0.26≤ET<0.6	MODERATE
0.6≤ET<0.7	HIGH
0.7≤ET<1	VERY HIGH

8. Conclusions.

The recognition or valuation of forest ecosystems is essential for the spatiotemporal planning work of forest fire managers. The importance of having an evaluation model of socio-economic impacts encompasses a wide range of possibilities, facilitating prevention, valuation and post-fire restoration work. Finally, the methodological approach presented here provides options for the combined study of suppression costs and residual economic valuation of natural resources after the impact of a forest fire. For example, the information produced permit managers not only to analyze and classify the results of agreed upon and applied fire suppression options, but also to make adjustments in the combination of suppression resources assigned if necessary. The VISUAL-SEVEIF software is an objective tool for use in fire economic planning and decision making.

Abstract
In this paper we will focus on the role of treated landscapes on suppression costs and suppression effectiveness. We will begin with a framework outlining the pathways through which treatments could influence wildfire management decisions and fire outcomes, rooted in treatment impacts on fire behaviour. We will then synthesize several emerging research threads seeking to characterize treatment impacts on suppression costs and effectiveness: (1) a simulation-based approach combining stochastic fire modelling with statistical cost modelling; (2) an econometric approach analysing historical suppression costs; and (3) a case study approach using spatial fire perimeter and fire line construction data to quantify fire line effectiveness. To conclude we will outline how these threads can be woven with improvements in fire and fuels modelling to better characterize spatiotemporal trends and trade-offs related to fuel treatment and suppression.

Keywords*: wildfire management, spatial analysis, simulation analysis, econometric analysis*

The views expressed here are the authors', and do not necessarily represent the views of the USDA

Introduction

High-quality wildfire suppression decisions require information on the conditions under which alternative strategies and tactics would be safe and cost-effective. Incident management decisions are premised on the acquisition, analysis, and application of timely and accurate fire information (Zimmerman 2012), and recur within a dynamic, uncertain environment (Thompson 2013). Important pieces of information that fire managers must consider include weather forecasts, fire behaviour and fire growth potential, firefighting resource availability and productivity, and the exposure and susceptibility of values-at-risk (Calkin *et al*. 2011). Accurate spatial data on current landscape conditions are essential to predict fire behaviour and identify management opportunities.

A critical component of landscape condition is the location of areas previously treated by wildland fire (i.e., wildfire and prescribed fire) and/or with mechanical methods. Post-fire analyses and simulation modelling demonstrate the potential for treated areas to alter fire behaviour, size distributions, and spatial patterns of burn probability, and to mitigate fire effects (Ager *et al*. 2010; Stephens *et al*. 2012; Parks *et al*. 2014). Less well understood are whether or how these fire-specific changes can meaningfully or measurably lead to changes in incident decisions, expenditures, or effectiveness.

A conceptual model for treatment impacts on suppression cost-effectiveness is presented in Figure 1. The impacts of treated areas have two main pathways. First, altered fuel composition and continuity can directly influence fire behaviour, which can also indirectly influence incident response. Second, the presence of treated areas on the landscape can directly inform the design of incident strategies and tactics, although this is premised on sufficient knowledge regarding the location, age, and type of treatment. In a post-fire environment, the degree and magnitude of treatment impacts may be discerned through interviews with incident management personnel, statistical analyses, and/or retrospective modelling (Moghaddas and Craggs 2008; Wimberley *et al*. 2009; Cochrane *et al*. 2012). In a pre-fire environment, however, treatment impacts are more uncertain and modelling is necessary. Importantly, recognizing the relative rarity of wildfire occurrence and the commensurate low likelihood of treated areas interacting with fire, evaluation of treatment impacts needs to occur within a probabilistic

framework (Thompson and Calkin 2011). Pre-fire risk assessment results can then be shared with fire managers to help inform incident response planning (Scott *et al*. 2012).

Building from this conceptual model, we synthesize several emerging research threads on the effects of treated landscapes on suppression costs and suppression effectiveness: (1) a simulation-based approach combining stochastic fire modelling with statistical cost modelling; (2) an econometric approach analysing historical suppression costs; and (3) a case study approach using spatial fire perimeter and fire line construction data to quantify fire line effectiveness. In concert with improvements in fire and fuels modelling, we believe these research efforts will enable significant advancements in spatiotemporal evaluation of trends and trade-offs related to fuel treatment and suppression.

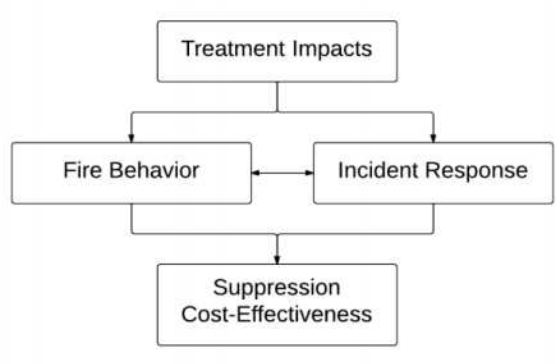

Figure 1. Conceptual model linking treatment impacts to suppression cost-effectiveness

Emerging Research on Suppression Cost-Effectiveness

Interest in whether treated landscapes can measurably influence suppression costs has been around for more than a decade, although only recently have researchers begun to rigorously quantify these potential impacts with geospatial analysis and fire behaviour modelling. Some of these modelling advancements came with the advent of the Collaborative Forest Landscape Restoration Program (CFLRP) in the United States, intended in part to facilitate the reduction of wildfire management costs. In a pilot study, Thompson *et al*. (2013) demonstrated the pairing of stochastic wildfire simulation with suppression cost modelling on landscape in the Deschutes National Forest, using models developed and used by the U.S. Forest Service (Gebert *et al*. 2007; Finney *et al*. 2011). Results indicated the possibility for significant savings given wildfire-treatment interactions, although after considering the likelihood of wildfire occurrence annual savings of any kind only occurred in 1 out of every 4 years.

Simulation of wildfire occurrence and behaviour across the landscape under existing and post-treatment conditions allows for the isolation of fuel treatment impacts on fire metrics and subsequent changes to cost distributions. The spatially-explicit modelling approach captures heterogeneity in fire likelihood and behaviour across the landscape, the size and location of treatments with respect to fire spread direction, and the location of ignitions with respect to factors influencing cost such as land designation and proximity to human development. These techniques are now being systematically applied to evaluate the cost impacts of landscape fuel treatment strategies funded under CFLRP throughout the U.S.

Concurrently with advancements in the coupling of fire and cost models and risk-based evaluation of treatment impacts, researchers have made advancements in the spatiotemporal resolution and predictive power of suppression cost models (Hand *et al*. 2014). One key improvement is the use of spatially descriptive data within the entire perimeter of the fire rather than information based off the ignition location alone, which is made possible by the compilation of a large dataset of spatial fire perimeters from recent fire seasons. The use of perimeters enables, for instance, a more accurate

characterization of the diversity of vegetative and topographic conditions. Additionally, the model can better capture variation in fire weather throughout the course of the incident. With these improvements, cost models will be able to better capture potential treatment impacts by considering not just changes to fire size distributions but also changes in the location and orientation of their footprints with respect to factors known to influence costs.

These improvements further open the door for novel retrospective analysis of historical wildfire-treatment interactions. By leveraging comprehensive, geospatial fire history databases (Short 2013), and possibly agency fuel treatment databases, we will be able to identify the degree to which our dataset of fire perimeters overlaps with previous treatments. Geospatial analyses will allow us to characterize the extent and severity of re-burned areas, and econometric analyses we will allow us to quantify the impact, if any, on observed suppression costs. Figure 2 compares and contrasts these two approaches, both of which should add to the knowledge base of potential treatment impacts on suppression costs.

Better understanding the cost component however does not by itself yield insights into treatment impacts on suppression cost-effectiveness. A third thread of research therefore relates directly to the characterization and quantification of suppression effectiveness. Though theoretical frameworks exist for efficient suppression (Mendes 2010), in practice significant data limitations and knowledge gaps present challenges for identifying factors influencing successful suppression and for characterizing conditions under which alternative strategies and tactics would be safe and effective (Finney *et al*. 2009; Holmes and Calkin 2013). One key challenge is the acquisition and alignment of incident management data from disparate sources such as firefighting resource ordering systems, incident status reporting systems, and operational fire management decision support systems, in addition to data generated and managed at the incident-level. As a result, on-site data collection during an actual wildfire incident is often the best option, despite being time and resource intensive. Specifically, we have been able to collect data on daily assignments by mission type, fire line construction productivity, and daily spatial fire perimeter growth.

With these data, case study analyses can yield new insights into the role of previously treated areas on suppression effectiveness. One initial approach is to query incident decision documentation to qualitatively ascertain the degree to which knowledge of treated areas influenced strategies and tactics. An extra layer of analysis can quantify fire line effectiveness in terms of percent of line held, and can statistically analyse fireline effectiveness within and outside of previously treated areas. The goal of these analyses is to improve our understanding of how suppression resources are used on wildfires and which factors contribute to effectiveness.

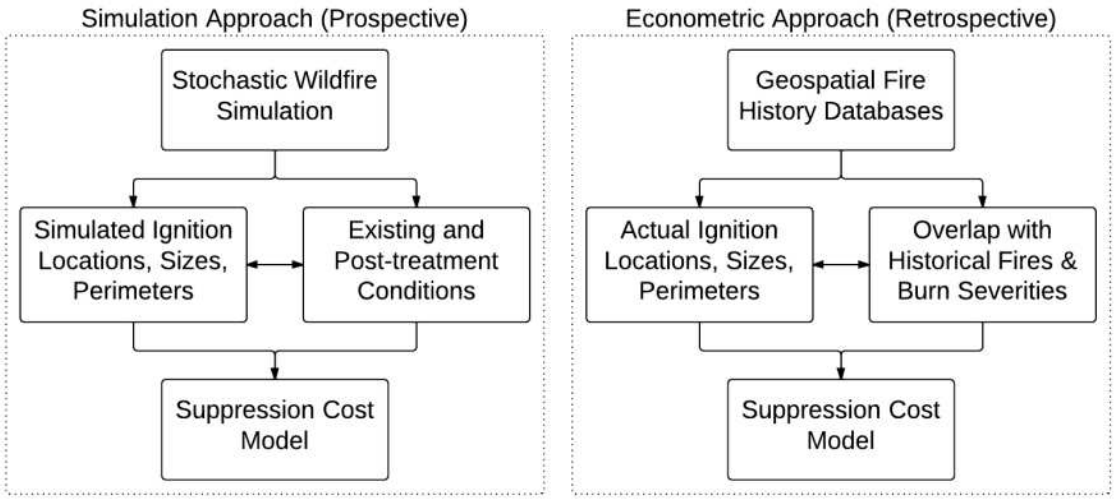

Figure 2. Prospective and retrospective approaches for characterizing potential influences of treated areas on suppression costs

Future Research Directions

The emerging research threads presented in the previous section will set the stage for a wide spectrum of integrated research opportunities. First and foremost we aim to leverage our research with advances in fire and fuels modelling as well as advances in decision support for fuel planning and incident response. Landscape-scale simulation of the spatiotemporal dynamics of wildland fire occurrence, spread, and resulting fuel and vegetation changes will set the stage for life cycle economic analysis of fuel treatment strategies, as well as the costs and benefits of different fire suppression policies. The analytical process can be designed to specifically target salient questions regarding how the spatial and temporal scales of fuel treatment (and retreatment) influence treatment costs and subsequent cost effectiveness. Ultimately the aim of this research is to support evaluation and prioritization of fuel treatment investments at programmatic and landscape scales, and to support risk-informed, forward-looking suppression strategy development.

Theoretical approaches for evaluating the economic efficiency of the aerial firefighting helping strategic planning

Agoston Restas

National University of Public Service, Budapest, Hungary, Restas.Agoston@uni-nke.hu

Abstract
Introduction: Aerial firefighting is very expensive solution; therefore it isn't useless to study it by the criteria of efficiency. But the meaning of efficiency for fire managers can be different from the meaning of efficiency for economists. Economic efficiency is stricter than technical efficiency. Method: this research created and used rectangular and concentric circles models, than made transport analysis and rate calculation. Results and discussion: The rectangular model shows the criteria of economic efficiency of aerial firefighting. The results from rectangular model can be transferred also to the concentric circles model. Based on the concentric circle model we can define both the economic efficiency of aerial firefighting and minimal criteria of successful suppression expressed by the elementary information we have regarding the actual fire. This paper points also at some principle mistakes often made by marketing to overrate the advantages of some aerial products, agents or procedures. Even if it is very difficult to take into consideration all circumstances and assumptions which are found during firefighting process but there are some theories that can help us to assess the economical effectiveness of aerial product, agent or procedure more precisely than rated nowadays by the marketing.

Keywords*: aerial firefighting, economic efficiency, rectangular model, concentric circle model, transport analysis*

Introduction

In this article author makes a difference between the professional and economical effectiveness that is efficiency. Efficiency is obviously stronger phenomena, in this case not just the professional effectiveness but the criteria of the efficiency must be satisfied. No doubt in the sphere of state protection (police, medical service, disaster management, fire service) it is very difficult to speak about efficiency, much easier about the political or social effectiveness. However author is sure there are ways to find the balance between useful actions and costs. Aerial firefighting is a very expensive extinguishing method; therefore it is not useless to look through some of its economic aspects.
Firstly, author makes two models, which are rectangular and concentric circle model, to make it easier to understand some features of the economic aspects of firefighting. Naturally, the assumptions in both models are idealistic, meaning that they require more development. After models, author focuses on extinguisher materials such as pure water, foam and retardant and gives some different aspects of their effectiveness than usual.

Rectangular model

First model examine a forested area limited by rectangular without concrete geometric data. Assumptions are idealistic, like homogenous forest, flat area; there is no wind, etc. In this model the fire front spreads linearly (Figure 1.). Author demonstrates this theory by more rectangular, placing them next to each other, which shows the fire development by geometric. Some part of this model is similar to the model used by Australian experts however not the same (Gould at al., 2009).
After starting the suppression (B) the controlled line takes „α" with the frame of this example edge (C). During the suppression this controlled line will continue till the opposite edge of the frame, meaning that the fire front is extinguished (D). Based on Pythagoras theory it is easy to understand

that the value of „α" depends on the speed of fire spread (v_{fire}) and the speed of suppression ($v_{suppression}$). The higher the speed of suppression related to speed of fire spread (R), the higher the angle „α" is and vice versa.

$$R\left\langle \frac{v_{fire}}{v_{\sup pression}} \right\rangle \uparrow\downarrow \Rightarrow \alpha \uparrow\downarrow \qquad (2.1)$$

Before the fire front forested area can be saved (M_{forest}), beyond it can be count as damages (K_{forest}). The main purpose of the suppression is that the value of saved forest be as high as possible or the damages be as low as possible. Author means, we search the end values of the positive options.

$$M_{forest} \Rightarrow \max \text{ ; illetve } K_{forest} \Rightarrow \min \qquad (2.2)$$

Above statement can be accepted by the view of professional but since it doesn't count with the cost of extinguishing the result can't be the standard for the view of national economy.

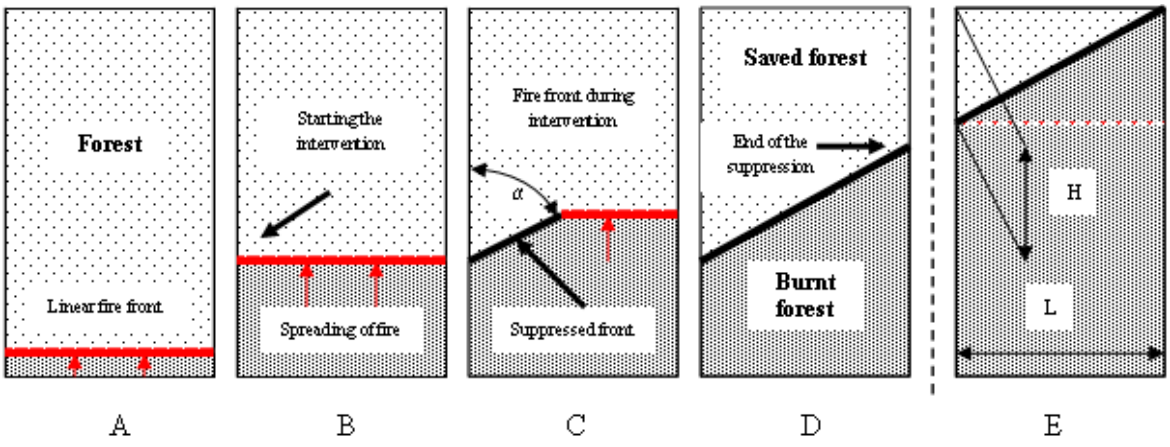

Figure 1. Rectangular model

To maximize the end value of the professional effectiveness' function can't be justify in all cases at the view of national economy. At the latest one all costs of resources must be counted, such as technical and human resources but even the in-material value of the forest and the higher risk of citizens caused by absence of firefighters from urban area.
If the cost of suppression is higher than the saved forest the action is uneconomical in view of national economy. Looking at the rectangular model the efficiency of national economy is valid till the saved forest is higher than the cost of suppression.

$$M_{forest} \geq \Sigma C_{AFF} \Rightarrow \gamma_{NE} \geq 1 \qquad (2.3)$$

M_{forest} – value of the saved forest [€]
C_{AFF} – cost of aerial suppression [€]
γ_{NE} – efficiency of the national economy [-]

Using the notation of the rectangular model the first part of formula (2.3) can be expressed also in another way.

$$\frac{1}{2} LHP_{forest} \geq \Sigma C_{AFF} \qquad (2.4)$$

L – width of the forest area [m]
H – fire spread from the beginning of the suppression till the end of it [m]
P_{forest} – unit value of the forest [€m^{-2}]

This model doesn't count with the burnt area at the beginning of the suppression, not during the action or at the end of it. In this case the efficiency of the suppression in view of national economy doesn't depend directly on the burnt area.
Triangles with „L" width fire front, „α" angles and „H" length in this model are same in any time of beginning the suppression and also same the costs belonged to these triangles.
Based on the rectangular model we get the threshold limit in that case, if the cost of aerial firefighting is equal to the value of the saved forest. In cases of later beginning of the suppression, the cost of aerial firefighting remains the same however the value of the saved forest is reducing continuously till that where remains only the „L-α-H" featured triangle (E). It means the threshold limit of the efficiency geometrically.

$$\lim_{M_{forest} \to \Sigma C_{AFF}} f(M_{forest}) = \Sigma C_{AFF} \qquad (2.5)$$

In this case, if both the above threshold limit is realized and the efficiency of the aerial firefighting is valid, in any earlier beginning time of the suppression will satisfy the requirements of the efficiency too. The earlier is the beginning of the suppression, the higher the value of the saved forest is. The limit value gives just the minimum threshold of satisfying the criteria of the efficiency.
The angle „α" of the suppressed fire front depends on the rate of fire spread and the speed of aerial firefighting. Higher fire spread causes lower angle „α" and longer time of suppression and vice versa. In view of higher efficiency the higher angle „α" is required.

Concentric circles model

The rectangular model counts with linear fire front however in the reality almost each fire starts from small ignition points. In case of ideal and positive spread conditions the fire front will spread radially.

Necessary but not yet sufficient condition for the efficient suppression
Model counts with small ignition point, „v_{fire}" speed of fire spread, „t_{freely}" time of freely fire spread, but other conditions are ignored. In this case the burnt area „A_{fire}" (Figure 2: $A_{t1} – A_{t3}$) can be given with the next formula:

$$A_{fire} = \left(v_{fire} t_{freely}\right)^2 \Pi \qquad (3.1)$$

Following time units (sec, min, hour) burnt areas form concentric circles. This model got its name of these circles. Distance between the circles depends on the rate of fire spread. The „K_{front}" fire front can be given by the formula (3.2) and the changing of it is by the formula (3.3).

$$K_{front} = 2\Pi v_{fire} t_{freely} \qquad (3.2) \qquad\qquad \Delta K_{front} = 2\Delta t v_{fire} \Pi \qquad (3.3)$$

In the formula (3.3) the extent of the „ΔR" radiation change can be given by the formula (3.4).

$$\Delta R = v_{fire} \Delta t \qquad (3.4)$$

The effectiveness of the suppression can be demonstrated by the length of the suppressed fire section per the time units, that is, the speed of fire front suppression.

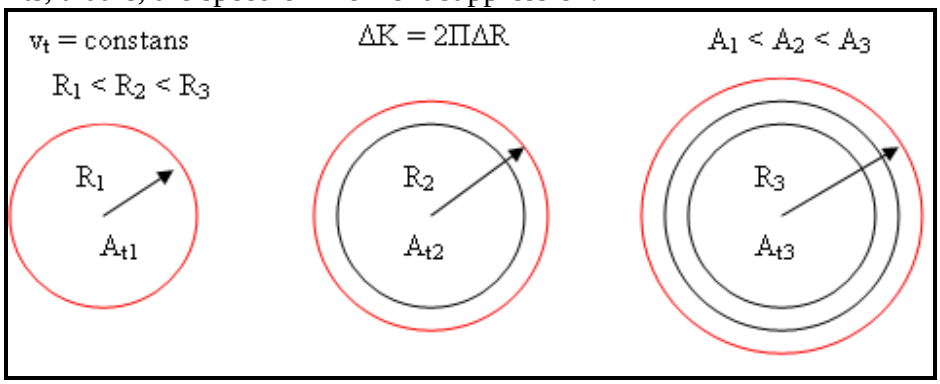

Figure 2. Concentric circles model

Based on the above for demonstrating the capability of the aerial means suppressing fire front author introduce the term of *speed of aerial firefighting* („v_{AFF}"). It means the length of the fire front suppressed by aircrafts.

$$v_{AFF} = \frac{L_{suppression}}{t_{suppression}} \qquad (3.5)$$

- v_{AFF} – speed of aerial firefighting [ms^{-1}; practically it can be $mmin^{-1}$ or $mhour^{-1}$];
- $L_{suppression}$ – length of the suppressed fire front [m];
- $t_{suppression}$ – time for suppression [s; practically min, or hour].

To extinguish the fire successfully, the condition must be met that the interveners suppress fire spread. The firefighters have to extinguish the fire front, whose growth per unit of time is equal to the change in perimeter based on the concentric circles model. Thus, the success and effectiveness of the firefighters' work should not be related directly to the speed of fire spread but rather to the change in perimeter! At the beginning of extinguishment, the speed of the extinguishment of fire front, in this case the speed of aerial firefighting must reach and later exceed the speed of the change of the fire front, that is, the change of the fire front within a given unit of time.

$$L_{suppression} > \Delta K_{front} \qquad (3.6)$$

Using the formula (3.6) to extinguish successfully, the next criteria must be satisfied:

$$v_{AFF} > \frac{\Delta K_{front}}{t_{suppression}} \text{ , or in other form: } v_{AFF} t_{suppression} > \Delta K_{front} \qquad (3.7)$$

By ordering the above, it becomes clear that in practice the initial condition can be calculated in a simplified way, where we need to take the speed of fire spread multiplied by 2Π.

$$v_{AFF} > 2\Pi v_{fire} \qquad (3.8)$$

Above in-equality is necessary but not yet sufficient condition for the efficiency of the national economy. Based on mathematical formulas and the logical deductions regarding the concentric circles model author made the following statements:

1. If the speed of extinguishing the fire front – in this case the speed of the aerial firefighting - is below the speed of changing the fire front, the aerials are unable to extinguish the fire (initial attack).
2. If the speeds above are identical, the length of fire front will remain but the burnt area will extend (beginning situation; later the balance follow 2Πrad).
3. If the speed of extinguishing made by aerials is higher than the increase of the fire front, fire can be suppressed.

Based on the above logical flow we can define both the economic efficiency of aerial firefighting and minimal criteria of successful suppression expressed by the elementary information we have regarding the actual fire. Naturally, the above statements are valid only at the time of beginning the suppression. Later, it modifies as changing the angle of suppressed fire front by the rules of 2Πrad.

Sufficient condition for the efficient suppression

In the examination of the rectangular model, the conditions of efficient extinguishment in terms of the national economy have already been recorded. Based on them, the extinguishment can be regarded efficient if the amount of the saved value reaches the total costs of the extinguishment. Then, the condition of efficiency is met satisfactorily (2.3). It applies to both the rectangular and the concentric circles model.

One feature of extinguishing forest fires is that regardless of the size of the forest burning, we tend to concentrate on the extinguishment of the fire front, which can be regarded as straight fire line suppression. It can be done or it can be accepted because in case of long-lasting uncontrolled fire spread, the curve of the fire front is hardly perceptible, in practice it can be ignored, so it's linear. If we concentrate on a very small section of fire front, the conclusions of the rectangular model can be applied here, too!

Provided we accept the above statements – the adaptation of the limit values of efficiency set in the rectangular model (2.4) to the very small section of the concentric circles model (3.7) – the formula can be created in the following way:

$$\frac{1}{2} LHp_{forest} \geq \Sigma C_{AFF} \Rightarrow \frac{1}{2} \Delta K v_{fire} t_{\sup pression} p_{forest} \geq \Sigma C_{AFF} \qquad (3.10)$$

Moreover, the limit value of the efficiency criterion of aerial firefighting out of formula (3.8):

$$2\Pi v_{fire} = v_{AFF} \qquad (3.9)$$

By reversing the equation and substituting the form pertaining to the actual time of formula (3.3):

$$C_{AFF}^{fly} t_{\sup pression} \leq \frac{1}{2} 2\Pi v_{fire} t_{\sup pression} v_{fire} t_{\sup pression} p_{forest} \qquad (3.10)$$

C_{AFF}^{fly} – unit costs of aerial firefighting [€h^{-1}; €min^{-1}]

$$C_{AFF}^{fly} t_{\sup pression} \leq \frac{1}{2} 2\Pi \left(\frac{v_{AFF}}{2\Pi} \right)^2 t_{\sup pression}^2 p_{forest} \qquad (3.11)$$

Ordering the above formulas and interpret it to a unit time, that is $t_{suppression}$ = 1 min, we can get for the speed of the aerial firefighting the distance of suppression per a minute, that is $v_{AFF} = l_{AFF}$ 1min^{-1}.

$$l_{AFF} \geq \sqrt{\frac{4\Pi C_{AFF}^{fly}}{p_{forest}}} \qquad (3.12)$$

Based on the above formula we can see that some data are enough for the statement of efficient suppression in view of national economy: as the length of suppressed fire front per unit (l_{AFF}), the unit cost of aerial firefighting (C_{AFF}^{fly}) and the unit costs of forest (p_{forest}). Remake the formula and apply it to speed of fire spread:

$$C_{AFF}^{fly} \leq \Pi p_{forest} v_{fire}^2 \qquad (3.13)$$

It has to take into account that the above values are limit values; satisfying them aerial firefighting will satisfy the criteria of efficiency in view of national economy too.

Investigating extinguisher materials

4.1. Extinguishing material is water – using external bucket for bombing

The most common and simplest extinguisher material is water. Using water we count actually only the cost of logistics that is aerial means. In this case the cost of unit water is a quotient of the aircraft cost and water capacity. It can be expressed by the next formula:

$$C_W = \frac{C_A}{V_W} \qquad (4.1)$$

- C_W = cost of water capacity [€kg^{-1}];
- C_A = cost of aircraft per hour [€h^{-1}];
- V_W= volume of water capacity per hour [kgh^{-1}];
- For example, in this article C_W = 0.3 €kg^{-1}

Water, as the most common and simplest extinguisher material, can be taken to the others as a reference regarding extinguishing effects. Therefore author introduce the term of water equivalent per unit of any extinguishing material regarding extinguishing effects ($C_{x=W}$). Naturally, water has its own water equivalent that is cooling effect caused by the specific heat capacity. Moreover not just the extinguishing effects of water but also the cost of water equivalent can be taken as a reference (C_W=$C_{W=W}$). Since the water has its own water equivalent, in the above case it is not important to discuss it. However, later, it gets an important role and as a starting point of a series it belongs logically to water.

Buckets can have significant losses of carried volume during the action, some observer estimate it more than 50 % (Jambrik, 2007; Imreh at al., 2009). Since the losses usually taken with high rate, in this examples author can't ignore it, on average he counts with 25 %. Because of the high rate of losses, we have to take into account not the bucket capacity but the part of it which is dropped to fire front. Consequently, in view of efficiency we have to share the cost of transportation (aerial firefighting) with a reduced volume of the bucket capacity (effective part), resulting higher cost per effective unit water. It can be expressed by the next formula:

$$C_{W\_eff} = \frac{C_W}{\gamma_B} \qquad (4.2)$$

- C_{W_eff} = cost of unit water dropped to fire front [€kg^{-1}];
- γ_B = coefficient of the bucket effectivity [];
- For example, in this article, in case of γ_B = 0.75, C_{W_eff} = 0.4 €kg^{-1}

Based on the above the effectiveness can be expressed by the next statement: the extinguishing capacity of 1 kg „water" at the beginning of the transportation (taking off) expressed by water

equivalent is equal to its own volume, it costs 0.3 €kg^{-1}, regarding the effective part of the capacity at the end of the transportation (dropping to fire front) is 0.4 €kg^{-1}.

4.2. Extinguishing material is foam – using internal tank

In this case the cost of foam concentrate multiplied with the mixing rate has to be added to the quotient of the aircraft cost and water capacity. It can be expressed by the next formula:

$$C_F = \frac{C_A}{V_W} + C_C R_{mix} \qquad (4.3)$$

- C_F = cost of foam solution capacity [€kg^{-1}];
- C_C = cost of foam concentrate [€kg^{-1}];
- R_{mix}= rate of mix [%];
- For example, in this article, in case of $C_C R_{mix}$ = 0.1 €kg^{-1}, C_F = 0.4 €kg^{-1}

Author's experiment shows that beside the cooling effect of foam, caused by the specific heat capacity of the water content, it also has an extra extinguishing effect caused by the structure of the foam that is isolation effect (Restas, 2012). This extra effect delays the ignition of the surface over time than reasonable just by the water content of the foam. This delay, as an extra extinguishing effect, can be expressed by water equivalent. It means, how much water quantity could equal the same delay that is caused by the structure of the foam.
In case of foam author found that it is twice more effective than water (Restas, 2012) however other experts state it 3 times more (Theo, 2009); it generates a coefficient of foam equivalent to water effect. Author insists on his own data; it means 1 kg foam has as much extinguishing effect as 2 kg water (cooling effect) has. In case of cost of extinguishing effect of foam the coefficient also has to be taken into account. It can be expressed by the next formula:

$$C_{F=W} = \frac{C_F}{Y_{exp}} \qquad (4.4)$$

- $C_{F=W}$ = cost of foam solution capacity equivalent to water effect [€kg^{-1}];
- Y_{exp} = coefficient of foam solution equivalent to water effect [];
- For example, in this article, in case of Y_{exp} = 2, $C_{F=W}$ = 0.2 €kg^{-1}

Obviously the on-board installed tank has less transport losses than buckets, many times it is ignored. Author takes into account the losses of on-board tank about 10 %; it means the coefficient of the effectiveness is 0.9. The cost of the effective part of the foam solution dropped from the tank expressed by water equivalent can be given by the next formula:

$$C_{F=W\_eff} = \frac{C_{F=W}}{\gamma_T} \qquad (4.5)$$

- $C_{F=W\_eff}$ = cost of useful part of foam solution capacity equivalent to water effect [€kg^{-1}];
- γ_T = coefficient of on-board tank effectivity [];
- For example, in this article, in case of γ_T = 0.9 , $C_{F=W\_eff}$ = 0.22 €kg^{-1}

Based on the above the effectiveness can be expressed by the next statement: the extinguishing capacity of 1 kg „foam solution" at the beginning of the transportation (taking off) expressed by water equivalent is equal to 2 kg, it costs 0.4 €kg^{-1}, regarding the effective part of the capacity at the end of the transportation (foam on surface) is 0.22 €kg^{-1}.

4.3. Results and discussion regarding foam applications

Based on the results of the practical example, we can deduct that failing to use foams is a professional mistake – if we presume the effectiveness of one unit is twice as much. Yet there is no practical evidence of frequent application of foams. Obviously, it might have numerous reasons. One of them must be the additional cost. It is a mistake to compare the extra cost of foam as an extinguisher to that of water. As water costs practically nothing, regardless of how cheap the foam concentrate is, it would be still significant compared to water. The mistake lies in comparing the costs of the extinguishers or those of the technical equipment (amortisation) instead of comparing the total costs of different extinguishing methods, including the operation cost of the aircraft. The latter one cannot be separated, since it represents a considerable amount within the total cost.

In the above example the difference between the cost of 1 kg water and 1 kg foam solution is very drastic (0 €kg^{-1} => 0.1 €kg^{-1}), but taking into account the cost of transportation (aircrafts) the difference is moderate (0.3 €kg^{-1} => 0.4 €kg^{-1}), it means only 33%! If the effectiveness of the unit foam solution in water equivalent rise also just with 33%, it means, economic point of view there is no difference between the extinguishers. However, the coefficient of the effectiveness of the foam solution in water equivalent is 2, which means the effectiveness rose 100 %!

We have to look for another excuse for failing to use it. In the author's opinion three basic things can hinder the application of foam concentrates.

1. Logistics: The application of foam concentrates requires logistics support. Water is freely available and the loading of aircrafts can be carried out without any external help, so this is the simplest method.
2. Tactics: In aerial firefighting the fire front is directly attacked with water, while in the case of foams the protection strip is targeted primarily.
3. Psychology: The additional related costs the need for logistics support and the difficulties in the application of foams may generate negative prejudices without any professionally valid researches.

Based on the above, in the example, the cost doesn't rise by 33% but in water equivalent reduces by 45% (0.4 €kg^{-1} = > 0.22 €kg^{-1}) !

4.4. Extinguishing material is retardant – using internal tank

In case of retardant the method is similar to the foam concentrate. The cost of retardant multiplied with the mixing rate has to be added to the quotient of the aircraft cost and water capacity. It can be expressed by the next formula:

$$C_R = \frac{C_A}{V_W} + C_{ret} R_{mix} \quad (4.6)$$

- C_R = cost of retardant capacity [€kg^{-1}];
- C_{ret} = cost of retardant [€kg^{-1}];
- R_{mix} = rate of mix [%].

Retardant also has an extra extinguishing effect, therefore the effectiveness in water equivalent – similar to foam solution – have to be counted with coefficient too. It can be expressed by the next formula:

$$C_{R=W} = \frac{C_R}{Y_R} \quad (4.7)$$

- $C_{R=W}$ = cost of retardant capacity equivalent to water effect [€kg^{-1}];
- Y_R = coefficient of retardant equivalent to water effect [].

The cost of the effective part of the retardant dropped from the tank expressed by water equivalent can be given by the next formula:

$$C_{R=W\_eff} = \frac{C_{R=W}}{\gamma_T} \quad (4.8)$$

- $C_{R=W\_eff}$ = cost of useful part of retardant capacity equivalent to water effect [€kg^{-1}];
- γ_T = coefficient of on-board tank effectivity [].

The extinguishing effect of the foam based on water equivalent was determined by tests R-20F (Restas, 2012) and R-10A (Restas, 2014). However, tests targeting the effectiveness of retardants have not been conducted yet so the author has not found any acceptable values to be compared in the specialist literature. Thus, to make practical calculations, I applied logical deductions, expert estimations and hypothesis analysis.

4.5. Results and discussion regarding retardant applications

n the test, the basic conditions are the same as the previous ones. The effectiveness of the retardants is definitely higher than that of water. To determine it, the author makes the following logical deduction:

1. The author accepts that retardants are able to provide protection against crown fire, that is, against fire intensity of 8.000 kWm^{-1};
2. Nobody implies – and there is no practical evidence – that retardants are able to withstand any fire intensity. Its extinguishing effect is obviously lower than the one which is able to suppress extreme fire of 18.000 kWm^{-1} intensity;
3. Based on the author's logical reasoning, the extinguishing effect of retardants is higher than the effect able to suppress fire of 8.000 kWm^{-1} intensity, typical of crown fire, but lower than fire intensity of 18.000 kWm^{-1}, which can be observed in extreme fires.
4. Aerial firefighting can be effective up to 3.400 kWm^{-1} (Silva, 2002). In the comparison of effectiveness its value is 1.
5. If the value of the effectiveness of water is 1 at 3.400 kWm^{-1}, the value of required effectiveness has to be 2.35 at 8.000 kWm^{-1}, and 5.3 at fire intensity of 18.000 kWm^{-1}.

Following from the above, the effectiveness factor of retardants can be considered „4÷5" expressed in water equivalent, based on expert estimation. It implies that it can suppress a quite fierce fire of intensity 13.600 kWm^{-1} - 17.000 kWm^{-1}, which is rather rare. This value takes into account the practical experience that retardants are not always able to provide effective protection against crown fires, though usually they are. For further calculations, the author has rounded the value of professional estimation up to 5, and it will be used for calculations.

In the assessments of the effectiveness of extinguishers, the author has met the opinion several times that foams are 3 times, retardants are 9 times more effective than water (Theo, 2009; George, 2013). The series (water=1, foam=3, retardant=9) obviously reflects rather a logical relationship than actual

effectiveness. The author seeks to determine the effectiveness of retardants with his own hypothesis analysis – because of differing values in his own tests with foams.
Based on the above, the author's hypothesis is that the effectiveness factor of retardants given by the distributor or producer companies reaches the value of 9. It can be examined in several ways, aimed at the following: A) the amount of the extinguisher; B) the intensity of the fire; C) cost-effectiveness. Obviously, there would be a fourth method as well, when all the above are examined together, but it is justifies only in the case, when the hypothesis is affirmed in one of them at least.
A) The producer suggests that the amount of extinguisher needed in one unit of surface is the maximum amount remaining on the foliage in the case of retardants, too. So, we do not meet increased effectiveness in terms of quantity. The hypothesis cannot be justified in terms of quantity.

B) In terms of fire intensity, the effectiveness factor of 9 means that the same amount can suppress fire of intensity which is 9 times higher. It implies that retardants have to be able to suppress forest fires of 30.600 kWm^{-1} intensity. However, practice does not consider such extreme fire intensity. In addition, as it was mentioned before, there is no guarantee that it can suppress fire of 18.000 kWm^{-1} intensity, which happens quite frequently. The hypothesis cannot be justified in this case either.

C) The third way to examine the hypothesis requires a concrete efficiency analysis, which will be detailed below. The price of the retardants has to be at least twice of the price of the foam concentrate; it is not possible to find a product cheaper than 8 $€kg^{-1}$. The mixing rate of retardants suggested by the producers and distributors is at least 25 %, so this percentage was considered in the calculations.
The value of the effectiveness coefficient is counted with 5, given this value by expert estimation, that is $Y_R = 5$. It means, the effectiveness of the retardant is 2.5 higher than the effectiveness of foam. Using on-board installed tank in both cases, the losses are also the same. Example for the above:

- $C_{ret} = 8\ €kg^{-1}$
- $R_{mix} = 25\ \%$
- $C_R = 0.3\ €kg^{-1} + 2\ €kg^{-1} = 2.3\ €kg^{-1}$
- $Y_R = 5$
- $C_{R=W} = 2.3\ €kg^{-1} / 5 = 0.46\ €kg^{-1}$
- $\gamma_T = 0{,}9$
- $C_{R=W\_eff} = 0.46\ €kg^{-1} / 0{,}9 = 0.51\ €kg^{-1}$

Based on the above, the conclusion should be that the efficiency of the retardant expressed by water equivalent is less than that of the water itself. This result obviously can't be logical if the practice uses retardants regularly as an effective extinguishing material. The solution is that the pure water itself is unable to suppress the fire above limited fire intensity (3400 kWm^{-1}), however the retardant is. Therefore, even if water is a cheaper solution in case of higher fire intensity its value is basically nothing. Although retardant seems to be irrationally expensive expressed by water equivalent but the capability extent to such a dimension, where water objectively can't be itself.

Theoretical solution for a logistic problem: how to raise the effectiveness of aerial water transport

Agoston Restas

National University of Public Service, Budapest, Hungary, Restas.Agoston@uni-nke.hu

Abstract
Introduction: As well-known, aerial firefighting is an effective solution suppressing forest fire, however there is no doubt, this tool in many cases can be the only one effective solution, even if it is very expensive. Following the above idea, any new method that is able to reduce the cost of aerial means supporting forest fire management, is worth examining as a new aerial solution. Methods: This article used practical experiments of the aerial firefighting, created a graphics model to understand the logistic problem, made assumptions to concentrate on the key problems and with mathematical backgrounds some logistic functions meaning distance and capacity axes. Results and discussion: The effectiveness of air tankers depends on the distance between the fire zone and water resource. The shorter the distance is between them, the higher the effectiveness is using aerials. This relation can be shown even at a function; however the change is not linear. The rate of the curve depends on the distance, larger distance means smaller change and vice versa, shorter distance means bigger scale of change. This result gives the tipping point where the higher costs of suggested solution – aerial water supply system - will be balanced by the higher amount of bombed water.

Keywords*: aerial firefighting, water transport, logistic problem, raising effectiveness*

Introduction

Each year thousands of hectares of forests burn causing a lot of damages in life, property and environment. As well-known forest fires cause also the 20% of the CO_2 emission generating greenhouse effects (Spessa, A. at al., 2013). Since the resources of managing forest fires are always limited, any new method, equipment or idea which can help managers is valuable to examine as a new solution.
As well-known, aerial firefighting is an effective solution suppressing forest fire, however there is no doubt, this tool can be the only one solution in many cases, even if it is very expensive (Ganewatta, G. and Handwer, J., 2009). Following the above idea, any new method or equipment, that is able to reduce the cost of aerial means supporting forest fire management, is valuable to examine as a new aerial solution. Higher effectiveness of aerial firefighting means that management can save more life, property and environment or can reduce the cost of intervention.

Problems and theoretical solution

Since the practice using aerial means for bombing water is accepted by the experts as a very effective tool fighting against forest fires, - but its high cost is commonly known also, - the question arises: how could the costs of this application be reduced or how could the effectiveness of this method be raised? Without deeper analysis, it is accepted, the effectiveness of the aerial firefighting strongly depends on the distance between the fire front and water resources. If the distance between them is relatively short, air tankers can take more cycles, it means high effectiveness; however long distance means obviously fewer cycles and lower effectiveness.
Since the distance between the natural water resources and fire front is independent from each other, forest services in many cases create fix, semi-fix or mobile water supply in the most threatened zones in the forest, for example for supporting helicopter attack. This water supply require resources, like

money, time to installation, humans to control, energy for upload, etc. however more and more installation means that, from the point of forest service view these tools are useful and its application is effective.
If fire occurs in the forest where these water supplies had been installed it means that this solution is or can be effective. If fire doesn't occur during the fire season in the forest where water supply had been installed before, all resources that forest service invested in these systems mean wasted money. The experience shows that, even if it has risks in necessity, a lot of efforts are made to install more and more water supply systems.

Figure 1. Mobile water supply system for supporting helicopter attack

The question is, if mobile water supply system is accepted as an effective tool for supporting the (aerial) fight against forest fire, – but it is obviously impossible to install and manage theme in each forest, even if it would be required by experts, – instead of these system an aerial version, like a huge air tanker as an logistic support can be used or not.
Scenario is as follows (Figure 3): a huge capacity air tanker carries the water between the water resource (airport/airfield) and fire zone. At the fire zone, this aircraft flies circles as an aerial water supply system and upload the water to the other, limited capacity air tanker(s). Smaller aircrafts are more mobile, they can bomb water in the most appropriate places, with more precision. In many cases, fire managers require just some water but in the right place to suppress fire, and huge air tankers carry many times more water than it is required for a precisions attack. The water bombed or used ineffectively means that, all the costs invested into carrying it from water resources (airport/field) to fire zone is lost money.

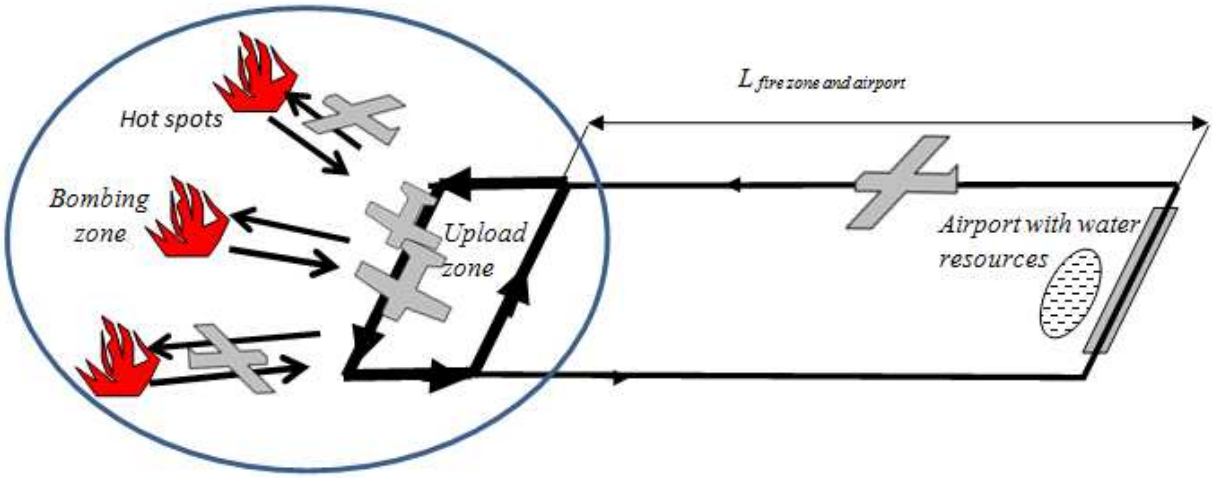

Figure 2. The structure of Aerial Water Supply System (AW2S)

The above scenario seems to be theoretical but not impossible. Many times, the aerial fuel tank is a normal procedure during military operations; therefore, it can be possible to solve the problem of aerial water upload. The question is less technical than economical: the scenario above can be economical effective or not; if the answer is yes, what conditions satisfy the minimum criteria of the required effectiveness?

This study focuses on the possibility of creating a new solution. Because of the limited time, resources and the frame of the study, author determined some assumptions. They make the theory easier to understand and find the essence of the advantages. Assumptions help readers not to get lost in the details but understand the essence.

Even if assumptions make this study simple, it is not allowed to generate false results at the end; counted assumptions are as follows:

- The scale of forest fire is large, aerial firefighting is required;
- Fire intensity is constant, forest area is homogenous, area is flat, there is no wind;
- Extinguishing material is water, aerial firefighting (bombing water) is effective;
- Study focuses on aerials' effectiveness from the logistics point of view but not from firefighting tactics;
- Study uses 2D logistic model;
- There is no problem with water upload from large tanker to small tanker(s).

Features of aerial activity

The effectiveness of air tankers depends on the distance between the fire zone and water resource. The shorter the distance is between them, the higher the effectiveness is using aerials. This relation can be shown even at a function; however the change is not linear. The rate of the curve depends on the distance, larger distance means smaller change and vice versa, shorter distance means bigger scale of change. This curve shows an exponentially decreasing function, where the index depends on the type of aerial tanks. Naturally, the curve never passes the axis; the close has an objective limit.

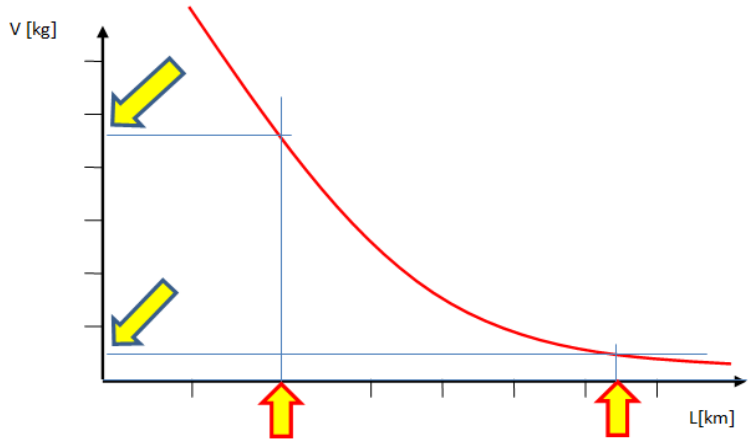

Figure 3- Effectiveness (bombed water) of aerial firefighting depending on the distance between the fire front and the water resource

Again, the shorter the distance is between the fire front and water resource, the more water is carried (bombed) water to fire front, in other words, higher the effectiveness of the aerial firefighting.

Essence of the aerial fire fighting's effectiveness

Experts rarely or never talk about the costs of disaster management. If human life, property or environment is suddenly threatened or hit by a disaster, like large scale forest fires, money doesn't count for politicians, even if the prevention or the higher readiness for response would cost much less. Ethically, human life is invaluable, thus in case of disaster speaking about the money or costs of the intervention is impoliteness.
Despite the above, it is easy to accept that, the essence of the effectiveness depends on the cost of intervention. Based on the given assumptions, the effectiveness takes into account with the amount of water - dropped to fire front, - carried by tankers, and the costs of operation hours paid for tankers' service. The rate of theme gives the costs of dropped extinguish (water) item (1 kg) at fire front (1).

$$\frac{\sum costs\ of\ aerials_{\$}}{\sum carried\ water_{kg}} = x\ \frac{\$}{kg} \qquad (1)$$

Basically, higher effectiveness means that we should carry more water with the same costs, or reduce the costs of the carried amount of water. This study approaches the above question with a special solution. This study examines the opportunity how the effectiveness changes if a large tanker as an aerial water supply is used. For this analysis, it considers two simple cases; they can be developed further based on the results this study determines, or giving up step by step the given assumptions.
In the first case, - let's say case of "A", - all water is carried to the fire front and dropped as usual by 1 small air tanker (2); its feature means:

$$A) \quad 1\ small\ air\ tanker\ (A) \rightarrow \sum water_A \rightarrow \sum costs_A \qquad (2)$$

In the other case, - let's say case of "B", - the water to fire zone is carried by a big air tanker (B) and there it is uploaded by airborne to the smaller air tanker (A). During this process the big tanker serves as a water supply system for the small tanker (A), meaning also that, small tanker can take shorter circles from water resource than without big tanker and resulting also higher amount of water, bombed to fire front (3); its feature means:

$$B) \quad 1\ small\ tanker\ (A) + 1\ big\ tanker\ (B) \rightarrow \sum water_B \rightarrow \sum costs_B \quad (3)$$

In case of "B", there is the same small tanker, as in case of "A", and also a big tanker as an aerial water supply system, meaning that, the total costs in case of "B" are naturally higher than in case of "A" (4):

$$\sum costs_A < \sum costs_B \quad (4)$$

The effectiveness can be expressed not just by the amount of water carried to the fire front, but also by the expenses, the water carried costs. If the costs or the amount of bombed water is equal, the effectiveness can be determined by ranking the other parameter. Since the costs in case of "B" are logically always higher than in case of "A", it is easy to sense that, this study focuses on the *tipping point*, where the higher costs is balanced by the higher amount of water bombed (carried).
Tipping point means that, - with the assumptions given above, - the costs of 1 kg bombed water are equal in both cases; in other words, in both cases the economical effectiveness is the same or equal. In this case, the rate of costs (5) is the same or equal to the rate of water carried (6).

$$R_{costs} = \frac{\sum costs_A}{\sum costs_B} \quad (5)$$

$$R_{water} = \frac{\sum water_A}{\sum water_B} \quad (6)$$

$$\frac{\sum costs_A}{\sum costs_B} = \frac{\sum water_A}{\sum water_B} \quad (7)$$

$$R_{costs} = R_{water} \quad (8)$$

Moreover, the same effectiveness means that, the rate of the costs and the water bombed is equal in both cases (9) (10) (11).

$$R_A = \frac{\sum costs_A}{\sum water_A} \quad (9)$$

$$R_B = \frac{\sum costs_B}{\sum water_B} \quad (10)$$

$$R_A = R_B \quad (11)$$

Since the expenditures of the planes' operation and also the water carried in case of "A" are known, the tipping point ($\Sigma water_B$) can be determined by ordering the above equals (12):

$$\sum water_B = \frac{\sum water_A \sum costs_B}{\sum costs_A} \quad (12)$$

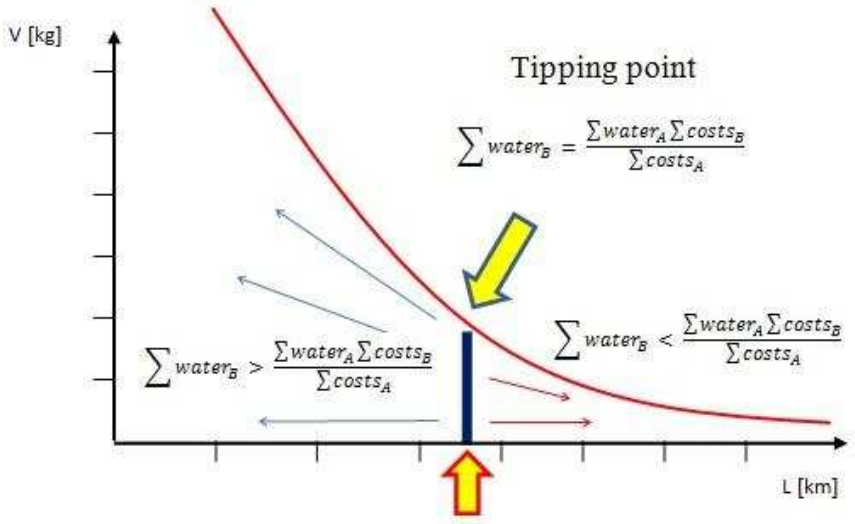

Figure 4. The structure of tipping point

This result gives the tipping point; in any case where the amount of water carried in case of "B" is bigger, the effectiveness is sure. The larger the difference is between the parts of the equal, the higher the effectiveness in the case of "B". Since the costs of case "B" is logically always higher than the costs of case "A", for the equal effectiveness the higher costs of case "B" must be balanced by the higher amount of bombed water.

Required data for finding the tipping point

Following the above, to determine the tipping point the distance between the water resource (airport) and the fire front, the costs of operation hour of used planes and the characteristic of the aircraft's effectiveness function are required to know; based on these data a rate is resulted. Required data for determining the tipping point:

- Characteristic of the aircraft's effectiveness function,
- Operation costs of air tankers (AW2S),
- Distance between the water resource (airport) and the fire front.

From the point of economical view there is no difference between the case of "A" and "B"; higher costs are balanced by more water. This equality doesn't count with the fact that, in the case of "B" the carried (bombed) water is obviously more than in the case of "A"; this fact is an extra advantage (effectiveness) of the case of "B". Considering this advantage or the evaluation of its real value requires another study but the recognition of this fact shows squarely the viability of the aerial water supply system.

Finding examples for the test

Look at an example; if the operation costs of a large tanker is 3 times higher than the small tanker's one, the total costs of the case of "B" are 4 times more than case of "A". Rate of costs is 4, meaning that the required water supply for equal effectiveness by the new system (AW2S) for bombing at the same situation is 4 times more too. Based on table 1, costs are not too far from each other; therefore, there is a chance for finding applicable solution for the aerial water supply system (AW2S).

Table 1—Examples for flying costs[1]

	Type	Costs of flying hour [€h^{-1}]	Costs of flying minute [€min^{-1}]	Source

7.	ShinMeiwa	16200	270	Company
8.	B-747 Super tanker	5500[2]	92	Company

To test the new system, author suggests the S-2T as the small aircraft and an often used military plane, example C-130, C-27 or An-26 as the cheapest version of "large" capacity air tanker. Each of them is robust, has relatively low operation costs and easy to test. C-130 can carry much more payload (water) than the difference between the flying costs of S-2T and C-130.

7. Some remarks regarding the results

There are three remarks, first is: naturally other platforms generate other results of the above rate. Even if it seems to be easy to choose or find a version of AW2S which is effective, but the effectiveness is not for itself; it must satisfy the criteria at as low costs level as possible. Results without the latest criteria can satisfy the requirements of the effectiveness of the aerial water supply system but they might not meet the requirements of the effectiveness of aerial firefighting.
Second remark focuses on the tipping point. From the point of economical view they are totally the same, the higher amount of water is carried by a complex system (case of "B" – AW2S) or by the rate times more single solution (in the above example: 4 x case of "A"). Naturally the above statement is valid only at the tipping point.
The difference between the rate of the tipping point and the rate of the payload (water) capacity (6) is very important. The higher the difference is between them, the higher the effectiveness of the aerial water supply system; it results also in a higher effectiveness of aerial firefighting.

8. Analysis of the function's characteristic

Depending on the characteristic of the air tankers' function, the distance between the fire front and water resource (airport) and the rate of costs "A" and "B" gives the orientation of the tipping point on the curve. Even if the above seems difficult, it is not so. If the aerial water supply system can serve more water than the rate is, the system is effective. Not just the payload capacity but also the operation costs of aerial tankers are known by the users, moreover, the distance between the fire front and the water resource (airport) is also known immediately after the fire alarm; thus, using the given equals above the fire management can calculate the tipping point relatively easily helping the quick and right *yes* or *no* decision.

[2] Special costs, given by the Evergreen service; it seems, must be critics.

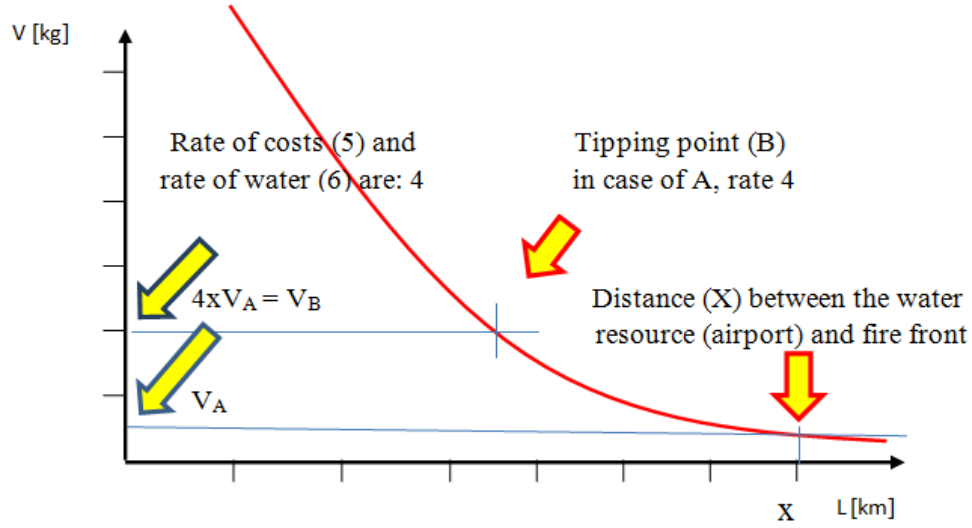

Figure 4. Analysis of the air tanker's effectiveness function

Moreover, to help the effective application even special software can be created for example by GIS based program. On the known parameters the program can classify different zones at the responsible area and indicate it on the intervention map, where the classification can quantify from the point of economical view the effectiveness of the AW2S application.

Based on the characteristic of the function, it is easy to sense that in case of large distance between water resource and fire front it is much easier to reach the tipping point, it is realized at lower level and vice versa, if the distance is shorter, to reach it is more complicated (higher level). Following this process there is a point where the case of "B" practically can't be better solution than the case of "A" because the system objectively can't carry as much water as the balance (tipping point) requires. It is necessary to count with the fact that, the rate of function is not linear, exponential curve has a negative index.

Since the idea generated in this study focuses on the problem of long distance between water resource and fire front, the above extremity is not relevant.

9. Short summarizing

Based on this study, the aerial water supply system (AW2S) is a good idea and can be an effective solution. Even if the study made assumptions, the end results of the evaluation shows that the AW2S is a viable method not just from the point of professional but also economical effectiveness view. The realization is rather a technical than economical question. There is no doubt, in certain conditions AW2S can be a better and more effective solution than the aerial firefighting pattern used today.
